These remarks lead me to speak of the origin of this communication. Until I met with Mr. Middlemore's pungent remarks upon Mr. Farar, I had never doubted that Mr. Farar's cases were of the same description as those I have sent you. A very careful examination of Mr. Middlemore's criticism has led me to state the following particulars whilst they are fresh in my mind, not with the expectation of establishing that Mr. Farar's were cases of congenital opacity of the cornea, but of showing that there is nothing unreasonable in supposing them to be such, and that Mr. Middlemore's decision is hardly warranted by the facts which were before him.

The question I have to consider is, whether Mr. Middlemore, in the year 1835, was warranted, as a critic, in coming to the conclusion given above, respecting Mr. Farar's cases.

1. Mr. Middlemore states that Mr. Farar has erred in supposing the cases he describes to be congenital.

2. Mr. Middlemore conceives that the appearances resulted from purulent ophthalmia after birth.

Mr. Farar gives three cases. Of the first he says that he did not see it until it was a month old. He neither says that the disease was, nor that it was not, congenital. Respecting the two remaining cases, Mr. Farar positively states that he saw them, and that they were " born with" these appearances. So far of Mr. Farar's expressed opinions. Respecting the first case, I see nothing whatever to countenance Mr. Middlemore's assertion, that Mr. Farar supposed it to be congenital. But to proceed to the two remaining cases: it may be objected that, although Mr. Farar has positively said that they were congenital, there is nothing unreasonable in supposing that his belief rested upon the testimony of others. Mark the construction of Mr. Farar's

* Middlemore — Treatise on Diseases of the Eye, London 1835, vol. i. p. 156.

narrative. Of the first case he *says* that he did not see it until a month after birth, and *does not say* that the disease was congenital. Of the second and third cases he *says* that the disease was congenital, and *does not say* when he saw them. How is this "opposition" to be explained? Respecting the first case, I take it that Mr. Farar wished the reader to see that it was impossible for him to say whether the disease was congenital or not, *because* he did not see the child until it was a month old. And if Mr. Farar would not trust to the testimony of others at the end of one month, why should he rely upon it at the end of two or three days?

Again: Mr. Farar does not allude at all to the employment of medicines, or to the existence of inflammation, or of purulent discharge.

Again: Mr. Farar's cases were published in the "Medical Communications." In the preface to the first volume of that work are the following words:—"The editors of this work having formed themselves into a society for promoting medical knowledge, by collecting and publishing such papers on medical subjects as they think worthy of being preserved, now offer a volume of their collection to the public." Mr. Farar's paper, therefore, was considered by this society worthy of being preserved. Here are the names of some of the members of the society: Dr. Carmichael Smyth, Dr. S. Foart Simmons, Dr. Keir, physician to St. Thomas's Hospital, Dr. John Sims, Dr. Bland, Dr. Osborn, Dr. Douglas, Dr. Willan, Dr. Crawford, Dr. Bromfield, Dr. Gartshore, Dr. Gray, Mr. Pearson, of the Lock Hospital, Mr. Henry Watson, surgeon to Westminster Hospital (the gentleman who presented Mr. Farar's paper to the society), Mr. Ford, of the General Dispensary, Mr. Cline, of St. Thomas's Hospital, &c. I need not say to you, Mr. Editor, that these are illustrious names: yet, illustrious though they be, if Mr. Middlemore's judgment be sound, they are fairly participators of Mr. Farar's "curious blunder." I ought not to say all of them, for that would imply that the most distinguished accoucheurs in London in the year 1790 (ten years after the publication of Mr. Ware's treatise on the purulent eyes of newly-born children) were so ignorant of purulent ophthalmia as not to have

inquired at the time whether these appearances did not arise from it,—a conclusion that I cannot bring myself to admit; moreover, it would imply that, in a matter of testimony, a surgeon living fifty years afterwards is to be credited before the most distinguished physicians in London living at the very time. I have no means of ascertaining who were present at the Society when Mr. Farar's paper was read, or who decided that it was worthy of being preserved; but this is certain, that Dr. Carmichael Smyth read his well-known essay on "the danger of wounding the epigastric artery in the operation of tapping for ascites" on the same evening on which Mr. Farar's paper was read*. Is it not reasonable to suppose that Dr. Carmichael Smyth would hear Mr. Farar's paper? Several persons died in London about this time from wounds of the epigastric artery in tapping, and the attention of the profession must have been generally directed to the subject; is it not very reasonable to suppose that there would be a full attendance of the members to hear a paper upon such an important subject, and written by so distinguished a man as Dr. Carmichael Smyth?

Notwithstanding the direct assertion of Mr. Farar that the two last cases were congenital; notwithstanding that it is implied in Mr. Farar's essay that he saw the children immediately after birth; notwithstanding the increased credibility of Mr. Farar's testimony, arising from the circumstances under which his paper was read to, and published by, a society consisting of the most eminent medical men in London; notwithstanding the incredible particulars which such a conclusion involves, Mr. Middlemore says that the appearances arose from purulent ophthalmia, and that Mr. Farar made a "curious blunder" in supposing them to be congenital.

Mr. Farar either is, or is not, a blunderer. I earnestly hope, for the sake of the eminent men that would be implicated, and for the honour of medicine in Great Britain after the death of the Hunters, that he is not; but that he will be found to be the first who has described an exceedingly rare form of ophthalmic disease.

The following remarks, which I have

---

* Medical Communications, vol. 2, p. 482.

translated from one of A. Louis's admirable essays in the Memoirs of the Royal Academy of Surgery of Paris, bear so closely upon the latter part of this communication, and appear to me to be so instructive, that with your permission I will conclude it with them. They prove how dangerous it is to attempt to reason away matters of fact. Upwards of 130 years after Covillard's book was published, M. Louis has to defend him from most unjust imputations. They are taken from "Mémoire sur plusieurs Maladies du Globe de l'Œil; où l'on examine particulièrement les cas qui exigent l'extirpation de cet organe, et la méthode d'y procéder*."

"Proptosis, or the complete protrusion of the eye from the orbit, presents so great facilities for amputating the globe, that it has been the general belief that there cannot be a case in which that indication is more urgent. Covillard† says that he was called to a man who had received such a violent blow on his eye with a racket-ball, that the whole circumference of the eyeball was completely thrust out of the orbit. One of the wounded man's kinsmen had got a pair of scissars to sever the parts by which the eye remained attached. Our author very luckily entered just in time to stop him: and, having put back, says he, the eye into its place as judiciously and promptly as he could, a cure followed. The pains he took were so successful that the wounded man was healed without any change or diminution of sight.

"Antoine Maître-Jan regards this case as false, but that it was founded on a fact of which the circumstances were boastingly exaggerated. He does not think that an eye completely thrust out of the orbit by a blow (although it held by some muscles or membranes), and united again in its socket, could be contained there, grow firm, and preserve its functions. After having examined all the circumstances of the case, and refuted without consideration every thing that he could at all find fault with, he gives us those points of it which he believes to be the true ones: the ball will have struck him, says Maître-Jan, upon the outer canthus,

where the edge of the orbit forms a sharp and prominent ridge; the conjunctiva will have been torn: this laceration, and the ecchymosis which would accompany it, would be enough to make a man who has had but little experience in these matters believe that the eye had perished, and was necessary to be taken away. Covillard interposes, and succeeds in preserving this organ. He had no obstacle to reunion to contend with, and there is no marvel, continues Maître-Jan, in that the vision was not at all diminished; seeing that it is possible that the eyeball had not been bruised, or if it had been bruised, it was so slightly that no part of the interior could have suffered the least derangement.

"This discussion has been transcribed in modern works, with a perfect assent to the opinions of Maître-Jan. The motive is highly praiseworthy. Indeed, we ought to be on our guard, and weigh the accounts and practical facts narrated by authors, before we put our entire trust in them. It behoveth that by a judicious examination of them, it be determined whether they are reasonable, and consistent with experience. But the fact given by Covillard is not the only one of the sort: we read in the observations of Lanzwerde, a physician, at Cologne, of a cure like it in every respect: the injury was occasioned by a blow with a stick. The famous anatomist, Spigelius (whom we cannot suppose capable of being deceived by appearances), with the view of proving that the nerves are loose, and that they can be stretched very much, mentions the optic nerve as an example, in the recital of an injury done to a child by a blow with a stone, which had made the eye protrude so far out of the orbit that it hung down as low as the middle of the nose. A skilful surgeon took charge of this infant: the eye gradually reinstated itself, and so perfectly that no deformity ensued."

After mentioning the opinions of Guillemeau, Louis gives the following remarks by the anonymous editor of the fourth edition of Verdue's "Pathologie de Chirurgie," published in 1710: "When the eyeball has been driven from the orbit by external violence, we may easily replace it therein, but we ought not to promise to be able to retain it there, much less to preserve its

* Mém. de l'Acad. Roy. de Chirurg. tome V. pp. 163, &c. Edit. en 4to. Paris, 1774.
† Observations Iatro-Chirurgiques, obs. xxvij. Covillard flourished about the year 1640.

functions; although there have been," continues he, " authors of so bad faith as to vaunt in their observations of having done these marvellous cures, such as Joseph Covillard, amongst others, a surgeon of Montelimard, whom M. Antoine, surgeon at Mery-sur-Seine, has very sagaciously confuted in the tenth chapter of the excellent treatise on the eye which he has lately published : for all these narratives of impossible cures are no more regarded by true judges than the blustering of the wind."

Louis sums up by saying that " this author's scepticism and abuse will not prevail against the truth : Lamzwerde and Spigelius narrate facts which confirm that which has brought so many reproaches upon the celebrated surgeon of Montelimard."—I am, sir,

ON THE

DETECTION OF ALBUMEN IN THE URINE.

To the Editor of the Medical Gazette.

SIR,

SHOULD you consider the following observations sufficiently interesting, you will favour me by inserting them in your periodical.—I am, sir,

Your obedient servant,
G. O. REES, M.D., &c.

Guildford Street,
Nov. 30, 1840.

The important nature and varied relations of the diseased condition of kidney described by Dr. Bright as existing in connection with coagulable urine, have rendered it a matter of considerable interest to determine with accuracy the existence of albumen in the secretion. It is not very long ago that the sole fact of a specimen of urine becoming opaque by boiling was considered as a sufficient evidence of the existence of that animal principle : and it was not till the more extended observations of Dr. Bright were published that the concomitant testimony of coagulability by nitric acid and by heat was insisted upon as necessary for deter-

mining whether or not albumen was present. The fallacy of the test by boiling was first noticed by myself*, and published in the Gulstonian lectures delivered by Dr. Bright (vide MED. GAZ. for June 1833, page 379). The explanation there given was only applicable to specimens which became less acid, neutral, or even alkaline, by heat. During some experiments, however, which were subsequently made by Dr. Barlow, a few specimens were observed which yielded a deposit on being boiled, which was redissolved by nitric acid, the urine being in these cases decidedly acid, and, moreover, increased in acidity by boiling, and the deposits on examination proving to be composed of the earthy phosphates. These instances at once set aside the conclusion that if urine remained acid after boiling, and coagulated during that operation, that then albumen was present ; for here were acid specimens affording a precipitate by heat, composed of the earthy phosphates†.

Upon this discovery, the strong necessity of using both nitric acid and heat, as concomitant tests of the presence of albumen, became still more evident, and both are now considered indispensable when investigating the albuminous condition of urine.

Another reason for using nitric acid in these examinations is, that albumen, when existing even in very considerable quantity, does not always coagulate by heat ; for specimens of urine are not very uncommon in which the alkaline condition is such as to prevent precipitation by this test, notwithstanding that the addition of nitric acid produces a copious deposit.

From what has been premised it is evident that a knowledge of the acid or alkaline condition of any given specimen of urine can in no way assist us in determining whether or not it contains albumen, by applying the test of heat alone, if a *positive* result be obtained ; for the coagulum may be caused by the earthy phosphates‡,

---

* This reaction was known to Dr. Henry, and was mentioned by him in his work long before 1833. I therefore have not to claim any originality, though certainly I was the first who mentioned the fact in connection with this subject.

† For an explanation of this phenomenon see my letter in Vol. I. of the Guy's Hospital Reports, page 401.

‡ The earthy phosphates, when precipitated from urine by boiling, are exactly similar to albumen in appearance.

whether the urine be alkaline or acid; but the case is different when the result is *negative*, since acid urine never prevents the precipitation of albumen by heat, though alkaline urine may, and, therefore, a specimen, if shewn to be acid, and not coagulable by heat, may safely be declared free from albumen. This fact, if borne in mind, will frequently save the practitioner much trouble, as it is not always convenient to carry nitric acid to the bedside of a patient.

Having stated the fallacies to which the test of boiling is subject, I shall proceed to those which render uncertain the indications afforded by nitric acid. It has been long known that where the lithates exist in urine in excess, that the addition of a small quantity of a mineral acid will occasion the deposit of lithic acid; but this is almost always of a brownish red colour, and in no way simulates in form or character the precipitate of albumen as produced by nitric acid, and cannot well be mistaken for it. I mention the fact, however, as part of the history of the subject. Nitric acid is frequently used to discover whether the precipitate afforded by heat be albumen or not, by adding it to the still warm liquor containing the coagulum obtained by boiling. In these cases, even if the precipitate be albumen, it is occasionally lost sight of by the uninitiated experimenter, and supposed to be dissolved, though, in reality, it remains suspended. This mistake arises in one of two ways; either the flocculi (which generally become darkened or corrugated) are carried up into the froth occasioned by the effervescence which occurs on the addition of nitric acid to the heated urine, or these corrugated flocculi (when the effervescence has not been so strong) remain in their altered condition in the fluid, and are entirely overlooked by a careless or hurried experimenter. I should not have mentioned these sources of error, which might naturally be considered improbable, but that I have more than once had occasion to observe their occurrence, and that too in the hands of practitioners not altogether unused to the test tube and spirit lamp. The last source of fallacy that I shall mention is one which has led to one of those loose unsupported assertions in which our profession abounds, and which have

not failed to attack the important discovery of Dr. Bright, by declaring that albumen exists in many conditions besides in the form of diseased kidney which he has described. That this may be the case is certainly not quite impossible; but the facts which have as yet come under my observation, in support of such an opinion, have proved to be as imperfect as that to which I have above alluded, viz. that patients who take copaiba have always an albuminous condition of urine induced. This statement has, I presume, originated in the fact that when copaiba has been taken (and more especially in an alkaline vehicle) the urine becomes coagulable by nitric acid; at least I have found it so in four consecutive cases which I have examined, and the cloudiness produced bore a great resemblance to albumen, and might be easily mistaken for that principle. These specimens, however, were not coagulable by heat, and were acid—a fact which alone might have assured the observer that albumen was not present. As some further history of this condition of urine may be interesting, I will briefly relate some observations which I made with a view of proving completely the absence of albumen, and of ascertaining the cause of the precipitate obtained by nitric acid.

Four specimens of urine from patients taking copaiba were similarly treated as follows:—

1. They were found acid on being tested by litmus paper.

2. Heat to the boiling point occasioned no opacity.

3. Nitric acid caused a distinct cloudiness. In two of the four specimens it was of a very dense character. The specimens so tested, when set aside, however, for twenty-four hours, were found not to have cleared above by the subsidence of the precipitate.

4. Acetic acid caused a very slight cloudiness, which was not increased by the addition of a solution of the ferrocyanuret of potassium.

5. Ether digested for two days on these specimens of urine was found to have dissolved out a substance (apparently resinous in character) smelling strongly of copaiba, and the urine, on being tested after having undergone this cleansing, was found to have lost the property of becoming clouded on the addition of nitric acid.

It may be well to mention that specimens of urine of this kind, if they contained earthy phosphates in abundance, would afford precipitates both by nitric acid and by heat, and lead many to the conclusion that albumen caused the reactions. I am at present engaged in an inquiry as to the existence of other resinous substances in the urine, which may tend to invalidate the nitric acid test, and shall take an early opportunity of publishing the results. I wish, however, to state here that specimens of urine which I obtained from five individuals, who were taking guaiacum resin, have afforded no reaction with nitric acid.

OBSERVATIONS

ON THE

ADVANTAGES PRESENTED BY THE EMPLOYMENT OF A STETHOSCOPE WITH A FLEXIBLE TUBE.

By GOLDING BIRD, M.D. A.M.

Member of the Royal College of Physicians ; Lecturer on Medical Physics at Guy's Hospital; and Physician to the Finsbury Dispensary.

[*For the London Medical Gazette.*]

<hr>

It would be no slight labour to account for the principles dictating the various constructions of the stethoscope, from the time of the discovery of auscultation by Laennec, to the present period; nor is it certain that an investigation of this kind would be worth the trouble, as it is by no means very evident that every variety of the valuable instrument alluded to has been based upon any definite scientific principle. It is, however, evident that the stethoscope must act in one, or both, of two ways, in conveying to the ear the sounds produced during the process of healthy and abnormal respiration, viz., the sonorous vibrations must be propagated from the sides of the chest to the ear, through the solid material of which the instrument is composed; or through the column of air contained in its centre, or, lastly, through both these media at once. To enable us to appreciate these three cases, it is only necessary to assume that any given portion of the surface of the chest is a vibrating plane; the particular manner in which the acoustic vibrations are communi-

cated from the included structures not being an essential point for consideration. Taking this view, then, if we place the smooth end of a solid cylinder of wood upon the surface of the chest, and apply the ear to the other extremity, every molecule of the wood will assume a vibratory movement, and thus sounds produced in the chest will be propagated, more or less modified, to the ear of the observer. Hence a simple unperforated wooden cylinder becomes an excellent stethoscope, and if care be taken to choose a cylinder in which the fibres run as nearly as possible in a direction parallel to the long axis, we can scarcely wish for a better instrument ; the only conditions necessary for its successful application being the accurate approximation of one end of the piece of wood to the surface of the chest, so that every particular line of molecules, of which the cylinder may be presumed to be composed, should be thrown into a state of acoustic vibration of equal intensity, and simultaneously with each other.

A cylinder of solid metal may be substituted for one of wood in the construction of a solid stethoscope, but certainly without advantage ; for in addition to many other sources of inconvenience, it will, from the pressure exerted by its mere weight upon the surface of the chest, tend materially to damp those vibrations which it is intended to propagate to the ear; and, moreover, whilst the conducting powers of tin, silver, cast iron, brass, copper, and hammered iron, for sound, are respectively as the numbers 7.5, 9.0, 10.0, 10.5, 12.0, and 17.0, that of wood varies, according to the direction of its grain, from $11.$ to 17. Hence, under its most unfavourable state for aiding the propagation of sound, it excels brass as a conductor, and in its best state equals hammered iron.

In the second case, in which the stethoscope is supposed to act by a series of alternate condensations and dilatations produced in the column of air contained in the centre of the instrument, there are certain conditions to be observed to insure the successful application of an instrument acting in this manner. The margin of the conical cavity at the end of the stethoscope must be applied as accurately as possible to the surface of the chest, so that the full effects of the vibrating surface

on which it is placed may be exerted on the base of the column of air, included between the thoracic parietes at one end, and the ear of the observer at the other. It is obvious that in the stethoscopes generally employed we can in no case have the complete and simple effect arising from the oscillatory movements in the included column of air exerted on the ear, for a series of acoustic vibrations will be propagated along the solid sides of the instrument, and thus two series of sounds, traversing different media, will reach the ear, constituting the third mode in which a stethoscope may be supposed to act. On a superficial view it might be presumed that the fact of having two conducting media in a stethoscope would not be without its value, and indeed it has been asserted that we have air in the centre of the instrument for the conducting of sounds produced by the vibrations of elastic fluids within the chest, and wooden sides for the purpose of conveying the sounds emanating from the solid structures. These ideas are too absurd to require refutation, for from whatever source the acoustic vibrations first arise, and through whatever media they move before reaching the parietes of the chest, they all ultimately produce the effect of throwing the latter into vibration; and it is these which the stethoscope can alone convey to the ear.

It is very evident that unless the acoustic vibrations, propagated through the central column of air, and the solid sides of a wooden stethoscope, do occur simultaneously, and impinge upon the membrane of the tympanum in similar places, interference of sound must occur,* and thus the sound, eventually audible, differs from that we should hear providing a solid or aerial medium alone existed between the ear and the walls of the chest. When we also recollect the impracticability, in many instances, of applying the edges of the conical cavity of the stethoscope accurately to the sides of the chest, on account more particularly of the inconvenient position in which the head has often to be placed in using a rigid and inflexible instrument, we see another source of loss of sound.

If a wooden stethoscope be preferred, undoubtedly the simpler the construction the better: it should be constructed of one piece of light wood, in the manner recommended by Dr. Billing,* excepting that the ear-piece should be rendered very slightly convex, and somewhat larger than he has suggested. One of the length of four inches, having a cup-shaped cavity, with a carefully-rounded margin an inch in diameter at one end, the other extremity being slightly convex, and about two inches in diameter, possesses, in addition to its extreme portability, every advantage which a solid stethoscope can offer. Nothing exceeds, or even equals, the simple application of the naked ear to the chest for all purposes in which the examination of sounds over an extended surface is alone required; the stethoscope being only necessary for the purpose of localising sounds, and, for appreciating those depending upon impulse, a simple cylinder of wood will answer just as well as a perforated instrument.

For the isolation of all the sounds generated during respiration, or the action of the heart, whether in health or disease, no form of stethoscope can equal, for convenience of application, as well as for permitting the due appreciation of sounds, one furnished with a flexible tube, providing it be so arranged as to permit the acoustic vibrations to be propagated to the ear through the column of air it includes. For this purpose Dr. Clendinning, and I have been informed also, Dr. Stroud, have for some time past employed the common snake hearing-trumpet. This instrument is much longer than is necessary, and hence is inconvenient in application, as well as from its diminishing the intensity of sound by causing it to traverse an unnecessarily long column of air: the little tube introduced into the meatus is also very disagreeable in practice, and not unfrequently productive of pain and uneasiness to those using it.

The following is a description of the modification of this instrument, which I have for some time employed, and which I am anxious to recommend to the notice of my professional brethren, as one which will be found most convenient in practice. The end which is applied to the chest consists of a thin

---

cup of ebony, an inch in diameter, and carefully rounded at its edges: a flexible tube, from sixteen to twenty inches in length, formed of a spiral iron wire, covered with caoutchouc, and bound tightly round with silk or velvet, having an internal diameter of about one-fourth of an inch, is fixed into the apex of this cup : the other end of the tube is cemented into a perforated ebony ball, on the top of which is screwed a slightly concave plate of ivory two inches in diameter, also per- forated in its centre.

When this instrument is used, the ebony cup should be held, between the fingers and thumb of one hand, against the walls of the chest, and thus, with the utmost facility, and without produc- ing unnecessary pressure, a tolerably air-tight approximation is effected. The ebony ball at the other end should be held in the other hand, and the ivory plate closely applied to the ear. In this manner we have a column of air, bounded at one extremity by the vi- brating surface of the chest, and at the other by the membrana tympani, which thus becomes placed in the position most favourable for assuming vibrations throughout its whole extent.* The cup of ebony has its vibrations *damped* by the pressure of the fingers grasping it, whilst the covering of silk or velvet performs a similar office, with sufficient accuracy, for the spiral wire forming the tube of the instrument, whilst from the convenient position in which the physician can place himself with regard to the patient, the necessarily close approximation of the end of the stethos- cope to the surface of the chest may be effected. In addition to this, the intensity of sound does not appear to be sensibly diminished by the flexure of the tube, and thus we can auscultate the sides and back of the chest by a very slight movement of the body of a patient whilst in the recumbent posi- tion. Indeed, no one can very well appreciate the convenience, or, if I may be allowed the expression, the luxury, arising from the use of an in- strument of this kind, except those engaged in Dispensary practice; for when called upon to visit a patient lying on the floor, or on a low and miserable bedstead, in too debilitated a state to be raised into the erect position

with safety, the physician can examine the state of the respiratory organs without risking his patient's safety by raising him, or his own comfort by placing himself in a position parallel to that of the poor sufferer whose condi- tion he is attempting to alleviate.

It is perfectly true that by aid of the instrument which I now take the liberty of recommending to the pro- fession, certain sounds of the heart, depending upon impulse, are not so perceptible as by means of the solid stethoscope, and in these cases the latter instrument, or the naked ear, should be employed. This, however, so far from being an objection, rather adds to the utility of the flexible stethoscope, for by isolating impulse from sound, I am quite convinced that certain soft murmurs existing in some states of cardiac disease, scarcely, or not at all, audible when the solid ste- thoscope is employed, become very dis- tinct when the attention becomes con- centrated on the sound alone by means of the flexible instrument. I have been much gratified by finding that my own experience has been supported by that of others, and that the flexible stethos- cope, with the flat or slightly concave ear-piece, which I first used at Guy's Hospital in last June, is now employed by many practitioners for the very reasons to which I have above alluded.

22, Wilmington Square,

NEW METHOD of CURE for SHORT- SIGHTEDNESS.

To the Editor of the Medical Gazette.

Sir,

When my "account of a new method of curing short-sightedness" appeared in your journal of August 28th, 1840, I attended a gentleman for an ophth- almic complaint, who was at the same time affected with a considerable degree of myopy. As this defect of his eyes had always been very annoying to him, he was happy to hear that there was a cure for it, and after having perused the above-mentioned account, in your journal, he lost no time in giving it a trial. As this is the first case in which Professor Berthold's method was em- ployed, I hope you will excuse the

---

* Müller's Physiology, by Baily, p. 1253.

CURED BY BERTHOLD'S METHOD. 443

rather long account; an early insertion of which in your valuable journal will greatly oblige, sir,

<div align="center">Your obedient servant,
Aug. Franz, M.D.</div>

1, Golden Square, Dec. 4, 1840.

Mr. J. W——, aged 24, of rather a scrofulous diathesis, having never been affected with inflammation or any other disease of the eyes, enjoyed a perfect sight up to the 12th year of his age, when he first perceived that distant objects appeared to him less distinct than they previously had done. During his education at school this condition of the eyes became gradually worse, until, in the course of a few years, a confirmed myopy established itself, which obliged him to have recourse to a pair of weak concave glasses. Being much devoted to study, and always holding the book in reading very near the eyes, and likewise neglecting to pay proper attention to his general health, caused him during puberty to suffer greatly from a sensation of fulness in his eyes, which had for its consequence a temporary intolerance of light, a slight weakness of sight, and a more rapid increase of the myopy, for which he thought the use of more powerful glasses would be the best remedy. He therefore, in his 16th year, changed his first pair of glasses for a higher power, but finding after some time that these also refused to aid his sight sufficiently, he changed them again, and this he was for the same reason necessitated to do at three different times, so that the last glasses were double concaves of six inches focal length, which he was in the habit of wearing constantly.

There was no ground for supposing that this gentleman's eyes were hereditarily predisposed to this defect, as he assured me that neither his parents, brothers, or sisters, had ever been affected with near-sightedness. Except a slight want of elasticity in the eyeballs, when lightly pressed upon, nothing particular could be observed either in their shape or external appearance: they were not unusually prominent; the convexity of the cornea, and the size of the aqueous chambers, appeared normal: the pupil was certainly larger than natural, which is always the case in myopic eyes, but the iris moved freely to the different degrees of light, and lay when expanded in a regular or vertical plane, *i.e.* the

inner margin did not incline forwards or towards the cornea, which is said to be the case in some myopic eyes, and to be a sign of too great a convexity of the lens. No difference existed in the degree of near-sightedness of both eyes. The power of adjustment was not wanting, as was proved by the circumstance that the patient used the same glasses for seeing distant and near objects, and, moreover, that he could read common print by means of the glasses at a distance of five and sixteen inches, almost equally well; but it appeared that the power of adjustment did not properly accommodate itself to the quantity of refraction in the transparent media of the eye. The myopy in this case was, therefore, merely want of proper relation in the visual apparatus, as it, in fact, always is, when the power of adjustment is still present in the myopic eye. The slight degree of weakness of sight, on the contrary, was an actual disease of the sensitive part of the eye or the retina, which was deficient in energy and continuance of action. The two complaints were, as is evident, of distinctly different nature, although both derived their origin from the same causes. These were, an improper management of the visual functions; an over-exertion of the visual organs by constant study; a too early and injudicious selection and use, and a too frequent change of glasses; and lastly, neglect of the general health, and especially of counteracting the determination of blood towards the head during the time of puberty. From what has been said, it may be concluded, I think, with tolerable certainty, that the myopy, at least in this case, was not an hereditary malformation of the eye, which many ophthalmologists maintain it always is, and as such may either be remedied, or made permanent, by a judicious or injudicious use of the eyes.

In the beginning of June last this gentleman suffered from scarlatina, with a decided affection of the brain and its membranes. While recovering he exerted his eyes too early and too much by reading and writing, the consequence of which was an excessive intolerance of light, with spasms of the lids, and an increased secretion of tears, for which complaint he first sought my advice. Opium rubbed in round the eyes; poultices containing Cicuta applied over them; two leeches to the

454 NEW METHOD OF CURE FOR SHORT-SIGHTEDNESS.

nostrils, several times repeated ; every second night a pediluvium; a few warm baths, and internally cooling aperients, were ordered. After these means had been continued for about a fortnight the local remedies were changed for the ophthalmic fountain*. Cinchona and iron were given internally, and besides, fresh-water baths and country air recommended. By this plan of treatment the photophobia, the blepharospasmus, and epiphora, were not only cured, and the existing weakness of sight greatly improved, but the visual organs were also placed in a favourable condition for the -treatment of the myopy.

On the 2d of Sept. the myopodiorthoticon was for the first time brought into use. It was regulated to that distance of vision where the patient could read large print with facility without glasses, which was in this case more than four inches and a half. The spectacles were altogether dispensed with. He was directed to look frequently at distant objects : all occupations with near objects. except reading and writing with the apparatus, were forbidden; the employment of the ophthalmic fountain was continued twice a day, for which the Pyrmont waters were used ; the leeches applied to the nostrils three times, repeated; a pediluvium, and some cooling aperient, now and then ordered, and the diet properly regulated. As the patient's occupation consisted chiefly in reading and writing, he pursued it daily without interruption. The apparatus was afterwards altered, in the manner described in my first paper on this subject, published in the Med. Gaz. August 28th, excepting that the distance of the cross-bar from the book read was increased in the be-

* Beer and Himly have proposed contrivances of different kinds for the purpose of directing a small stream of water against the eyes, but they are more or less complicated : that of Prof. Jungken answers the purpose quite as well, and is by far the simplest. His ophthalmic fountain is made of a common barometer-tube, about three feet in length, the upper extremity being bent backwards, in the form of a hook, six inches long ; the lower, bent in the same form, is but two inches long, having a very small opening. After the upper part has been immerged in a tumbler filled with water, placed at a convenient height, and the air been then drawn out of the tube through the opposite part, the water follows in a continued stream, over which the patient holds his eye, either at some distance from the opening of the tube, or close to it, if a more powerful action is intended. Cold spring water, or water impregnated with carbonic acid gas, may be used.

ginning every 2d or 3d day about one-half or a whole line, then every day about one, and afterwards two or three lines, by which means the distance of vision became gradually elongated in the same proportion as these alterations of the instrument were instituted, so that now, after the lapse of three months, the patient reads the same print at twelve inches and a quarter distance, which he at the commencement of the cure was able to read only at four inches and a half. In the same proportion has the sight also been improved with regard to objects more distant, so that he sees now those objects well defined and more distinct of which he could formerly perceive confused outlines only, and he does not require the use of glasses even when looking at very remote objects. When reading or writing, the power of vision continues, moreover, its regular function for a longer time than before, *i. e.* the sight does not become so easily fatigued, and whenever he feels it somewhat tired, one or two minutes' rest bring it immediately back to its normal strength. Although the sight is at present in a satisfactory condition, he intends to continue the use of the instrument some time longer, in order to elongate it still more for near objects, but more especially to bring it to a higher perfection in regard to remote objects, and the improvement already gained leaves no doubt that he will successfully obtain the desired end.

It cannot be denied that this mode of treating near-sightedness requires patience and perseverance, but, when we consider the annoyance the complaint is to some persons, and its severity in some cases, it is, in my opinion, well worth the trouble to submit to the treatment : so much the more so as we had no actual cure for myopy, and, as is proved by the present case, this new method has been attended with perfect success. The practical worth of the ingenious construction of the myopodiorticon by Professor Berthold, cannot, therefore, be doubted.

Another advantage is likewise derived from the cure of myopy, which, although of less importance, should not be overlooked, viz. that the person is freed from the inconvenience of wearing glasses, and from the annoyance of being compelled to clean them frequently, as, for instance, when coming from the

cold into a warm room ; and lastly, from being obliged to move the head in the exact direction of the intended object, which always causes some bodily exertion. It should, moreover, be remembered, that spectacles, as Prof. Beer said, are but crutches for the eyes.

LATERAL CURVATURE OF THE SPINE.—STRABISMUS.

To the Editor of the Medical Gazette.

Sir,

I have just seen Mr. Child's report of his operation for lateral curvature of the spine, by division of the muscles of the back; and whilst I am gratified to find that other British surgeons are directing their attention to what I consider a most valuable and interesting operation, I must beg leave to correct a mistake into which he has fallen in stating that the operation had "never before been performed in England." I have performed the operation myself *four times :* the first case was on Friday, the 13th of this month, which is *five days before* Mr. Child performed his; so that, whatever credit may be due to the *first* performance of the operation in England, as far as I at present know, belongs to me.

A matter of still more general interest is the fact that all my four cases are going on most satisfactorily ; one, a boy, seven years and a half of age ; another a young lady of twenty, who had been severely afflicted with spinal curvature for eleven years; another young lady of twenty-two, who laboured under the complaint for eight years ; and the fourth a girl fourteen years of age, who had suffered from that affection for many years.

As the result of the first case is, in a great measure, already attained, it may be interesting to your readers to have a slight sketch of its history and progress.

Master George B., seven years and a half old, became weak in his lower extremities about twelve months since, which rendered him liable to stumble when either walking or running, especially if there were the slightest inequality in the ground. This debility of the limbs increased until the beginning of

February last, when of a sudden he was entirely deprived of the use of the lower extremities. Two eminent surgeons were consulted, who prescribed for the case, but without any benefit. One proposed placing issues at both sides of the spine, and confining the patient in the horizontal position for two and a half or three years. This practitioner, however, expressed himself very doubtful whether even this mode of treatment would actually restore to the patient the use of his limbs: the father would not, therefore, consent to adopt such a course with prospects so chilling. The boy was brought to me on Friday, the 13th of Nov. 1840. His situation was as follows :—General health tolerably good, but destitute of all power of voluntary motion in the lower extremities ; they were, moreover, cold, and almost devoid of sensibility. The fifth, sixth, and seventh dorsal vertebræ, formed a very prominent projection backwards, and below there was a considerable *lateral curvature ;* the convexity of the arch being towards the left. I considered that the division of the muscles on the concave side of the arch would at once relieve the tendency to *lateral* curvature, and at the same time take off part of the strain from the posterior curvature, and that this, with the discharge which would take place, might relieve the diseased state of the vertebræ and spinal cord. The father immediately consented to have the operation performed, and held the boy on his knee whilst I performed it, in the following manner:—The patient's body being a little bent forward, I passed a small bistoury under the muscles on the *concave* side of the curve, as close to the ribs as possible, directing its point onwards to the spinal column, when I elevated its point and withdrew the bistoury, so as to cut through the muscular part without injuring the integuments ; then, reversing the cutting edge, I made sure of every fibre being divided, at the same time taking care not to injure the intercostal muscles. The operation occupied about half a minute, gave but little pain, and so decided were its results that the father instantly exclaimed, "Why, the back is straight already;" and it was so, as far as the *lateral curvature* was concerned. I am happy to be able to add that now the posterior curvature is much diminished; the lateral curvature

evidently gone. The wound was not the size of a leech-bite, and is now closed; the divided muscles reunited; and the patient is this day (being the seventeenth after the operation) able to walk across the room.

I intend shortly to send you an account, with cases, of an operation which I have repeatedly performed, with invariable success—as some of the most eminent members of the profession can testify—for a variety of talipes of an entirely paralytic nature, without contractions of any of the tendons, for which the Stromeyerian operation could be of no service—an operation which I believe will be found never to have been performed by any one but myself, or those to whom I have shown it. I may farther add, that my researches on this subject have happily led me to a method of treating paralysis generally, with a success so remarkable that it must be seen to be credited. Its effects have been witnessed by hundreds, including several eminently scientific gentlemen; and when I can command as much time, and have made some farther experiments, I shall deem it a duty I owe to the profession and humanity, to publish on this subject, as well as on the operation of talipes generally, as I am pretty certain I have had far more experience in the treatment of talipes than any person in the kingdom; the operation being almost a daily occurrence with me. I have even had as many as *seven new* cases in *one day*, beside contractions of the legs, arms, and other parts of the body. My total number of operations for talipes amounts to about 200, embracing every age from fifty-three years to *two days* old. I have been enabled not only to improve the surgical part of the operation, but also to simplify the mechanical apparatus, so as to render it more effective than the Stromeyerian boards, and Scarpa shoes, used by them. My apparatus for extension costs only about *one shilling* for *each foot*, whereas the Stromeyerian boards, with pads and straps and Scarpa shoe, costs about *five pounds ten shillings* for *each foot*—an expense sufficient of itself to preclude the possibility of the poor being cured of that distressing and unseemly deformity.

On Strabismus I can also furnish some important hints, having operated on about 450 cases with the most satis-factory results, embracing every age from 63 years to 22 months. In ordinary cases the securing and dividing the tendon does not occupy me more than from a quarter to half a minute, and so little injury is inflicted on the eye that out of all the number I have operated upon, except in a few cases, arising from *great imprudence on the part of the patient*, none of my operations have been followed by consecutive inflammation worthy of notice. I have never required, during the after treatment, to put a single patient to the pain of applying a caustic to the eye. My present mode of performing the operation is this—supposing the case to be an internal squint. The patient being seated on a chair, with a back sufficiently high to support the head, and the eyelids kept apart by spring specula, I desire the patient to look outwards, and then with a small blunt hook pinch up a fold of the tendon and conjunctiva near to the caruncula lachrymalis, which I then divide at the same time by a pair of sharp scissors a little anterior to the point of the hook. It, of course, requires a little dexterity to get the knack of catching the tendon without injuring the conjunctiva, and, perhaps, to beginners, it might be as well to adopt the plan I at first pursued, to pinch up a fold of the conjunctiva with a small pair of forceps, and snip it across so as to admit the point of the hook, which is then to be used, and the operation completed as, already stated. I always apply a fold of calico and bandage over the eye for a few days, which is kept wet with lotion, and the results, as already stated, have been satisfactory in the highest degree. I am quite certain that the whole of the operation, as now described, inflicts less pain than the application of the hooks alone for fixing the eye, which have been used by many preparatory to the cutting part of the operation; and I can confidently say they are wholly unnecessary, as the eye may be commanded with the utmost certainty by pinching up the tendons as I do.

In some very extreme cases, however, notwithstanding the tendon has been completely divided, there may be a slight tendency to the original maldirection of the eye, arising from the relaxed state of the antagonist muscle after the position of the eye has been so much altered by the new direction given to it.

In such cases I have found a second division of the tendon first cut, with care to keep it in the proper direction during the healing process, has always been sufficient to correct this, if the other eye is not at fault, with the exception of a few cases where it arose from absolute paralysis of the antagonist muscles.—I am, sir,

Your obedient servant,
JAMES BRAID,
M.R.C.S., Edin.

10, Piccadilly, Manchester,
30 November, 1840.

DIVISION OF THE MUSCLES OF THE BACK

IN A CASE OF LATERAL CURVATURE OF THE SPINE.

To the Editor of the Medical Gazette.

SIR,

THE insertion in the last number of your journal of Mr. Child's interesting letter, in which he describes a new operation for lateral curvature of the spine, induces me to transmit to you the particulars of a case in which I performed a similar operation so far back as September the 11th.

The patient was a youth, aged 17, who, being the son of respectable parents, had not been under the necessity of engaging in manual labour. He suffered from an extreme lateral curvature of the spine to the *left*, (a distortion much rarer than the *right*), which implicated the lower cervical and six or seven upper dorsal vertebræ. The trapezius and rhomboid muscles of the convex side could be felt as a thick mass between the spine and the scapula, while those on the concave side were attenuated and scarcely perceptible. The ribs on the right side were flattened, and comparatively motionless; on the convex or left side they were considerably excurvated.

My patient's health was so delicate that absolute confinement would have been injurious. He was, therefore, directed to keep the supine or rather lateral position for a few hours daily: to have the right or concave side shampooed, and rubbed with a stimulating liniment; and to take such exercise as might call the respiratory muscles of that side into action. He also took carbonate of iron. In three months, under this plan, his health was much

improved: the flattened ribs became more convex, and took a more active share in the respiratory movements, and he gained considerably in height. He still, however, had very considerable deformity, which remained unaltered by the above treatment. I then recommended the use of mechanical means, and proposed Guérin's operation, and ultimately performed the latter on the 11th of September last, as stated above. I proposed the division of part of the trapezius and the rhomboid muscles, and for this purpose I placed the patient prone upon a bed, with his left arm hanging over the edge, and a pillow under his chest. I then pinched up a fold of skin at a point midway between the postero-superior and inferior angles of the scapula and the convex border of the spinal column, and slipping the left side of a long narrow-curved bistoury under it to the hilt, in the direction of the trapezius, I turned the edge of the bistoury to the muscles, depressed the point, and cut about an inch and a half out. I then allowed the fold of skin to fall, and finished the incision. The remaining undivided portion of the trapezius and rhomboid muscles was divided by a second incision. I could feel the retraction of the muscles at the moment of division very distinctly. Arterial blood flowed freely from the two punctures, but on compressing them with a pledget the hæmorrhage ceased instantly and entirely. An elastic swelling immediately occupied the line of incision, formed, no doubt, by effused blood; and subsequently this part appeared yellow, as if it had been bruised. The patient scarcely complained. On the third day the punctures were cicatrized; on the fourth he was walking on his crutches as usual, having experienced no pain or indisposition whatever.

A short notice of this case may be found in a work on the Nervous Diseases of Women, which I published a few weeks ago, and in which the pathology of spinal distortions and of spinal neuralgiæ is discussed. I also communicated the fact of my having operated, to M. Guérin, more than a month since.

I believe any farther discussion as to the *safety* and *practicability* of this and similar myotomical and tenotomical operations is quite unnecessary. Judging from my own experience I would

venture to say, that they are less dangerous, and really require less skill, than venesection. It is of much greater importance to ascertain in what cases they are actually *useful*, at what period they should be performed, and with what curative means they should be accompanied, and what is the extent to which the functions of the divided muscles are impaired. Observation and experience can alone instruct us on these points. If we consider the results of accidental injuries done to muscular and tendinous structures, as in contusions, dislocations, and fractures, there is some ground for fearing that the divided muscles may, at some uncertain period subsequent to the operation, become the seat of neuralgic or rheumatic affections.—I am, sir,

Your obedient servant,
T. LAYCOCK.

York, Dec. 5, 1840.

DISSECTION OF A CLUB-FOOT.

To the Editor of the Medical Gazette.

SIR,

I ENCLOSE you an account of the dissection of a case of club-foot, in which the sole was turned inwards and upwards, the patient treading on the upper surface of the os cuboides, which had become rough and irregular, giving rise to an extensive ulceration on the instep, for which the limb was amputated; but the case did not do well, owing to the formation of abscesses in the thigh, and a subsequent attack of hemiplegia.

I am, sir,
Your obedient servant,
PHILIP B. AYRES, M.B.
M.R.C.S.

Thame, Nov. 27, 1840.

Tendo Achillis very much shortened, preventing flexion of the ankle-joint.

Tendon of the tibialis anticus very short, preventing eversion of the foot.

Tendon of the extensor longus pollicis rather shortened, but nearly natural.

Tendons of the extensor longus digitorum natural.

Tendon of the peroneus tertius elongated and expanded.

Extensor brevis digitorum flabby and very thin, but otherwise natural.

Tendon of the flexor longus pollicis rather shortened.

Tendons of the flexor longus digi-

torum somewhat shortened, but very slightly so.

Tendon of the tibialis posticus slightly shortened.

Tendons of the peronei natural.

Short muscles of the foot natural.

The bones of the foot, although the patient was 27 years of age, and the disease congenital, were apparently in a natural state, and would certainly, judging from their appearance, have allowed the foot to have regained its natural position had the opposing tendons been divided. The principal opposing tendons were those of the gastrocnemii and soleus, and the tibialis anticus, so that by dividing these tendons, the remainder, which were nearly in their natural state, would have permitted the foot to have righted itself. I am not aware that there is any novelty in this case; but as in new operations every fact possesses some value, I have sent this dissection for publication.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Practical Remarks on the New Operation for the Cure of Strabismus or Squinting. Illustrated with Lithographic Engravings. By EDWARD W. DUFFIN. Churchill, 1840.

THE numerous excellent communications on the subject of strabismus which have recently appeared in this journal, from the pen of Mr. Duffin, render it unnecessary that we should review in detail the contents of the volume, the title of which stands prefixed to this article. To do so would, in fact, be to reprint a great deal of what has already been presented to our readers in these pages; since the papers or communications alluded to may be said to form the groundwork of the essay in question. Thus far, however, we may observe, much new and important matter has been incorporated with the original articles, and a great deal that was speculative and illusory has been very judiciously rescinded; so that the whole, revised, and in a more comprehensive and connected form, is now presented to the professional public.

We do not ourselves pretend to be so

learned in optical science, or sufficiently conversant with the numerous interesting and curious facts that we are aware have of late been revealed in reference to strabismus, to discuss the several queries suggested by the author. Neither are we prepared to canvass the merits of the different theories he advances, to account for the diversified morbid changes that, it would seem, occasionally present themselves as pathological complications of the various forms of this affection. A knowledge of these, however, we conceive to be important, if not essential, to those who undertake the cure of such cases. The numerous candidates for operative popularity, if we may be allowed the expression, who have of late joined in the strabismal mania, and favoured the public with the results of their practice, have hitherto led us to believe that failure in the performance of the new operation—or any thing short, indeed, of the most complete success—is next to impossible, even in the hands of the merest tyro in surgery. But on perusal of Mr. Duffin's remarks our opinion in this respect has undergone considerable modification; and we now feel convinced that, if the truth were told by every operator with the same candour and openness that he has manifested, it would be seen that, although in almost every instance an improvement may be effected in the personal appearance of the patient, yet, in comparatively few cases, is the deformity so completely remedied that the cure can be pronounced to be perfect. By this we mean it to be understood, that the eyes, whether one or both be operated on, recover their normal direction, freedom of motion, and harmony of action, without exhibiting any unusual appearance that could attract attention. That it would be possible to attain this degree of perfection under all circumstances, or even in the majority of cases, no reasonable person, we should think, would be hardy enough to maintain; yet thus far no other writer has had the candour to admit, or point out the contrary: while, on the other hand, we perfectly coincide with the author that many cases in which this standard might be attained are left imperfectly cured for want of judgment, practical knowledge, and surgical dexterity on the part of the operator. From what we have stated, it will be seen that the

volume apparently bears the impress of truth, and is on this account especially entitled to notice. The author's object does not appear to have been to court popularity, though doubtless, like other professional writers, he has had an eye towards making himself known, but to communicate useful and practical information; and this, from the extensive experience we have reason to believe he has enjoyed, it may be presumed he is competent to do. The remarks are throughout strictly professional, and free from quackery. Were they otherwise, we should at once distrust them. The cases exemplify equally failure and success; and the difficulties that may beset the operator under particular circumstances, and foil his best endeavours, whatever his talent and address, are fairly admitted and forcibly insisted on. "No operation in surgery," he justly observes, "can, by any possibility, be always equally fortunate in its results, although that for the cure of strabismus may be regarded as the most uniformly so of any:" and we feel satisfied every well-wisher to his profession will respond the following sentiment expressed in the prefatorial remarks:— "He who exposes the real value of any curative means by honestly stating the true ratio of success that attends their employment, or who points out the source of failure—be it in only one untoward case—confers a greater benefit on the public, and contributes more to the legitimate advancement of the cause he espouses, than the man who unblushingly blazons forth a hundred examples of untarnished success, while he conceals all the incidents of a contrary nature, which, if detailed with equal fairness, and the same circumstantiality, might serve as most invaluable beacons of safety to his professional brethren."

The remarks, we have said, are exemplified by numerous cases. Such only, however, have apparently been selected as are calculated to explain unusual circumstances attending the operation. The more interesting of these are illustrated by neat, well-executed, lithographic engravings, delineated from nature by an artist of known talent and celebrity as a pathological draughtsman. The work is neatly and creditably got up, and possesses in addition the high recommen-

dation of being sold at an unusually moderate price, considering the number of engravings with which it is illustrated.

Outlines of a course of Lectures on Medical Jurisprudence. By THOMAS STEWART TRAILL, M.D., &c. Regius Professor of Medical Jurisprudence and Medical Police in the University of Edinburgh. Second Edition. Edinburgh, 1840. 12mo. pp. 222.

THIS volume has been carefully drawn up, and will be exceedingly useful to the professor's pupils. The last fifty-six pages are dedicated to Medical Police, and will be consulted by other readers, as it touches on subjects which are, for the most part, passed over by Beck. Such are, the effects of profession and trade on health; climate; sites for towns and habitations; drains and sewers; cemeteries; hospitals; schools; prisons, &c., &c. We wish that Dr. Traill would publish this portion of his book in an expanded form.

MEDICAL GAZETTE.

Friday, December 11, 1840.

MANAGEMENT OF LUNATICS.

THE interests of the professsion, in both a scientific and a pecuniary point of view, are never more in danger than when they are interfered with by the public. There is much in medical practice that requires the understanding to be exercised free from the control of the more tender parts of our nature, and which none can safely undertake to manage whose heart has not been long accustomed to yield before the calm and reasonable dictates of the head. Hence, in great measure it is, that in all cases of eminent medical or surgical importance the public are utterly unable to act aright. Their feelings are so wrought on by the idea of the means that must in these cases be

employed, that their understandings cannot be brought to acknowledge the propriety or even the necessity of adopting them. In judging of a surgical operation, for example, the kind-hearted among the people first, and as if it constituted the most important feature of the case, call to their minds all the horrors of the cutting pain, and exaggerate in their imaginations all the agony that knives, and saws, and hooks, can be supposed to inflict; and when their minds are well impressed with these terrors, they then first begin to reflect on the ultimate good which may result when the pain is done. No wonder that their understanding is but rarely able to master their feelings. It is notorious that in the majority of cases operations are more readily permitted by the patient himself, who is urged to them by the fear of death and the long continuance of his sufferings, than by his friends, who can only appreciate the terror of the main infliction; and it is probable that if operations were to be recommended and performed only with the agreement of the public, surgery would soon cease to be an occupation.

We are very far from holding that a perfect surgeon must be a man utterly devoid of feeling—there is no reason in the world why his feelings should not be most sensitive, but they must be under the subjection of his understanding; he must not regard them or call them, as the public do, the best parts of our nature, but must ever consider them subordinate to that which in his profession is far more worthy of attention— the understanding. That great faculty having decided what is desirable, then, and then only, can the feelings be admitted to have a voice in determining whether the end is worth the price of the means that must be paid to attain it.

What we have said of surgical opera-

tions may apply with equal force to the treatment of the insane, about which public feeling has of late been much excited, without, as far as we can see, any probability of great benefit accruing either to the profession or to the patients. Every one must readily acknowledge that there is no branch of medical practice in which tenderness of manner and a kind disposition are more essential than in this; but there is certainly none in which these should be more under control, nor one in which the honest practitioner should be more completely unfettered to pursue the course which his judgment dictates. There should be no further restraint upon his proceedings than that which is exercised by the friends of those who are committed to his charge, and certain authorized persons having frequent access to the asylum which he directs. It is not to be tolerated that the public should undertake by clamour, or any other means, to dictate the modes of treatment that should be adopted, or (to take at once the part of treatment which is now the subject of agitation), the mode of restraint that should in necessary cases be resorted to.

There is no question, even in medicine, on which they are less capable of forming a correct judgment; and high as are the talents of some among them, who are now chiefly taking interest in this matter, it is plain that even these have not their feelings in the necessary subordination to their understandings. They evidently hold the forcibly restraining madmen from injuring themselves and others in such abhorrence, that scarcely any consideration in their minds can justify its adoption; and they embrace a system in which it is professed that restraint is not employed, with an enthusiasm which shows that they will not suffer themselves to see the faults in any system but that which they condemn.

Now we do not mean that the cha-

racters of the persons by whom the systems are respectively maintained bear any relation of comparison to each other; but it does seem to us that the scheme at present promulgated, of the treatment of the insane without restraint, is of the same kind as that of the treatment of cancer without the knife; of cataract without operation; and some others. In each case the main feature of the new scheme is, at the best, the adoption of some means capable of attaining the same end by the same general plan, only in a manner less offensive to the public feeling. The remedies, other than the knife, for cancer, are violent escharotics, which in the majority of cases, with less safety, produce all or more than the pain of the cutting operation; hence the cases are comparatively few in which judicious surgeons employ them, though in these few none would think of neglecting them for the sake of what the public imagine all surgeons must have — a great love for cutting. In the same manner it is notorious that the person who in the present day most loudly professes his ability to cure cataract without operation—that is, without extraction or depression, is in the habit of stirring up soft cataracts with a needle, passed through the cornea at the time he is pretending to be merely examining the eye. And so in the treatment of the insane without restraint, so loudly applauded, not as in the preceding case by quacks, but by some honest men;—it is not that there is no restraint, but only that the wrist-straps and straight jackets, so terrible in the public mind, are thrown aside, and the patient is restrained (less securely, it must be confessed, to both parties) by the hands of stout and strong keepers, or placed in some circumstances different from, though not less disagreeable than those of the usual restraint, in which he can do himself no mischief.

Now we do not wish to imply that

the professional supporters of the so-called non-restraint system had any eye to public favour in their promulgation of it; we believe them to be too honest for such a purpose ; but we do urge them to refuse to have their system degraded by popularity. If it be founded on scientific principles—if it be by experience proved to be better that a maniac should be restrained by hands than by straps and straight-jackets—then let the system be established and constantly practised on the basis of its truth and utility, and not on that of popular applause. A popular cry has been raised in its favour, and so long as this cry lasts the system can have no professional reputation : let the popular opinion be treated with all the respect that every thing founded on benevolence and sympathy with the afflicted deserves, but let it never be regarded as a prevailing motive to a particular line of medical practice, unless by some unusual coincidence it is unanimous with the results of professional experience.

In recommending this comparative neglect of popular opinion in a case in which the disputed modes of practice have an apparent rather than a real difference, we feel assured that we give that counsel which will soonest lead to the establishment of the best practice, and the greatest amount of public benefit. Let us recur to the case of operative surgery. The public have always believed that surgeons are devotedly fond of cutting, just as they believe now that mental physicians prefer strict restraint : none of them, indeed, have ever raised a clamour against surgeons, nor exercised any greater restraint upon the supposed propensities than that of refusing an operation individually, or for their friends, when they had not confidence enough in their surgeons to accept their recommendations ; and what has been the result ? Have operations,

for want of occasional suppression by public clamour, become more and more frequent ? Have the uncontrolled propensities of surgeons grown more and more sanguinary ? Far from it : the best surgeons of the present day do not now perform one operation where their predecessors in the same situations performed ten. The progress of science has shown what diseases are amenable to cure without operation, and has discovered their remedies ; and surgeons daily employ them, though the public believe them to be as attached to operations as ever, and think the only people who really abhor operating are those who sell nostrums more torturing than knives and saws.

And just so must it be in the case of the practitioners who take charge of the insane. Already the progress of science has banished the truly terrible imprisonments to which the lunatics of the last century were consigned ; and if further improvement in this respect be attainable, it must in due time come to be established. There is no reason to believe that the mental physicians of the present time are more bigotted to the practice of by-gone days, or more regardless of human suffering, than surgeons are ; they are, of course, quite open to conviction, by good evidence, of the superiority, if it really exist, of the new method of restraint called non-restraint ; and as soon as its advantage to the patients is proved it will be readily adopted by them. Neither they, nor any other class of practitioners, are, nor is it desirable they should be, able to free themselves altogether from the influence of public opinion ; for, *cæteris paribus*, those will always attain the greatest amount of practice who can best fulfil their own desire of curing *cito, tute, jucunde*. In the case of lunatics these modes of curing will be best fulfilled by the adoption of the most *speedily* curative method which is compatible with the

bodily *safety* of the patient and his attendants, and a due regard to the *comfort* of the former. No doubt the last intention is greatly involved in the first ; but its fulfilment must not be sought by the neglect of the second, and must be put out of sight in the few, and we believe constantly decreasing number of, cases in which it is incompatible with the first. Where the public see these results best obtained, they will bestow their patronage ; they err much less in their judgment of results than in their choice of means ; and the advocates of the new system need not fear, if it really possess all the advantages which they claim for it, that it will bring them an abundant harvest of reputation and of fees. But let them beware of raising a popular clamour in their favour; it is not likely to secure them either a desirable reputation or a permanent reward; they can never more thoroughly acquire the confidence of the friends of their patients than many of those possess who still practise in the abused style, convinced of its necessity and utility, but combining it with all gentleness of manner and deportment. In a future number we shall take occasion to remark on another part of this question, in which the public opinion has undoubtedly a greater claim to attention, inasmuch as the subject of it is one of which the intelligent portion of the public can form a tolerably accurate judgment—we mean the measures preliminary to the consignment of a supposed lunatic to an asylum.

REMARKS
ON CERTAIN
MUSCLES OF THE FACE, AND A NEW MUSCLE OF THE EAR.

By PROFESSOR HYRTL, of Prague.

NUMEROUS as are the observations of Albinus, Walther, Rosenmüller, Gantzer, Kelch, Sels, &c. on the deviations of ar-rangement in the muscular system, and carefully as Meckel and Soemmering have collected the more important among them in their anatomical manuals, yet certain cases occur to every practical dissector which are not contained in the works on this subject, and which therefore deserve to be made generally known. Such irregular arrangements of muscles have, in addition to the interest of novelty, a higher physiological importance, and inasmuch as they are for the most part repetitions of normal arrangements in animals, they afford the means of illustrating more clearly the relation of the organization of animals to the higher organization of man. In no part of the human body do the muscles vary so much as in the face ; and the study of them is the most difficult, and consequently the most incomplete, part of the whole of myology. No dissection requires more attention, patience, and dexterity, than the demonstration of the organs of motion in the face, of their exact relations to one another, and of their manifold connexions. More especially those fibres have hitherto been for the most part overlooked which go to the skin, and which, by their contractions, form the pits and the folds which regularly characterise a certain expression of the countenance.

Physiognomy might be based on more scientific foundations if anatomy were capable of pointing out what groups of muscles, and what subdivisions of them, are in action, and in what degree each acts, in embodying in the countenance any passing state of the mind, or any permanent mental constitution.

The anatomist must set himself the question, what muscles are in action in a given expression of the countenance ? he should at least endeavour to explain what moving powers produce the expressions of the different states of the mind, or of the acute paroxysms of mental emotions. On these points science is still far behind-hand ; for as the question now stands, all that we know is limited to the simple acts of the raising or drawing down of certain parts of the face. If in any case accuracy and a circumstantiality bordering on minuteness be necessary, it certainly is in that intricate field, in that confusion of fibres and fasciculi of muscle, which traverse the skin of the face.

The industry of Santorini, and his accuracy in the detection of the smaller fasciculi of the muscles of the face, are unequalled by any modern anatomist: on the contrary, pains have been taken to cut down his works to give them a convenient form for anatomical text-boks. I have myself given much attention to the subject ; I have confirmed many of the demonstrations of the excellent anatomists of former times, and have observed many things that are new. I may be allowed, therefore, to put together the ob-

servations that I have made in the following remarks.

1. The frontalis muscle arises neither from the root of the nose, or the glabella, nor, as Meckel* asserts, from the nasal process of the superior maxillary bone; but it developes its muscular fibres from an aponeurosis which covers the dorsum of the nose, and which must be regarded as the result of the interweaving of the tendons of the compressor of the nose. Hence one cannot wrinkle the forehead without at the same time moving the skin of the bridge of the nose. The layer of cellular tissue which covers the frontal muscle, and is very firmly attached to it, is, in parts, intimately connected with the subcutaneous cellular tissue (probably fascia superficialis) by means of short tough fibres, so that when the muscle contracts, and the skin covering it is thrown into wrinkles at right angles to the direction of the muscle, the depressions of the wrinkled skin correspond to the situations at which those connections exist.

The fibres of the muscle which arise from the upper border of the orbit coalesce with the corrugator supercilii, pass through the orbicularis palpebrarum,† and then turn considerably outwards on the forehead, and not unfrequently reach to the superior auris. A very constant bundle of fibres passes downwards on the dorsum of the nose, arches towards the sides, passes to the pyramidalis nasi, and then again leaves it, and loses itself in the labial portion of the levator labii superioris, alæque nasi. Santorini has described this fasciculus as the M. procerus.

The breadth of the frontalis muscle on each side is commonly equal to half the diameter of the orbicularis palpebrarum. In women it is generally smaller; it is broadest in heads that have a frontal suture. I have never observed a continuity of the fasciculi of the frontalis with those of the occipitalis, such as Sandifort and Ludwig say that they have seen.

2. The orbicularis palpebrarum arises not only from the ligamentum palpebræ internum and the nasal process of the superior maxillary bone, but also from the inner part of the lower border of the orbit by tolerably numerous parallel fibres, which have hitherto been described only by Heister,‡ who made a musculus depressor palpebræ inferioris of them. A fasciculus also, sometimes, but not constantly, arises from the malar bone, from which also there is always sent off a small

* Handbuch der Menschl. Anat. Bd. 2. p. 480.
† This arrangement is normal and constant. Even in very weakly-muscled individuals one finds one part of the orbicularis below the other which is placed on the frontalis; the latter muscle slides as it were between the two portions of the former.
‡ Compend. Anat., p. 174.

bundle of fibres, which attach themselves to the outer edge of the levator labii superioris, and remain united to it, or pass to that part of the skin in which, during laughing, the furrow forms which leads down from the side of the nose to the angle of the mouth. The fasciculus going to the zygomatiens major or minor is not always present.

It is incorrect to call the layer of muscle which extends over the tarsal cartilages a circular muscle. Accurate examination shows that the fibres of the lower and those of the upper eyelid are never continued into one another. Each lid has its own independent and separately acting fibres. This is proved not only by dissection, but by an experiment which shows that the motion of the lower eyelid is quite distinct from that of the upper. If we measure off on the border of each of the two lids an equal distance from the internal angle of one, for example the left, eye, and mark them with black dots, and then shut the eye, we can see, by looking in a glass with the right eye, that the black point on the lower lid does not correspond with that on the upper, but is carried almost a line nearer to the internal angle of the eye; which could certainly not occur if the upper and lower lids had one circular constrictor muscle.

3. The muscles of the nose can be profitably examined only in very muscular individuals. The levator labii superioris alæque nasi, which Santorini named pyramidalis, and which Winslow first described as a distinct muscle, is always connected at its origin with the constrictor of the eyelids, and sometimes with the frontalis also. We are consequently unable to close the eyelids forcibly without at the same time drawing up the alæ nasi, and wrinkling the skin on the dorsum of the nose. But before the muscle gets to the lips it sends a separate fasciculus to the skin, which is increased by a similar fasciculus from the levator labii superioris. These fasciculi together appear to perform the principal part in the formation of the wrinkles in laughing.

4. The muscle of the apex of the nose, which is figured by Santorini, is found only in very broad noses, on which I have frequently seen a small extra cartilage, lying between the triangular and alar cartilages, of an irregularly quadrilateral form, and firmly connected with the ligament which unites those two cartilages.

5. There is no depressor alæ nasi, though it is figured in all anatomical works. What Soemmering, Meckel, Hildebrandt, Krause, and others, describe as the depressor alæ nasi, is that which Santorini called the dilatator proprius pinnarum, which is in part covered by the compressor nasi (the transversalis nasi of Santorini). If the sides of the nose be lightly touched with the fingers,

and a strong inspiration be then made through the nostrils, as in taking snuff, the action of this muscle in dilating the nostrils is very distinctly felt. If I pass the tip of the little finger into one nostril, and make a similar inspiration, I feel that the short canal into which the apertures of the nostril lead acquires a more vertical direction towards the ethmoid bone, while in quiet respiration it looks more horizontally backwards towards the fauces. This is probably what Bell would call a respiratory motion of the nose; it occurs in snuff-taking, because, in snuffing up, the apertures of the nostrils are intentionally opened and shut, so that in inspiration through the nose the air passes forcibly into the nostrils, and in consequence of the more vertical position of the nasal passages carries the narcotic powder towards the upper regions of the cavities, where the terminations of the olfactory nerves ramify. In gentle inspiration, on the other hand, the more horizontally-directed passages into the nose carry the snuff towards the fauces and the larynx, as every one who breathes over finely-powdered snuff will learn by the coughing that it excites. It is only thus that we can explain why snuff and other sternutatory powders do not get into the lungs, into which they might else just as well pass as the dust of roads, which we inspire through the nostrils. In excited or difficult respiration, in severe inflammations of the lungs, and in the death-rattle, the respiratory office of this dilator of the nose is most clearly exhibited. If the nervous trunk that supplies this muscle be paralysed, the nose ceases to exercise its respiratory function. While in healthy men in deep inspiration through the nose, the nostrils are dilated by the action of this muscle, in those who are apoplectic, or whose faces are paralysed, the nostril is compressed in inspiration because the ala nasi yields to the pressure of the air like a valve, which is again raised up in expiration.

6. In the skin of the cheeks I have several times, and especially in lean subjects, seen a muscular fasciculus which both originated and terminated in the skin; arising in the region of the malar bone, and ending above, or on the outer side of, the angle of the mouth. It never exceeded a line in breadth; and its length varied from an inch to an inch and a quarter. It constantly presented itself in the same manner, and therefore could not be regarded as a mere accident. Its absence in men with fat cheeks might perhaps be explained by its becoming atrophied in consequence of the compression which it suffers from the accumulating adipose substance.

7. More rarely a similar fasciculus passes from the anterior edge of the tendon of the masseter to the skin of the cheek.

8. I once saw an accessory fasciculus of muscular fibres passing from the fibrous investment of the parotid gland to the zygomaticus major. The zygomaticus often gives delicate fibres to the skin, of which one, which separates from its lower edge, appears especially developed. If this accessory to the zygomaticus be pulled with the forceps, a pit is formed in the cheek at the point of its insertion in the skin.

9. The depressor anguli oris has a similar fasciculus at its outer edge, which is often attached to the malar bone, and runs upwards upon it.

10. On no muscle is there so little agreement among anatomists as on the risorius Santorini. Meckel and Krause see nothing more in it than a prolongation of the platysma myoides. But this it is not, and it cannot be, because the direction of the platysma crosses that of the fibres of the risorius. According to my observations it always arises from the fascia parotideo-masseterica, and never loses itself in the skin at the angle of the mouth to produce there the dimples of laughing, but is regularly connected with the insertion of the depressor anguli oris. Its discoverer himself regarded it as different from the platysma myoides, and said, "Alius omnino a quadrato,* indeque non derivatur, quod huic ille subjicitur." It is rarely absent, and sometimes acquires a breadth of two lines. It is sometimes double, and Santorini saw it even triple.

11. The platysma myoides sometimes sends a separate fasciculus over the fascia parotidea to the zygoma, where it unites with the masseter, in the same manner as a similar fasciculus from it, which passes behind the ear to the occipitalis, is attached to the outer edge of that muscle.

12. The musculus anomalus maxillæ superioris, that paradox of a muscle, has only an historical value. It proves clearly enough how easily an error in anatomy propagates itself by tradition, and how little pains have been taken to rid the science of such absurdities.

13. From the angle of the lower jaw of a man 40 years old, there arose a thin muscle two lines wide, which passed over the outer surface of the parotid to the meatus auditorius externus, to be attached to the anterior and lower border of the ridge of the meatus (musculus maxillo-auricularis).

That this muscle has the power of enlarging the entrance of the meatus auditorius is evident from its anatomical relations. Perhaps it occurs only in men who have an acute sense of hearing. One might explain

* The πλατυσμα μυῶδες of Galen was named quadratus genæ, and tetragonus colli by Douglas and Camper.

the dilatation of the external meatus when the mouth is opened (which is felt when a finger is put into the ear, and masticatory motions are performed by the lower jaw) as well by the action of this muscle as by the relation of the condyle of the lower jaw to the cartilage of the meatus.

14. In about every sixth corpse there may be found a muscle passing from the styloid process to the lower part of the circumference of the cartilage of the external meatus. It arises on the styloid process, above the origin of the stylo-glossus, with which it is connected by fleshy or tendinous fibres. It passes upwards on the outer surface of the process, gradually diminishes, and is inserted in the lowest prominence of the meatus auditorius cartilagineus by a radiating tendon. In consequence of this anatomical arrangement, this muscle acts as a depressor of the external ear, and a dilater of the meatus, and might fairly be named musculus stylo-auricularis. It is enclosed in a peculiar sheath which affixes it to the styloid process; it receives a nervous filament from the nervous occipitalis minor, and an artery from the stylo-mastoid or occipital. It is usually spindle-shaped, varies in width from half a line to a line and a half, and is sometimes two-bellied, in which case its lower portion is a fasciculus derived and passing upwards from the stylo-glossus.

I first saw this muscle when I was prosector at Vienna, in the body of a robust man, and I noted it as an interesting extra-development of muscle. In following years, and in this last, I have often found it again, and I believe I am justified in saying that it is more than a mere anomaly. In strongly muscular subjects, with short necks and tough aural cartilages, it is very rarely absent. Its influence on the dilatation of the cartilaginous meatus which leads to the membrana tympani renders it physiologically interesting. In the cases in which it is absent, there is at always tendinous band going from the origin of the stylo-glossus to the same part of the auditory passage; and this I regard as the empty sheath of the deficient muscle—a shell without its kernel.— *Medic. Jahrb. des k. k. österreich. Staates.* Bd. xxx. St. 3.

ABERDEEN INFIRMARY REPORTS.

Cases and Observations by —— LAING, Esq. One of the Surgeons of the Hospital.

CYSTIC OR HYDATOID DISEASE OF THE TESTIS.

A. M., æt. 29, admitted April 11th, 1838, with a large swelling of the left side of the scrotum. The tumor is puriform, somewhat elastic, and has an indistinct fluctuation, but by no means the feel of hydrocele. The cord seems to be sound. He says the swelling began several years ago, without any known cause, commencing towards the lower part of the scrotum. The opposite testis is considerably enlarged and hard. On examination a cicatrix was observed at the lower part of the scrotum, which he says was the result of an abscess which occurred there about two years ago, and burst spontaneously, but soon healed. It burst again last winter, and discharged for several weeks. His complexion is florid; but his constitution is feeble, and seemingly scrofulous. A calomel pill was ordered, followed by Epsom salts, and a cooling lotion, to relieve the superficial inflammation, which seemed to have been excited by the journey.

April 19th.—An operation having been determined on, an incision was cautiously made through the integuments of the scrotum and tunica vaginalis, when a bluish semitransparent membrane presented itself. Into this a small trocar was cautiously pushed, but only about half an ounce of transparent serum escaped. On withdrawing the instrument another similar membrane appeared, which was drawn outwards with dissecting forceps, and punctured, and found to contain only two or three drams of serum. In this manner many similar cysts were successively drawn forward and opened, to the number of upwards of thirty, as the quantity of serum amounted to sixteen ounces. The wound was then closed with adhesive plaster.

Two days after the operation he was seized with febrile symptoms, which were treated by saline and antimonial medicines; and this was followed by erysipelas of the face: the pulse rose to 125, and he had much confusion and delirium. The head was shaved, cold lotions applied, and a band one inch broad made between the face and the scalp by nitrate of silver. These means, with purgatives, saline and antimonial medicines, subdued the fever and the erysipelas of the face; but the wound in the scrotum was still considerably inflamed.

Adhibeantur Cataplasmata.

30th.—He is now convalescent; pulse 84; tongue clean; the wound of the scrotum discharging healthy pus.

May 12th.—The opening in the scrotum contracting, and the discharge much diminished. The testis of the left side is now little above the natural size, though the scrotum is still thickened and enlarged. The right testis is still hard and somewhat painful to the touch.

23d.—Dismissed.

This patient returned to the hospital in

July, 1839, on account of a different disease. The testis formerly operated on was found quite sound, being scarcely larger, but somewhat softer than natural, without any pain. This was evidently a case of the disease called by Mr. Guthrie, and others, cystic or hydatoid disease of the testis, but differed from most of the cases recorded in the size of the cysts, which are usually described as being from the size of peas to that of grapes.

CASE OF DISEASED TESTIS.

E. A., ætat. 35, wright, was admitted on the 9th January, 1840, with a large tense elastic swelling of the left side of the scrotum, neither affected by coughing nor change of position, but extending up the cord as far as the abdominal aperture. It gave him little uneasiness, unless what arose from its bulk. On the whole the symptoms closely resembled those of hydrocele, but the tumor was not transparent, and the fluctuation was less distinct. It commenced about twelve months ago, without any known cause, and extended gradually upwards. On the 13th an incision was cautiously made through the integuments and the tunica vaginalis, when a hydatid of considerable size presented itself. This was punctured, and was immediately followed by another, which was also punctured, exactly as described in the preceding case; and thus ten or twelve ounces of serum were evacuated. As soon as the first cyst appeared, I sent for two of my colleagues, and they were witnesses to the successive puncturing of the cysts. When the scrotum was reduced nearly to the natural size, the edges of the wound were brought together with adhesive plasters.

14th.—The wound continued for some time to ooze out a watery fluid. To-day the scrotum is slightly swollen and inflamed.

Adhibeantur Cataplasmata. Low diet.

15th.—Was seized with severe pain of the testicles soon after yesterday's visit. The scrotum is now much enlarged, red, tense, and extremely tender; pulse frequent; tongue furred, and white; bowels opened by medicine this morning.

℞ Antimon. Tartar. gr. iv.; Aquæ Cass. ℥viij.; Solve Capiat. unciam, tertiis horis. Continuentur Cataplasmata et Fotus.

18th.—Swelling still great, but pain diminished. The integuments have assumed a gangrenous appearance in several places. Four or five incisions were made into the scrotum, which discharged blood and serum.

Continuentur Omnia.

20th.—No sloughing has taken place on the left side of the scrotum, the matter having found vent by the incisions; but a large

slough, four or five inches in length, by two in breadth, has formed on the right side.

Omittatur Mistura. Continuentur Cætera. ℞ Opii gr. i., formâ Pilulæ, omni nocte.

23d. — The slough, which comprehends almost the whole fore part of the scrotum, is now detached, and the right testis threatens to protrude. It is retained by adhesive straps. The febrile symptoms have nearly subsided.

He was ordered porter and Sulphuric Acid mixture. Continuentur Pilulæ Opii bis die, et Oleum Ricini pro re nata.

February 10th. — Health improved, and strength returning rapidly. The ulcer is granulating and cicatrizing steadily. The testis of the affected side is reduced nearly to its natural size. Pergat.

18th.—Going on extremely well. The ulcer is diminished to the size of a crown-piece.

Omittantur Pilulæ Opii.

March 10th.—The wound has continued to contract gradually, and is now healed. The cicatrix is extremely small, compared with the great size of the ulcer. Dismissed cured.

Although the treatment adopted in these two cases proved successful, yet the symptoms were so severe, and the cure so tedious, that I doubt whether extirpation of the testis would not be preferable.

CASE OF SECONDARY HÆMORRHAGE CURED BY LIGATURE OF THE FEMORAL ARTERY.

J. C., æt. 24, a pilot, was admitted on the 22d of April, 1838, with both legs severely fractured. The accident was occasioned by his legs being entangled in a rope attached to a ship in motion. The left leg had suffered a compound and comminuted fracture, the tibia protruding through the wound. The bones of the right leg were comminuted, but did not protrude. There was, however, an external wound, and much contusion of the soft parts. There was also considerable hæmorrhage from the wound of the left leg, which was, however, soon checked by cloths soaked in cold water. It being determined to attempt saving both legs, they were set as accurately as possible, and splints and bandages applied. An anodyne draught was ordered at night, and the usual treatment in all other respects.

On the 25th the wound of the right leg had assumed a gangrenous appearance, which rendered it necessary to remove the splints from it, and apply poultices, fomentations, &c. The wound of the left leg was looking well. It was dressed, and the splints reapplied.

On the 5th of May a large portion of the tibia was extracted from the wound of the right leg, which soon after began to assume a more favourable appearance; but, about the 10th, the left leg and knee were attacked with phlegmonous erysipelas, and diffuse abscesses formed near each molleolus. These were opened by the lancet, and discharged profusely. His strength was now supported by nourishing food, wine, porter, &c., and the wound of the right leg began to granulate favourably; but the abscesses in the left leg discharged copiously, and the heel began to slough from pressure. He was also affected with irregular fever, and occasional diarrhœa, for which astringents, opiates, and quinine, were employed. In the month of July the ulcers in the right leg were nearly cicatrized, and the bones had begun to reunite: but the bones of the left leg remained loose and bare, the sloughing of the heel continued, the os calcis became carious, and his strength was so much reduced by the discharge, that it became necessary, in the beginning of August, to propose amputation of that limb, in order to save his life. The operation was accordingly performed on the 14th, at the usual distance below the knee, a flap being formed from the calf by transfixion. On the 20th the stump looked well, union by the first intention having taken place to a considerable extent. On the night of the 24th copious hæmorrhage occurred, in consequence of his having started up in bed from some sudden alarm. It was arrested by cold and pressure. On the 25th it recurred with greater violence. On taking off the dressings the lips of the wound were found to be forced asunder by coagulated blood. On clearing it away, the state of the stump was found to be such that it was impossible to seize and tie the bleeding vessels. A piece of sponge was, therefore, placed over them, and pressure applied by means of compresses and bandages.

27th.—Hæmorrhage has returned with violence four or five times since yesterday. Each attack of bleeding is preceded by severe pain in the stump. His strength is now alarmingly reduced, the lips and caruncula lacrymalis being pale, the pulse 160, feeble, and undulating. Amputation above the knee being considered inadmissible from his great debility, I proceeded immediately, with the assistance of my colleague Dr. Dyce, to tie the femoral artery, as the only remaining alternative. The incision was made in the usual place, the inner edge of the sartorius muscle raised, the sheath of the vessels opened, and a single ligature passed round the artery. Fortunately not a teaspoonful of blood was lost during the operation, as the patient had very little to spare. The coagulated blood was now removed from the face of the stump, but no hæmorrhage

followed. The flap was, therefore, reapplied, and the wound dressed. From eight to twelve hours after the operation the temperature of the limb was six or seven degrees lower than that of the opposite side, notwithstanding the application of warm bottles, flannel, &c. Next morning it was only two degrees lower, and in the course of the following day became quite natural.

On the 2d September, the pulse had fallen to 112, and was firmer, and his colour had begun to return. The wound in the fore-part of the thigh had adhered by the first intention, except where the ligature passed out. The stump also was granulating freely, and had begun to cicatrize. Wine. quinine, and nourishing food, were continued. From this time he continued to improve steadily.

On the 18th the ligature came away from the artery, and soon after the wound closed. The stump also was nearly skinned over, and his strength much restored.

On the 14th of October the stump was entirely healed, and the right leg firm, and but slightly deformed. He was soon after dismissed, quite well.

CASE OF TETANUS.

To the Editor of the Medical Gazette.

Sir,

Thinking that the accompanying case will be an acceptable contribution to the profession, on the treatment of an obscure disease, I shall feel obliged by your giving it insertion in an early number of your valuable journal.—I remain, sir,

Your obedient servant,

Thos. Lewis, M.B. M.R.C.S.L.

2, Rodney-street, Liverpool,
Dec. 3, 1840.

Tetanus following the reduction of an old partial dislocation of the ankle by a bone-setter. Useful effects of the Extract of Indian Hemp—Pleuritis—Pneumonia—Death—Autopsy.

Mr. J——, a patient of Mr. Bickersteth's, æt. 29, of middle conformation, sanguineo-melancholic temperament, enjoying good health. Nine months ago, while exercising in a gymnasium, he dislocated the right ankle, and fractured the fibula near its lower extremity. The dislocation was not completely reduced, but left some deformity; the foot was turned too much outwards. He has been lame ever since, and obliged to use one or two walking-sticks.

On the 21st of last month (Oct.), a quack bone-setter undertook to rectify the deformity. A relative of the patient states that he used a good deal of force for about seven

minutes, and the patient states he felt the reduction. For three days previously to this, the foot and ankle were immersed in a poultice of grains. After the reduction a plaster was applied round the ankle, which blistered the surface. The patient states that he has been able to walk better since the reduction ; but his relative states that she has observed a marked alteration in him—he has been lower in spirits than usual.

On the 10th Nov., he went in the morning to his office as usual, and early in the afternoon returned home. He was now seen for the first time : he said that he felt last evening an oppression and constriction of the chest, with inability to open his mouth, but had slept well last night : he also felt stiffness about the eyelids. These symptoms have so much increased as to oblige him to return from his duties. The eyelids do not appear too much closed, though he says he cannot open them as usual. The mouth cannot be opened any more than to allow the end of the little finger being introduced : masseter muscles not rigid : there is no pain ; pulse quiet ; skin cool : there is no pain in the ankle ; the cuticle is desquamating in large scales upon it; breathing slow.

Ordered to take—a warm bath ; Calomel and Dover's powders at bed-time ; and a saline draught every four hours.

Nov. 11th.—Took a vapour bath, and not the warm bath as ordered ; slept tolerably well last night. 2½ P.M.—There is no improvement of the symptoms. 9½ P.M.—He had been lying on a sofa all day, and in going up stairs to bed he became pale and faint, with a great increase of the oppression of the chest : he now feels more easy.

A Liniment of Soap, Camphor, and Tinct. Opii, ordered to be rubbed into the buccal region. Calomel and Dover's powder to be repeated to-night.

12th, 4½ A.M.—Has had some sleep, but the sense of constriction of the chest is much increased, so that he cannot lie long upon his back ; he prefers lying on his side : the jaws are more closed. There has been no stiffness about the neck, nor inconvenience in swallowing. There is a rash out over the whole body ; face flushed ; pulse 102, not full ; no rigidity of the muscles ; no pain in the head : he said he had pain in the forehead the night before. Mr. Bickersteth recommended counter-irritation to the spine ; and to take Morph. Mur. gr. ss., Calomel, gr. iij., every three hours : bowels costive since yesterday. Ordered a senna draught. Potassæ fusa was well applied on each side of the cervical spinous processes. 12¾ A.M.— No improvement ; pulse 100. The rash has now almost entirely subsided. 11½ P.M.— Mr. Bickersteth saw him this afternoon, and

ordered the senna draught to be repeated : since then he has vomited several times, and has thrown up the draught. The thoracic oppression is still increased, which makes him very restless ; he requests to be moved from one position to another every two or three minutes. Complains of feeling very weak ; he cannot turn himself in bed ; pulse 120. The mouth is somewhat more relaxed. The upper extremities have been a few times spasmodically moved just at the time of falling asleep : complains of a feeling of fatigue in the back of the neck, which leads him to change his position every few minutes.

Ordered—an injection of Castor Oil and Turpentine, aa. ʒj. in ʒvj. gruel.

℞ Ferri Sesquioxidi, ʒiv. ; Thereacæ, ʒviij. ; Coch, j. ampl. 2nda. vel. 3tia. q. q. Hora Sumend. ; Pergat in usu pil. Morph. et Calom.

℞ Ungt. Hydr. Fort. Spino dorsi. infricand. ter die.

13th.—The oppression of the chest is worse ; an attempt to swallow is followed by very strong contraction of the jaws ; after a short time the spasm relaxes, and the mouth can be opened so as to admit the end of the little finger. A piece of wood was placed between the molar teeth while some of the electuary of iron was given, but the attempt to swallow produced such contraction of the jaws as to give pain, and the wood was removed with some difficulty. The temporal and masseter muscles are now felt hard and rigid ; there is stiffness of the lower extremities, but he can move them : has stiffness in the back of the neck. Pulse 110. Says he feels much weaker : cannot turn himself in bed. The electuary has not been given regularly : he could not be made to swallow it. The bowels have moved twice since the injection. The breath has rather a fœtid odour.

14th, 2½ A.M. — Yesterday evening he complained of great pain across the right side of the chest, for which Mr. Bickersteth ordered a mustard poultice : he was relieved by it for a short time, but the pain is now very severe in the right mammary region. He could not inspire without sharp, cutting pain, and appeared to be relieved by pressure upon the part : he makes attempts to suppress respiration. A distinct friction sound is heard just under the right mammilla ; pulse strong and full, 120 ; face much flushed. The trismus about the same : says there is less stiffness about the neck.

Ordered—ten leeches to the mammary region, to be followed by a mustard poultice. The Calomel and Morph. had not been given yesterday. A pill was to be given after the application of the leeches.

6 P.M.—Had considerable relief after the

leeches ; but the pain came on again, and at 6 A.M. eight more leeches were applied, with relief. At present there is much less pain in breathing ; there is great stiffness of the muscles of the back, and of the left thigh ; he cannot bend the trunk, nor flex the thigh on the pelvis. The other symptoms are the same : pulse softer, and not so full as in the morning. He was now seen for the first time by Dr. O'Donnell, who proposed pursuing the purgative plan of treatment.

℞ Calomel, Pulv. Scammonii, aa. gr. v. 2nda. q. q. hora s. After purgation— to take Acidi Hydrocyanici dil. ℔v. every two hours, until some effect is produced.

15th, 9 P.M.—Six of the powders have been given, and three more of double their strength, but without any effect. Dr.O'Don-nell remained with him this afternoon, and administered about four doses of Hydro-cyanic Acid. Dil., of ten minims each, at short intervals, without effect. Friction to the trunk and extremities was ordered. It was thought that the acid might have been weak, and the following mixture was obtained from the Apothecaries' Hall (out of a fresh bottle).

℞ Acid Hydrocyan. Dil. ʒij. ; Aquæ Cin-namomi, ʒij. ; M. ft. Mist.

Dr. O'Donnell and myself staid to administer this. I will just describe his state at this time : pulse about 150, soft and moderately full ; great prostration ; decubitus on the back ; jaws closed, but by a little force may be separated a quarter of an inch ; does not complain of pain except when the spasmodic paroxysms come on, which is every two or three minutes, affecting the muscles of the trunk and lower extremities : an attempt to move his thigh will bring on a spasm. The left lower extremity is more affected than the right. During the paroxysm the features are distorted and the chest thrown forwards, but there is not well-marked opisthotonos. The stomach would appear to be contracted at the time with the voluntary muscles, for, simultaneously with the general paroxysm, he throws up a dark mucous fluid, which he spits out : there is a good deal of saliva mixed with it. A little of the tongue can be seen, and appears dark in the centre. He speaks very little ; it is a labour for him to do so. The bowels have not moved; no urine passed for seventeen hours ; abdomen soft. Four doses, ʒj. each, of the above mixture, were given in the space of twenty minutes, which, after being retained two or three minutes, were ejected during the general paroxysm. The only effect noticed was a fluttering of the respiration. After an interval of twenty minutes three teaspoonsful of the same mix-ture were given at once, but without any effect, and was soon ejected.

Mr. Bickersteth having proposed the use of he extract of hemp, it was kindly fur-nished by Dr. Jackson, of Mount Pleasante A solution was made of twelve grains in five drams of alcohol and water. At 10½ P.M., a teaspoonful of the solution was given, and retained. At 11½ P.M., he passed about half a pint of dark-coloured ammoniacal urine. The paroxysms were now very much abated. The same dose was ordered to be repeated at 12 P.M., and then every two hours until sleep was induced. The Calomel and Morphia were omitted since yesterday morning, and the electuary of iron this morning.

16th, 8½ A.M.—At an early hour the friends of the patient sent to say that the jaws were opened, and that he had had some sleep. It was ascertained that the second dose of the solution was ejected, and another given was retained. Shortly afterwards he fell asleep, which continued for about three hours and a half. There were frequent con-vulsive motions of the head and trunk during this sleep : about an hour and a half after awaking he was able to open his mouth, and converse rather freely : the paroxysms were then very much abated. A fourth dose of the solution was given about 6 A.M. The jaws are still free; no rigidity ; occasional spasm of the trunk, but very transient : there appeared to be a smile upon his countenance, and an expression of being happy. He spoke rather freely, but was delirious ; pulse 160, very weak ; bowels not moved.

Ordered—Injection to be repeated, and to take some beef tea.

12½ A.M.—Seen by Mr. Bickersteth and Dr. O'Donnell : since last report has had nearly two hours' sleep ; countenance much altered for the worse ; pulse varying from 140 to 160, very weak and small ; hands were cool and moist, and of a bluish colour ; bowels have just now freely moved ; evacuation liquid, of black colour.

Ordered—ʒij. wine every hour, and beef-tea.

He was now observed for half an hour, and had no spasm, but was inclined to sleep. The remaining dose of the solution of the extract of hemp not to be given while the effects of the former dose remained. 3 P.M. —Had two convulsions since last report, and has been in a comatose state, but may be roused ; took two ounces of wine, and some beef-tea ; pulse now hardly perceptible. From this time he gradually sunk, and died without a struggle at 3¾ P.M.

Autopsy, twenty-one hours after Death.

Exterior.—Considerable rigidity of the extremities. Extensive livid discolouration of the integuments of the back, especially of

the lumbar region. Percussion rather dull in the right axilla.

Spinal cord.—Nothing more than moderate congestion of the vessels of the pia mater was observed, and this was more marked on the posterior than the anterior surface.

Brain.—The dura mater adhered very firmly to the inner surface of the skull. Some congestion of the pia mater on the posterior part of the brain. A thin layer of bloody serum under the arachnoid made the membrane appear very red in some parts, especially on the left posterior lobe. The same was observed on the anterior lobes, but to a less extent. The cortical substance was of a deep colour, and contrasted well with the medullary ; the latter was considerably congested. After section the red points were very numerous, the blood which oozed out being of a very deep colour : no softening observed : no fluid in one of the lateral ventricles, and only about half a dram in the other : the cerebellum was not so congested as the cerebrum.

Chest.— Both lungs had collapsed. A small quantity of bloody serum in the right pleura. *Right lung.*—On the anterior and lower part of the upper lobe there was a thin layer of lymph ; on its lower margin it was about the thickness of a shilling. There were two or three small masses of hepatization just beneath the lymph. The lower lobe, and the depending part of the upper, felt heavy ; broke rather readily on pressure, emitting a spumous bloody fluid, not hepatized, but much congested, The large bronchi contained a frothy mucus tinged with blood. Smaller ones not examined. The *left lung* was in a similar state of congestion as the right.

Heart.—Judging by the eye, it appeared somewhat smaller than natural ; very flaccid ; all the cavities quite empty, except the right ventricle, which contained a gelatinous looking coagulum, about the size of a filbert : there was little or no blood within it. All the valves were thin, translucent, and healthy.

Abdomen.—Numerous old adhesions of the liver to the diaphragm and abdominal wall. Three or four biliary calculi, size of hempseed, in the gall-bladder, which was distended with bile. *Spleen.*—Small and firm. *Stomach.*—Moderately distended with gas ; contained only two or three drams of a thick dark-green fluid, having a very acid odour. The mucous membrane along the lesser curvature presented a patch of ecchymosed spots : the remainder pale and normal. A few large injected veins ran across the anterior and posterior surface of the organ. I did not smell any hydrocyanic acid in the stomach. *Intestines* rather inflated ; contained some black liquid fæces, which in the descending colon had the odour of turpentine. Other parts not examined.

REMARKS.—The object intended in publishing this case has been to direct attention to a remedy which in India and in this country (as proved in the foregoing case) has been found to possess power in controlling spasmodic action of the muscular system ; and though the case did not terminate favourably, yet such facts have been elicited as to entitle the extract of Indian hemp to an early administration in future cases.

It is to be hoped that some channel for its introduction into this country will be soon opened, so that the remedy may be accessible to the profession generally. At present, I believe, it has only been introduced through private hands.

THE EXTENSION OF VACCINATION ACT.

To the Editor of the Medical Gazette.

Sir,

You doubtless, Mr. Editor, remember the occasion on which Æsop represents one of his characters as exclaiming, " Oh ! my sons, behold the power of unity." The medical men about Brentford have nobly illustrated the truth of the sage's remark : we, too, the medical officers of the Edmonton Union, have followed in their wake ; see the result— here is the brief detail :—

On the 29th of October, the Board directed their medical officers to be written to, to ascertain whether they were willing to vaccinate in their several districts, according to the new Act, at 18d. per case. A meeting of six, of the medical staff of seven, took place ; we answered the Board by declining to enter on the provisions of the recent Act at less than half-a-crown per case.

It was late before our joint tender was sent in ; scarcely more than one-tenth of the guardians was present : we had not expected any decision till the next Board-day, yet this fraction considering, that as medical men had generally vaccinated gratuitously, and as we had " vaccination included under our present contract," resolved that 18d. was a sufficient remuneration, and again offered the said sum.

The only surgeon who did not attend the meeting of his *confrères* accepted the 18d. The six non-contents, however, met again ; urged the attendance of a full Board ; renewed their application for the half-crown. At the next Board-day they were warmly seconded by the more liberal guardians, and had the gratification of carrying the half-crown by a majority of 15 to 9.

A guardian proposed that the seceder be promoted to the level of his half-crown brethren, which was resolved accordingly by the Board. It is but justice, however, to this

gentleman to remark, that he has coalesced to-day with us from whom he so injudiciously separated, owing, it appears, to some erroneous notion he entertained that paupers only would be vaccinated under the new Act. He has, with much good feeling, withdrawn his original tender of 18d., and now, with us, refuses to accept the same, even should the Commissioners decline to confirm the half-crown appointment. We wait their decision ; but we have thought it well to put on record and circulate, as soon as may be, the above detail, that other surgeons, situated as we were, may be like-minded ; and feel, when impelled by a sense of what is due to themselves and their profession, that they are not travelling altogether a " terra incognita," or destitute of the "chart and compass" of other men's experience.

I am, sir, on behalf of my colleagues, the medical officers of the Edmonton Union,

Your obedient servant,

CHARLES F. J. LORD.

Hamstead, Nov. 25th, 1840.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

A LECTURE pointing out the true nature of vaccination was delivered by Dr. Cowan, at the Town Hall, Reading, on Friday, the 4th instant.

Similar efforts throughout the country would materially aid in removing the prejudices against, and in promoting the practice of this invaluable discovery.   A.

Reading, Dec. 7, 1840.

ON UTERINE HÆMORRHAGE.

To the Editor of the Medical Gazette.

SIR,

THE following statement is made by Dr. Francis Ramsbotham, at page 473 of his work, with plates, now publishing in parts :—
" It has for a long time been known that the placenta may be found at the os uteri under labour ; and this malposition was noticed by Guillemeau, Mauriceau, Amand, Astruc, Dionis, in France ; Daventer, in Holland ; Bracken and Pugh, in this country, besides others ; but they all held the opinion that it was not originally apposed to this part of the uterus by nature, but that in consequence of some peculiar accidental circumstances it had become loosened from its attachment above, had fallen down by its own weight, and had thus accidentally placed itself over the uterine orifice."

I am aware that a statement similar to the preceding has often been made, though destitute of foundation.   There is no passage either in the works of Guillemeau or Mauriceau to support it ; and there are expressions employed by them in describing cases of placental presentation, from which it may be inferred that they believed the placenta in such cases to have been originally adherent to the neck of the uterus.

But Paul Portal, in his treatise, 1685, states in the most clear and decided manner that he found in not less than five cases the placenta adhering all round to the neck of the uterus.   It is evident from the following extracts that he was as well acquainted with the circumstance as any accoucheur is at the present time, that the placenta was not, as Dr. Ramsbotham has asserted, " loosened from its attachment above, and had fallen down by its own weight, and had thus accidentally placed itself over the uterine orifice." Paul Portal's 39th case was one in which the placenta presented, and he recommended immediate delivery, by turning the child, as the only means of saving the patient's life. He introduced his fingers, and found the placenta adhering all round to the cervix.

" Sur cette assurance je glissay mes doigts dans les orifices, où je *sentis* l'arriere faire qui se presentoit et qui bouchoit l'orifice de la matrice de tous cotés avec adherence en toutes ses parties, excepte par le milieu, qui se trouvoit divisé jusqu'à la membrane,"

In his 66th case the same thing was observed ; and in case 68 he says he felt the placenta adhering firmly to the cervix uteri. " Alors je les evacuay, et je glissay mes doigts plus avant, où je sentis l'orifice interne ouvert à passer trois doigts fort mollet, tendre et delie ; et introduisant le doigt, je sentis l'arriere faire qui se presentoit, et qui étoit *fort adherent et attaché à l'orifice de la matrice de toutes parts*, ce qui causoit cette grande perte de sang." There are several other cases, exactly similar, in Portal's work, to which it is unnecessary particularly to refer.

I am sure Dr. Ramsbotham will be glad to render justice to Paul Portal in the next number of his work, and also to Mauriceau, who first pointed out the great distinction between the treatment required in cases of placental presentation, and those of uterine hæmorrhage in which the placenta had adhered to the upper part of the uterus, and been detached by some accidental cause.

If Dr. Ramsbotham will take the trouble to read Mauriceau's cases, he will find that after the year 1682, where the placenta did not present, he always ruptured the membranes, and left the child to be expelled by the natural efforts, as was afterwards so strongly recommended by Pugos. It is not, therefore, to our countryman, the late Dr. Rigby, as he asserts, but to Mauriceau, that

we are indebted for this great practical improvement in the treatment of flooding at the commencement of labour. If I have n ow stated what is incorrect, let Dr. R. point out where the error lies.

Your obedient servant,
A STUDENT OF MIDWIFERY.

Dec. 5, 1840.

GLOUCESTERSHIRE MEDICAL AND SURGICAL ASSOCIATION.

Established for the purpose of *protecting the Character and legitimate Interests of the Profession*, and of *encouraging friendly and social feelings amongst its Members.*

RULES.

I. The president shall be elected annually, *and shall not hold the office for two years in succession.* If he can conveniently be present, he shall conduct the business of the society at each of the quarterly and annual meetings. In his absence another member shall be nominated to the chair.

II. The members shall be divided into those of the central, and those of the several district sections. Every medical practitioner shall be eligible to become a member of the association, and shall be admitted on the nomination or recommendation of any three members ; but every member, if required to do so by the secretary, shall produce, within one month, proof of his legal qualification, or cease to be a member.

III. The *central section* shall consist of the members resident in Gloucester and its immediate neighbourhood, but its meeting shall, at all times, be open to any member of the association. Its peculiar duty shall be to prepare and lay before each annual meeting a report, based upon the proceedings of the several district sections and quarterly meetings.

IV. Each district section shall consist of the members resident in one of the larger towns of the county or its neighbourhood. It shall appoint its own secretary, and have the absolute controul of its own proceedings, transmitting them from time to time to the secretary of the association.

V. The secretary, who shall also act as treasurer, shall be annually elected ; he shall be a member of the central section, and resident in Gloucester, and shall, at the expiration of his office, be eligible for re-election. He shall act as general correspondent of the society, receiving also and collecting the annual subscriptions, and paying any reasonable demands upon the association. He shall give notice, by public advertisement, of each general meeting ; and shall, a fortnight at least before such meeting, give information, by letter, to the secretaries of the several district sections, of any motions or questions which, by notice previously given, stand for consideration at that meeting, in order that the said district secretaries may lay the same before the members of their respective sections a week at least before such general meeting. He shall (himself or by deputy) attend each quarterly and annual meeting, and take minutes of the proceedings. He shall submit the proceedings of all quarterly meetings, in their original form, to the annual meetings, and lay before the central section all the documents in his possession, and give such other information, connected with his office, as may be required. His travelling, and all other expenses (not including his annual subscription), shall be paid out of the general fund.

VI. Quarterly meetings, which every member who can make it convenient is expected to attend, shall be held at 3 o'clock on the first Tuesdays respectively of January, April, and July, at Gloucester, or at one of the larger towns of the county, the particular places of meeting having been determined at the previous annual meeting. The decisions of a quarterly meeting are not intended to be final, as regards the society at large, but rather to be looked upon as suggestions for the foundation of the annual report, and for the further consideration of the annual meeting—but, for the consideration of any important subject, which cannot be conveniently deferred until the annual meeting, the president may, by a public advertisement to that effect, give to any quarterly meeting the character and authority of an annual meeting, as far as that particular subject is concerned.

VII. The annual meeting shall be held on the first Tuesday in October, at *Gloucester*, or *one of the larger towns of the county.* The peculiar duties of this meeting shall be to appoint the officers, determine the places at which the quarterly meetings of the ensuing year shall be held,— take into consideration the proceedings of the previous quarterly meetings, and the report of the central section, and, upon these proceedings and report, frame such additional laws and regulations, and adopt such other proceedings, as, in the opinion of the majority of the members present, may promote the objects of the society. No existing law, however, shall be expunged, superseded, or altered, unless so determined by three-fourths of the members present. The meeting shall also be competent to originate and determine, by a majority of the members present, any professional question which may be brought before them.

VIII. Every member shall pay an annual subscription of seven shillings ; such annual subscription being always considered due on the first of October.

IX. A dinner shall be provided at each quarterly and annual meeting, the expense of which, including wine, &c., shall not exceed *eight shillings* a head ; and every member who does not attend the annual dinner shall forfeit the sum of two-shillings-and-sixpence, towards the general expenses.

X. Amongst the subjects to which the attention of the society will be more particularly directed are the following :—

The public interests of the profession, and legislation in Parliament thereon.

The internal regulation of the profession, and the intercourse of its members.

The remuneration of medical practitioners, either by public bodies or by individuals in general.

Medical police, and the protection of the public health.

XI. Members who are unable to attend the quarterly or annual meetings are authorized to communicate their opinions on any of the avowed objects of the Association, by letter addressed to the secretary, who shall lay the same before the next general meeting.

At a meeting of the Association held at the King's Head, Gloucester, on Wednesday, the 17th of November, 1840, the above rules were read and adopted.——Dr. Shute, of Gloucester, was elected president, and Mr. Wilton, secretary, for the year ensuing.

A CAUTION TO MEDICAL MEN.

To the Editor of the Medical Gazette.

Sir,

You will oblige me by taking notice, at your earliest convenience, of the following fraud, and by so doing I trust put your numerous readers so on their guard as to prevent its repetition.

On Friday last, the 20th, between the hours of 2 and 3 in the afternoon, when I was not at home, a middle-aged rather stout man, dressed in a blue pilot coat, drove up to my house in a private cabriolet and inquired for me : not finding me at home he then inquired of my assistant whether I practised cupping : being answered in the affirmative, he requested the loan of my cupping instruments, which were presented to him. He left, saying, " my compliments, my name is Parkinson, and I will return the case of instruments in *an hour*." I need only add that hour has not yet arrived, and never will. I fear this is not an uncommon way of robbing medical men ; but should the same thing be attempted again I hope it will fail.

I am, sir,

Your humble servant,

Francis Ward,
Surgeon, &c.

Balham Hill,
Near Clapham, Surrey.
Nov. 25th, 1840.

NOTE FROM MR. WHITEHEAD.

To the Editor of the Medical Gazette.

Sir,

I should feel much obliged if you would allow me a word or two in your next Friday's Gazette in explanation of a passage in my communication on the operation for spinal distortion, published in your last number. which some of my friends appear to have misapprehended. At the conclusion of the article it is observed that the dorsal muscles of the right side (the side opposite to that on which the division was made) " continue to act in the manner above mentioned, and to increase in size." My meaning was, that the muscular mass was larger and more tangible, not, in all probability, from an increase in its structural development—an accession of new matter, as they seem to have understood it, as such a change could hardly be expected in the space of four or five days —but from an improvement in its tone, and attempt at approximation of its attachments.

Your humble servant,

J. Whitehead.

NOTICES.

P.S. to Mr. Braid's communication, page 445 :—" Since the above was written I have performed the operation three times, being in all *seven* times, with the most satisfactory results.—J. B. Dec. 7, 1840."

In the report of the Royal Medical and Chirurgical Society last week, Mr. Walter Jones, of Worcester, is erroneously stated as of Stafford.

FRIDAY, DECEMBER 18, 1840.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XIII.

Treatment of Inflammation. Antiphlogistic regimen. Blood-letting.

Treatment of inflammation.—I proceed to speak in a general manner of the measures that are proper to be adopted, when we are called upon to administer to the relief of a person labouring under inflammation : of what is sometimes called the *cure ;* but, more correctly, of the *treatment* of inflammation.

In describing the phænomena and progress of inflammation, I took *external* inflammation as a *type,* and I shall keep that type principally in view in what I have to say respecting its *treatment* : making, however, such reference to the inflammation of internal parts as the subject will permit. You will bear in mind that my design at present is merely to explain the *principles* of treatment, generally : I shall point out, by and by, the application of those principles, and the modifications they may require, in respect to particular cases. I speak also, now, of *common* inflammation occurring in a previously healthy person. There are many observations that concern all inflammations alike, whether external or internal, and by despatching these in the outset, I hope to save much repetition hereafter.

In all cases of inflammation, our first object is, if possible, to obtain *resolution* : and if that be not possible, we next aim at securing that *event* of inflammation which would be the most fortunate in the particular

case before us. In external inflammations *good suppuration* will generally be the most desirable event, after resolution : in internal inflammations it will be sometimes *suppuration,* sometimes *adhesion.*

It is necessary to keep in mind the distinction between the treatment proper for the inflammation itself; and the treatment that may be required for the *effects* of the inflammation. At present we are concerned only with the inflammation itself.

I stated to you in a former lecture that a knowledge of the *cause* of a disease might help us in its treatment. Knowing the cause, our first care must be to remove it, if we can. In the case formerly supposed, we should extract from the inflamed arm the fragment of glass. If the inflammation has been excited by the extremity of a *fractured bone,* of a broken rib, for instance, we take measures for bringing the separated bones into their proper places, and for keeping them there : if the mere *displacement* of a part has occasioned the inflammation, as the dislocation of a joint, the protrusion of the bowel in hernia, the first thing to be attended to is the restoration of the part to its natural situation : if there be any *chemical* source of irritation, (in the stomach, for instance, threatening or producing inflammation there), we eject, neutralise, or dilute it.

I know of but one exception to this rule, and it belongs to surgery : to wit, when a bullet or a splinter is so lodged in the interior of the body, that its extraction would be more hurtful or hazardous than its remaining where it is.

A knowledge of the cause of an inflammatory disease may help us in another way. We do not treat a joint that is inflamed in consequence of external violence, as we should treat the same joint when inflamed in rheumatism.

But it is very seldom, except in external inflammation, that we can accomplish the removal of the cause. In most internal

cases, either it cannot be got at, or it has already ceased to be applied ; as when the inflammation has been excited by exposure to cold.   But it may be possible, and it is of the utmost importance when possible, to prevent any *re*-application or repetition of the same cause, which would be likely to frustrate our endeavours to bring about resolution.

Antiphlogistic regimen.—Next in importance to the removal and avoidance of the exciting cause, must be placed, in most instances, the observance of what is called the *antiphlogistic regimen.* This may seem an old-fashioned phrase, but it is a very convenient one ; being a brief form of expressing the sum of several distinct provisions for the welfare of the sick, and for the conduct of their attendants. The word antiphlogistic is derived, indeed, from an obsolete theory ; but we retain it as a useful arbitrary term, without reference to its etymology, or to its original meaning.

The object of the antiphlogistic regimen is to put and keep the patient in that state which is most favourable to the natural subsidence of the disease, or to the sanative influence of remedies.   This regimen consists in the avoidance of every stimulus that can be avoided, whether external or internal. Common sense will suggest to you the details.   It implies a total abstinence from animal food, and strong drink of all kinds. It prescribes the exclusion of all that may excite or exercise the mind, or produce a strong impression upon the senses : noise ; bright light ; great heat or cold.   The patient should be kept in a temperature of about 62°, and in a well-ventilated apartment.   He must not be allowed to converse, or to attend to matters of business ; unless, indeed, his mind happens to be disturbed and anxious about some point which a short interview with a friend may effectually settle. All causes of strong emotion, and mental agitation, should be strictly guarded against. Whatever tends to quicken the circulation is to be shunned ; and therefore not only those influences which operate through the nervous system, but also all needless bodily effort and exertion, must be prohibited.   The patient (in the serious cases I am now contemplating) must remain in bed : and in a position which facilitates, or at least does not impede, the free return of the blood by the veins from the suffering organ.   If the inflammation is seated in or about the head, that part should be elevated by pillows.   If one of the lower extremities is affected, even when the disease is not so intense as to require confinement to bed, the limb must be sustained horizontally, or be even still more raised up.   On the same principle it is that we suspend an inflamed hand or forearm in a sling.   In some cases of internal

inflammation—in pleurisy for example—the patient will choose his own position.   He is admonished, by the pain and distress they occasion, that certain postures would be hurtful or dangerous, and he carefully avoids them.   We often derive much information from this instinctive caution on the part of the patient.

The function of the organ inflamed should also be spared its exercise whenever, and in as great a degree, as that can be done. As you would not allow a patient to move an inflamed joint, so you must not permit him to use an inflamed eye ; to speak more than may be absolutely necessary with inflamed lungs : to exert by thinking, and by attention to external excitements, an inflamed brain.   This last rule is essential, even when the brain is not the seat of the inflammation : it is to be observed in all febrile disorders.

The adoption of this antiphlogistic regimen is not, indeed, necessary, nor even proper, in all cases and stages of inflammation.   The inflammation may be so slight as not to require it : particularly in external cases, of which the causes and extent are known ; as slight contusions, trifling wounds, and some kinds of eruption.   But this exception must always be applied with great caution to cases of internal inflammation, about the causes, and extent, and tendencies of which we may be less sure.   In chronic forms of inflammation again, as in scrofulous inflammation of the lymphatic glands, or of the eyes, attended with but little pain or heat, the antiphlogistic regimen would often fail to be beneficial : the state of the general system being such as to require support and strengthening measures, more than the local symptoms call for an opposite treatment. So also when suppuration or gangrene have supervened, the antiphlogistic regimen must generally be modified, or abandoned.

But in the outset of all cases of serious inflammation, when the strength is entire, and the inflammation intense enough to produce pyrexia, all the particulars of the antiphlogistic regimen may require to be observed.

Blood-letting.—Of all the *direct remedies* of inflammation, the abstraction of blood, bleeding, or blood-*letting,* as it is called, is by much the most effectual and important. We should, I think, be prepared to expect this, prior to any experience of it.   Blood being the natural stimulus of the heart, we should deem it probable that the removal of a portion of that fluid would diminish the force with which the heart contracts : and as an inflamed part contains a preternatural quantity of blood, and as (with the exception of resolution and mortification, which really are *terminations* of inflammation—as with these exceptions) all the *events* of inflamma-

tion consist of the effusion of certain parts of the blood from its containing blood-vessels, we should be inclined, *a priori*, to believe that the amount of those effusions would be checked and limited by lessening the supply of blood to the inflamed organ, as well as by abating the force with which the blood reaches it. And we find it in fact to be so. The results of experience confirm, in this matter, the suggestions of our reason. Blood forms the pabulum of the whole process. " If," (says Mr. Lawrence) "we may be allowed to use figurative language, the obvious increase of heat in the part is analogous to that of fire ; and blood is the fuel by which the flame is kept up : in fact if we could completely take away its blood from the part, we should be able entirely to control or arrest the increased action."

But it is not every case of inflammation that requires or warrants the abstraction of blood : and when blood-letting *is* requisite, the mode of taking away the blood, the quantity proper to be taken, and the propriety of repeating the bleeding, all vary greatly in different cases. It is obviously of vast importance that you should learn so to use this valuable remedy as not to abuse it. Its power is great for evil as well as for good : and in rash or inexperienced hands it too often becomes an instrument of fatal mischief.

There are, as you are all aware, several modes of abstracting blood : phlebotomy, arteriotomy, scarification, cupping (which is merely a variety of scarification), the application of leeches. Bleeding performed in either of the two first of these methods is called *general bleeding*. The rest are, in most instances, topical or *local* : but they are not *merely* topical in all cases. The main object of general bleeding is to diminish the whole quantity of blood in the system, and thus to lessen the force of the heart's action. The object of local bleeding is, in most instances, that of emptying the gorged and loaded capillaries of the inflamed part. Sometimes the blood is thus taken directly from the turgid vessels themselves ; more often, I fancy, topical blood-letting produces its effect by diverting the flow of blood from the affected part, and giving it a new direction, and so indirectly relieving the inflammatory congestion. General bleeding has also incidentally a similar tendency to deplete the vessels concerned in the diseased process : and, on the other hand, a dexterous cupper, under favourable circumstances, will take away blood from a part as copiously and rapidly as if it were made to flow from an opened vein : and then the effect upon the *system* will be alike in the one case and in the other. The same may be said of leeches, when they are applied in the enormous numbers which our neighbours, the French,

are fond of using. In whatever way the blood is drawn, whether from a vein or from an artery, or by the pressure of a cupping glass upon a surface previously scarified, or by the suction of leeches, the general effect upon the system will be in proportion to the quantity of blood abstracted in a given time. The most convenient and effectual mode of general bleeding, upon the whole, is certainly the common one, from the veins at the bend of the arm. But sometimes those veins are small or deep, especially in fat people ; and we fail in our efforts to get the blood to flow from them in a full stream : and then we may open some other vein or an artery, or call in the cupper to our assistance, or cover the neighbouring surface with leeches ; according to the situation of the part inflamed, and other circumstances.

Let us now briefly consider what the indications are by which we judge of the expediency of taking away blood. We are guided very much by the degree of pyrexia ; by the quality of the pulse ; by the importance of the organ affected ; by the intensity of the inflammation, in what manner soever that may be measured ; by the period or stage of the disease ; by the age, and sex, and general condition of the patient ; and frequently also by the ordinary character and course of the disease, when inflammation happens to be, or to accompany, an epidemic disorder. It is not one of these circumstances alone, but several of them, that we have to take into the account, in most cases : and what I have now to say in reference to them must needs be very general.

The presence of pyrexia, especially when the febrile disturbance is well marked, admonishes us, indeed, to search after other indications of the propriety of blood-letting, and confirms them if they are found ; but is not, of itself, a sufficient reason for resorting to that remedy. There may be high febrile symptoms without any inflammation at all : as in the hot stage of an ague fit : and a smart attack of fever may spring out of local inflammation, and yet the known course of the disease, or the nature of the part affected, may render the abstraction of blood unnecessary, and therefore improper.

Our judgment is more often determined by the quality of the pulse, although we are by no means to be *wholly* directed by this. The quality of the pulse which—other things being the same—bespeaks the necessity of blood-letting, is *hardness*. I described this quality to you in a former lecture : it may coexist with a large or a small, a slow or a frequent pulse. Most commonly (and yet the exceptions are numerous), most commonly in acute inflammations the pulse is full and frequent as well as hard. The hardness is ascertained and measured by the resistance which the throb of the artery

makes to the pressure of your finger. The pulse is sometimes said to be incompressible; which means that, although you apply your finger with considerable firmness, the blood still forces its way through the vessel beneath it.

Now this hardness of the pulse is sometimes our best warrant for active depletion by means of the lancet: yet I say we must not trust to this alone: for a hard pulse may habitually exist, where there is no inflammation. Certain chronic diseased conditions of the heart may occasion it; and it probably results also sometimes from some unnatural state, which is not inflammation, of the whole of the circulating system. When you happen to know your patient, and have ascertained what kind of pulse he has when he is well, and are previously aware that his pulse during health is *not* a hard pulse, that circumstance will certify that the new quality it has now acquired denotes the presence of inflammation; and usually of active inflammation, likely to go on, if not controlled, to the destruction of the part it has seized upon.

Many persons, and young practitioners in particular, are apt to look to the *frequency* of the pulse, when they wish to ascertain the expediency of blood-letting: but really its frequency is very subordinate in importance to its hardness or softness: and this is very unlucky, because any body with his stop-watch in his hand can *count* a pulse: but it is not every one who can tell a hard pulse when he feels it. The finger requires a certain education for that purpose; and there are some persons who seem never to attain the *tactus eruditus.* I should advise you to attend particularly to this quality of the pulse, and to compare your perceptions of the hardness or softness of the pulse in individual cases, with those of other persons.

The frequency of an inflammatory pulse ranges for the most part between 90 and 120. When the hard pulse is much more frequent than this, it commonly occurs either in young children; or in persons who are more than usually nervous and susceptible; or in persons who were previously labouring under some chronic and wasting complaint, in which the pulse was already frequent, though not hard: as, for example, in phthisical patients, when acute pleurisy supervenes upon tubercular disease of the lungs.

As the hardness of the pulse is, with certain exceptions at which I have just glanced, our lawful warrant for general bleeding; so the disappearance of that hardness is a token that the blood-letting has been carried far enough.

Again, the nature and importance of the organ affected will influence our judgment in respect to the question of abstracting blood.

If the organ inflamed be a vital organ; or if we are not sure about that, but have any reason to suspect that it may be a vital organ; I need scarcely say that we must act upon the worst supposition, and bleed. But if the part be of less importance in the economy of the body; or if inflammation is known to run its course in that part without producing any abiding damage; it may not be worth while to have recourse to this potent remedy, even though the fever be high and the pulse hard, for the sake of subduing inflammation which is attended with so little danger. In this predicament may be placed many instances of cynanche tonsillaris, and of acute rheumatism. The subsequent debilitating effects of the loss of blood upon the system may be more certain and more hurtful than the effect of the bleeding upon the local inflammation is likely to be beneficial.

The period or stage of the disease forms a most important element in the question before us. It is of inflammation while yet in its early progress, that blood-letting may emphatically be pronounced the cure; while the disease is still within the possibility of resolution; before there is any great amount of effusion, or any serious disorganization of structure. The sooner we bleed, the more surely will the inflammatory process be moderated and limited, even when it cannot be wholly quenched. In no case within the range of medical practice is the maxim "principiis obsta" more imperative. Those among you who happen to be attending the wards of the Middlesex Hospital may wonder indeed, after hearing my estimate of the power of blood-letting over inflammation, that I so seldom prescribe venesection there. The truth is, not that I undervalue the remedy, but that the time for its employment has generally gone by. The poor are unwilling to relinquish the occupations by which they subsist: they struggle on as long as they can, and resort to hospitals only when they are compelled to do so by the exigency of their malady. Many of them, labouring under inflammation, have been freely bled before admission. It is commonly too late, when they present themselves, to expect that the course of the disease can be so arrested. The first effect of blood-letting is to deplete and relieve the labouring circulation. But when it is again and again repeated, it becomes (as the French say) *spoliative*; it robs the vital fluid of its nutrient and plastic materials. Pushed still farther, it produces a peculiar state of the nervous system, marked by great weakness and irritability. Now although blood-letting is the *summum remedium* for inflammation at its commencement; there is a point beyond which it not only does no good, but is positively injurious. And this point it is not

always easy to hit. On one side is the danger that the inflammatory action may continue and extend ; on the other the danger that the strength of the system may be so reduced as to prove unequal to the process of restoration : for, to remove the interstitial extravasations, and to repair the damage that has accrued, a certain degree of vital power is requisite, and a sufficient quantity of healthy blood. Bleeding will cure inflammation, but it will not always cure the effects of inflammation ; nay, it may render them lingering in their departure—or even determine their fatality. I cannot too often, or too strongly, inculcate the precept, that in order to check and extinguish acute inflammation, you must, above all, bleed *early*.

We judge that the bleeding has been carried far enough when the inflammatory fever subsides or changes its character; when the pulse regains its softness, or undergoes some marked alteration ; when any of the signs (already specified) of suppuration appear. Upon these points I hope to give you more explicit instruction when we come to special instances of inflammation.

Whenever inflammation supervenes on other chronic disease : whenever it arises in the progress of idiopathic fever, or whilst the constitution is contaminated by some specific poison : whenever suppuration is inevitable, or even probable : in all these cases general blood-letting may be necessary, but it must be employed with great caution.

Nor can we, safely, neglect the age, and sex, and general condition, of the sick person, when we are turning in our minds the propriety of bleeding. The very young, the old, and the feeble, do not bear well the loss of much blood. This consideration is not to deter you from bleeding such persons when they are attacked by dangerous inflammation ; but it especially enforces, with respect to them, the general rule, that no more blood should be abstracted than is absolutely requisite to control the disease.

It is also very necessary to study the character and tendency of the reigning epidemic : whether that may depend upon some predisposition silently and gradually produced in men's bodies by the agency of causes that are but little understood ; or whether it may result from some peculiarity in the exciting cause of a particular epidemic disease. I have been long enough in practice in London to have learned, in common with others, how much the character of continued fever may alter. Since about the time when the virulent form of cholera made its first appearance among us, continued fever has neither required nor borne the abstraction of blood as it did bear and require it for some years prior to that period. Perhaps some variation in the intensity of the poison may partly explain the comparative malignity

—the greater tendency, I mean, to the typhoid type—which marks certain epidemics of scarlet fever, small-pox, and measles. The influenza, or epidemic catarrh, which was almost universal in this town and kingdom in the years 1833 and 1837, afforded a striking illustration of the point I am endeavouring to set before you. The inflammatory symptoms—the bronchitis, and sometimes pneumonia—were in many cases strongly marked, and it was necessary to abstract blood ; but persons suffering under influenza bore bleeding exceedingly ill, and where the use of the lancet could not be avoided, it was never resorted to without reluctance and misgiving.

When we bleed in acute inflammation of an important organ, we endeavour, I say, to effect our purpose as speedily as possible, and with as little expenditure of the vital fluid as possible. It would be quite ridiculous to pretend to give any precise direction as to the number of ounces of blood that should be taken. You must stay by the patient, and bleed, in such cases as I am now contemplating, until you produce some distinct impression by the bleeding : and one of the best guides in this matter is the state of the pulse. If you find, as you sometimes will do, that the most pressing symptoms give way while the blood is still flowing— that the pain, for instance, is mitigated—that the respiration (when the lungs are concerned) becomes easier and deeper—that (in affections of the brain) the patient emerges from a state of stupor or delirium—you may be sure that you are doing right in bleeding ; but you must keep your finger upon your patient's wrist, and suffer the blood to flow, until the hard pulse is sensibly softer, or until symptoms of impending syncope appear ; and then you had better tie up the arm, and wait a few hours, and repeat the bleeding if the symptoms which at first demanded it again become urgent.

As it is desirable to produce the necessary effect upon the system as quickly as may be, the blood should be taken *pleno rivo, i. e.* a sufficiently large orifice should be made in the vein ; and sometimes it may be right to open a vein in both arms : and the patient should be bled in the upright position. Faintness and syncope depend upon a defective supply of blood to the brain ; and therefore will be likely to occur the sooner when the force of gravity facilitates the descent of the blood from the head through the veins, and retards its ascent towards the head through the arteries. And conversely, the first thing to be done towards remedying syncope is to lay the person flat in a horizontal posture, or even with his head lower than his trunk.

If you neglect these smaller matters, and make an insignificant slit in the vein, and

suffer your patient to lie down when you are bleeding him, you will be obliged to take much more blood in the end; or you may drain him of his blood and of his strength by repeated bleedings of this sort, and make no impression after all upon the disease. It is one of the numerous cases in which parsimony is not true economy.

The quantity of blood requisite to be taken in order to produce the due effect is exceedingly various. It is a remarkable circumstance, well worth attending to, and much insisted upon of late years, especially by Dr. Marshall Hall, that a patient under the influence of mere inflammation will bear to lose a far greater quantity of blood without becoming faint, than he could bear in health : that the state of the system produced by the presence of inflammation protects it from the ordinary consequences of loss of blood. The amount of the bleeding necessary to occasion syncope will be in proportion to the exigency of the case. This fact—if it be really a fact, as indeed I believe it is—is evidently one of the highest value and importance, for it furnishes, what is always so desirable, especially in an uncertain art like ours, a simple rule of practice. Yet it is not a rule so firmly established as not to admit of exceptions. If the mere state of syncope was the curative influence required, we should have no difficulty. That the faintness does constitute a part of that influence I fully believe. Dr. M. Solon even relates a case in which it sufficed to the cure of erysipelas of the head and face, attended with high fever. The patient fainted from alarm, before the vein was opened. The inflammatory symptoms thereupon ceased: but with returning animation they presently recurred. Again preparation was made for venesection ; and again this time the inflammation and fever disappeared, never to return. She is described as having been quite well the next day. I cannot, however, entertain a doubt that the withdrawal of a certain quantity of blood is, in almost every case, essential to the permanent control of common acute inflammation, attended with pyrexia : and it may be advisable to keep persons who, like M. Solon's patient, are of a timid disposition, and liable to syncope from slight causes, in a recumbent posture, in order that the requisite discharge of blood from the system may be obtained.

In equivocal cases (and there are many such), where it is questionable whether the symptoms proceed from inflammation or not, the diagnosis may often be settled by observing the quantity of blood which, taken in the upright posture, suffices to bring on incipient syncope.

Dr. M. Hall's book " *On the Effects of*

Loss of Blood," is well worth your attentive perusal. He suggests that a scale of diseases might be formed, representing the protective influence of some diseases against the effects of blood-letting ; and the opposite influence of some others in producing preternatural susceptibility of those effects. " It would begin (he says) with congestion of the head, or tendency to apoplexy; inflammation of the serous membranes, and of the parenchymatous substance of various organs, would follow ; then acute anasarca ; and lastly, inflammation of the mucous membranes. This part of the scale would be divided from the next by the condition of the system in health. Below this would be arranged fever ; the effects of intestinal irritation ; some cases of delirium ; reaction from loss of blood ; and disorders of the same class with hysteria ; dyspepsia, chlorosis, and cholera morbus."

With respect to the propriety of *repeating* venesection, it is his remark, that if at the first blood-letting much blood flowed before any tendency to syncope manifested itself—an early repetition of that remedy will probably be required—and at any rate an early repetition of our *visit* to the patient will be proper. But this last precept is of universal obligation in all cases of serious inflammation.

I am almost afraid to tell you how much blood I *have* seen taken at one bleeding, lest I should seem to encourage you to imitate such heroic practice. I once stood by, and saw, not without trembling—although I was quite free from responsibility in the matter—a vein in the arm kept open until seventy-two ounces (four pints and a half) of blood had issued from it : and then, and not till then, did the patient become faint. The event of the case quite justified the bleeding in that instance, for the man got perfectly well. It was a case of general dropsy, which had come on suddenly, in a young and robust man. It occurred in the clinical wards of the Infirmary at Edinburgh: the physician had desired the clinical clerk to bleed the patient in the erect posture, until some sensible effect was produced upon his pulse : and no such effect could be perceived until the enormous quantity I have mentioned had been abstracted. It is very seldom that such large bleedings are required : you will generally find that five-and-twenty or thirty ounces, taken properly, will be sufficient to accomplish the purpose of the measure. Sometimes one such bleeding will extinguish, as it were, the inflammation ; sometimes two or three, or half a dozen, may be necessary : and we judge of the propriety of repeating the venesection by the effect of the former bleeding ; by the character of the pulse ; by the appearance of the blood already drawn. It would be impossible, in a general account like the present, to lay down any minute directions on this head.

I have hitherto been speaking of bleeding, as we perform it for the cure of active inflammation, occurring in a person previously healthy, affecting an important organ, and attended with febrile disturbance of the system. But the abstraction of blood is scarcely less valuable as a remedial measure in *chronic* inflammation, when the system at large scarcely sympathises at all with the local disease. And here it is that what is properly called local bleeding is so useful—by cupping glasses, or a moderate number of leeches. The object is always the same, viz. to unload and relieve the turgid capillary vessels of the part: and this we could not do by general bleeding without carrying it to an extent which would be dangerous to our patient's existence. These local bleedings for chronic inflammation usually require to be often repeated. Considered as a remedy, blood-letting resembles some other remedies in this, that it must be proportioned and adjusted to the rate of progress, and the duration, of the disease. The remedy must be used chronically when the malady is chronic. A patient may lose, on the whole, much more blood for the cure of a chronic inflammation, than for the cure of one that is violent and acute: but then the bleeding must be spread over a larger space of time.

With respect to the relative merits and advantages of cupping and leeches, as topical remedies for local inflammation; it may be said in favour of cupping. that the precise quantity of blood taken away is more accurately determined in that manner, and the operation is sooner over, and is less fatiguing, than the suction of leeches. But on the other hand the leeches seldom bungle in the operation; while the surgeon often does. It requires a good deal of practice to become handy and dexterous in the application of the glasses—to avoid torturing and burning the patient—and on that account it is that in large towns, as in this metropolis, cupping is an art carried on by a distinct class of persons. You may apply leeches also to parts where the cupping glasses could scarcely be used.

General bleeding then is best adapted to acute inflammation; and topical bleeding is most appropriate in that which is chronic and slow. But a combination of the two is often highly proper and useful. You may lessen the force of the general circulation by venesection; but the small vessels of the inflamed part may remain unable to rid themselves of their excess of blood, and continue dilated and full. Such, at least, we may reasonably suppose to be sometimes the case; and certainly we often act successfully upon that theory; that is, we bleed from the arm, and at the same time, or presently after, we empty the capillaries of the labouring organ, or the neighbouring vessels,

by the help of leeches, or the scarificator and exhausted cup. The effect of local bleeding, after the general febrile disturbance has abated under venesection, is often very marked in the relief of *pain*.

I have recommended blood-letting to you when, among other circumstances, the pulse is full and hard; and have stated that the blood should be suffered to flow until some distinct impression is made upon the system. But I wish also to apprize you, that you ought not to be deterred from bleeding merely because the pulse is small. It is very apt to be so in dangerous inflammations within the abdomen; and it is a very curious thing that the pulse will often rise, and the artery develope or expand itself during the time the blood is flowing. Now you must look upon *that* circumstance as a distinct impression made upon the system, although it is one of a rather different kind from what I spoke of before. You had better, in my opinion, pause when this effect is fairly obtained: for so great is the tendency to death by syncope in abdominal inflammation that it would not be prudent to urge the effect of the blood-letting farther, at one time, than the change I have just mentioned. Wait therefore, and repeat the venesection if the circumstances should again render it necessary.

LECTURES

ON

MORTIFICATION,

Delivered in the Medical Theatre of St. George's Hospital,

BY SIR BENJAMIN C. BRODIE, BART.

F.R.S. &c.

LECTURE I.—Nov. 25, 1840.

A PART of the animal body may lose its vitality, while the rest continue to live. We say then that it is mortified; and the process by which this change is brought about we call mortification, or sphacelus. The term gangrene properly signifies the commencement of mortification, or that condition of the affected part which immediately precedes mortification. But it is somewhat loosely employed, and not unfrequently is used as synonymous with mortification and sphacelus. This change, by which a living organ returns to the state of dead matter, viewed in connection with the changes by which it is preceded. and those which follow it, is one of the most interesting subjects in the whole science of pathology, and the treatment to be employed under these circumstances forms one of the most important inquiries belonging to practical

surgery; and I am sure that you will not think your time ill bestowed if I call your attention to these matters in this and the following lectures.

The causes of mortification, as I shall explain to you hereafter, are various. If the part affected be one immediately concerned in the vital functions, the death of the entire animal is a speedy, if not an immediate consequence. If the part affected be one not directly necessary to life, still if mortification exist to a very considerable extent, so great an impression will be made on the whole system that the same result will probably ensue. Otherwise, after a certain period of time, another process becomes established, by which the dead part is separated or thrown off from the living. We distinguish this process, when it occurs in soft parts, by the appellation of sloughing, and the part separated is called a slough. When, however, it occurs in hard parts, as in the bones or cartilages, we call it the process of exfoliation, and we give the name of exfoliation to the dead bone which has become detached.

Sloughing and exfoliation are accomplished by ulceration of the living parts in contact with the dead. A thin layer of the living parts is absorbed, and the dead part is left lying loose on the ulcerated surface.

The period of time required for the completion of the process of mortification differs according to the circumstances under which the mortification takes place: it may be very slow; it may be rapid; it may be almost instantaneous; as I shall explain to you more fully hereafter. The period required for the completion of the after-process of sloughing varies also; *first*, according to the state of the system, and the activity of the vital powers generally; *secondly*, according to the organization of the part in which the disease occurs: thus, other circumstances being the same, the sloughing of the skin is much sooner accomplished than that of tendon, or than the exfoliation of bone; *thirdly*, according to the state of the neighbouring living parts, without reference to the state of the general system: thus, if there be much inflammation in them, the ulcerative process proceeds much more rapidly than when the inflammation is very slight; and *lastly*, as long as the mortification continues to spread there can be not even the commencement of the process of separation. The reason of this is so obvious that it can require no explanation.

I have seen mortification begin in an old man's toe, and be gradually spreading, even for months, up the foot and leg, without the least appearance of a line of demarcation, or the least attempt at sloughing. In the same manner a piece of dead bone may continue adherent to the living even for some years. If the disease, on which the death of the

bone depend, can be arrested, as it sometimes can (by mercury, for example, or by sarsaparilla) the exfoliating process begins immediately, and when begun it is completed as soon as under ordinary circumstances.

The separation of the dead part is followed by another series of changes, which terminate in healing—or cicatrization. But these changes are not at all different from those which occur when there is a loss of substance in other ways, and it is not my intention therefore to enter into the consideration of them at present.

Having offered these general observations on the subject, I shall proceed to consider the various circumstances under which mortification may take place, and the treatment which it requires, accordingly as it arises from one cause or from another.

Mortification from Inflammation. — Mortification is described as one mode' in which inflammation terminates. A very intense degree of inflammation may lead to this result in any structure, or in any constitution; but a moderate degree of inflammation may lead to it also in particular cases. Inflammation of cellular membrane terminates in mortification more readily than inflammation of the skin; and, in persons of bad constitution, the cellular membrane is more likely to mortify than in others. You see examples of this over and over again in the cases of the diffuse cellular inflammation which occurs in dram-drinkers. A small puncture of the leg, or a compound fracture in which the injury is apparently trifling, may, as you know, cause inflammation extending gradually from the foot to the buttock, and the whole cellular membrane may in the course of a few days become a putrid slough. I have seen a case in which a patient became affected in this manner from a leech-bite; and another in which a similar mischief followed the sting of a bee, and both these patients died. From what has since fallen under my observation, I have little doubt that they were both dram-drinkers, though I was not sufficiently acquainted with the subject to have my attention directed to it at the time. In the case of the man stung by the bee, however, something may perhaps be attributable to the operation of the animal poison; and I shall revert to this point hereafter. I once lost a patient with diffuse cellular inflammation ending in mortification after the simple operation of castration; and I was disposed to attribute this unfortunate result, in a great degree, at least, to the operation having been performed after a long course of the tincture of iodine.

If inflammation of the skin terminates in mortification, independently of any antecedent inflammation and mortification of the cellular

membrane beneath, the inflammation is usually intense; the surface of the skin is of a dark-red colour, and there is severe pain and tenderness. As the inflammation advances, the skin assumes a livid appearance; a serous fluid is thrown out under the cuticle, which is thus elevated in the form of blisters; and then the skin itself perishes. If the mortification takes place to any great extent, the general system suffers. The pulse is feeble, irregular, intermitting; the countenance is anxious; the skin becomes cold; there is an utter incapability of exertion; and after a few days, and sometimes sooner, the patient dies. If the constitution does not suffer in this manner, or if the patient survives the shock, after a few days the separation of the slough begins to take place, and this is the first step towards a complete recovery.

In cases of diffuse cellular inflammation the occurrence of mortification is preceded by an abundant infiltration of serum. In some instances the serum is of a peculiar yellow colour, and the skin over the whole body, and the *tunicæ conjunctivæ* of the eyes, may assume the same appearance. I do not know to what cause this yellow tinge is to be attributed. The patient looks as if he were jaundiced; but he is not so in reality, for there is no bile in the urine. When mortification of the cellular membrane has begun to take place, the constitution suffers in the manner which I have already described. If the patient survives the shock, or lives for some time under it, the mortification of the cellular membrane is invariably followed by mortification of the skin over it to a greater or less extent.

Allowing for the difference of function in the affected organs, the foregoing description will apply pretty nearly to all cases in which inflammation of the soft parts terminates in mortification. If there be mortification of the intestine, there is an effusion of dark-coloured serum into the abdominal cavity. Whenever the part which mortifies is situated internally, so that the putrid serum formed round the slough cannot escape, the constitution suffers much more than where it is situated externally, and especially an intermitting pulse and hiccough are often added to the other symptoms. Probably these more aggravated symptoms are to be attributed to the pent-up putrid matter being in part reabsorbed into the circulation. I shall mention some circumstances hereafter which seem to favour this opinion.

It proves an interesting subject of inquiry, how is it that inflammation terminates in mortification; or what is the pathological explanation of this phenomenon? and this leads us to the question as to the nature of inflammation itself. Mr. Hunter describes it as consisting in an increased action of the small blood-vessels. If increased action be indicated only by a greater degree of contractility in the coats of the vessels, the theory is evidently wrong; for microscopic examination proves that there is no such thing. But, in fact, this is not what Mr. Hunter meant: and in another sense of the words he is clearly right; for the vessels of an inflamed part secrete serum, lymph, and pus, and build up new structures; in short, they do many things which they do not do under ordinary circumstances; and all this affords an abundant evidence of increased action. Another theory of inflammation which has been of late promulgated in opposition to that of Mr. Hunter is that the essential part of it is a debility, a weakened state, of the capillaries; and the propounders of this theory refer to the dilatation of these vessels in proof of it. But I own that I can discover no reason to believe that the dilated state of the capillaries proves any thing, except that there is something in the condition of an inflamed part which makes a greater supply of arterial blood necessary, and that they have the power of adapting themselves to those new circumstances. Nor is this power limited to the capillaries. It exists in the arterial trunks, in which the capillaries have their origin. Thus, in an animal killed by arsenic, in whom the poison produces extensive inflammation of the mucous membrane of the stomach and intestines, the branches of the mesenteric arteries are seen dilated to double their natural diameter. In like manner, when muscles are in exercise, or when a gland is pouring forth an abundant secretion, the capillaries become dilated so as to admit the increased quantity of blood which under those circumstances of greater activity of the organ is required; but no one dreams of their being therefore in a state of debility, and I see no difference, in this respect, between those cases and that of inflammation. But microscopic examination proves something more than the mere dilatation of the capillaries. " The blood itself is affected. It loses its globular structure, and previously to this the globules themselves are observed to have lost their repulsive properties, and either to agglomerate together or to adhere to the sides of the vessel in which they are contained," and not unfrequently they seem to stagnate, so as to choak up the vessel altogether, and destroy the circulation in it. Now if this happens in many vessels, the vitality of the part cannot be maintained, and thus the occurrence of mortification is easily explained. There is, however, something more than this in some instances. For example, let us suppose a case of inflammation of the cellular tissue of the scrotum. The cells are filled with serum. They are fully distended, and the skin is on the stretch. If nothing be done to the part, the cellular membrane

first, and the skin afterwards, will mortify to a great extent. But make some incisions with the point of a lancet, and the serum escapes in sufficient quantity to relieve the tension, and the mortification is in great measure, or perhaps wholly, prevented. It is reasonable to suppose, that, in consequence of the extreme distension, the fluid in the cellular membrane causes so much pressure on the vessels which supply the skin as to impede the passage of the blood through them, and that the punctures of the scrotum and the escape of the serum prevents the mischief which would otherwise have ensued, merely by removing the pressure. When a common abscess opens, as it sometimes does, by mortification and sloughing of a portion of the skin over it, we are not to regard the mortification as the mere result of inflammation, any more than in the case which I have just stated. The ulcerative process going on under the skin destroys a portion of the vessels by which the skin is supplied, and the pressure of the matter probably prevents the free passage of the blood through those which remain ; and thus a due supply of blood being prevented, the skin perishes.

Treatment of cases in which inflammation terminates in mortification.—Whatever tends to lessen the violence of the inflammation, ought to prevent, or check the progress of, the mortification ; and, on these grounds, the patient ought to derive benefit from the abstraction of blood.

But, on the other hand, the abstraction of the blood by which the life of a part is supported, if carried beyond a certain point, is of itself an adequate cause of mortification ; and the abstraction of even a small quantity of blood may lead to this result under certain circumstances.

It is not by a reference to principles alone that you can learn how you should act in this dilemma. Experience is our safest guidance, and on this as on many other occasions, the mere practical surgeon will have a great advantage over the mere scientific pathologist.

If the inflammation be intense, if the pulse be strong and full, the countenance flushed, and the skin hot,—that is, if there be marks of great general excitement of the system, it is probable that the patient will derive benefit from blood-letting ; and if you have reason to believe that he is of what may be called a sound constitution, blood may be drawn to a considerable extent, and the blood-letting may be repeated. I have often adopted this practice under these circumstances with the greatest success, not only where the purple colour of the skin and the existence of vesications shewed that mortification was impending, but where it had actually begun; and have had the satisfaction of seeing the progress of the mortification immediately suspended. You will have no better opportunity of watching the benefi-

cial results of such a mode of treatment than in some cases of sloughing sores or chancres on the *glans penis.* While you administer opium and stimulants, the marginal inflammation increases, and the sloughing continues to spread. Take some blood from the arm, and the inflammation becomes abated, and the progress of the sloughing is suspended. Repeat the blood-letting, and the sore assumes in a short time a healthy aspect. In such cases I have known nature accomplish what was wanted, while a timid surgeon was doubting how to act. There has been a spontaneous hæmorrhage ; the patient has lost half a pint or even a pint of blood. Immediately the pain, the tension of the surrounding part, the redness, and the general excitement, have been relieved ; and in the course of a week the sloughs have separated, and the sore has become covered with healthy granulations.

But there are other cases in which blood-letting would be as mischievous as it is useful under the circumstances which I have just described.

Let us suppose a patient who has been a dram-drinker, or who, belonging to the more affluent classes of society, has indulged in too copious libations of wine, or whose constitution has been otherwise impaired, and that he has received some injury of the leg, followed by diffuse inflammation, which threatens to terminate in sloughing of the cellular membrane, and afterwards of the skin ; or in whom the mortification of these textures has already begun : let us suppose also that although inflammation is spreading rapidly, it is not marked by any very urgent symptoms ; that the pulse is small and feeble; and the countenance expressive of anxiety. Now, if, under these circumstances, you abstract even a moderate quantity of blood, it is probable that you will hasten the progress of the local mischief ; and if blood-letting be employed to a considerable extent, it will certainly destroy what little chance there might otherwise have been of the patient's recovery. Let us suppose another case. There is a chancre or other sore on the penis. It is surrounded by a languid inflammation ; the neighbouring parts are gradually assuming a dark livid appearance ; the pulse is small and quick, or no excitement of the general system. Under these circumstances also, the abstraction of blood, instead of checking, will cause a more rapid progress of the disease.

Now it is highly important that you should learn to distinguish these two classes of cases from each other : and in a great number of them you will have no difficulty in doing so. You cannot, however, draw any exact line between them : and cases will occur in practice, in which you cannot exactly determine, in the first instance, which is the proper course for you to pursue. Here you must proceed

cautiously, watching daily the operation of the remedies which you employ, and persevering in one mode of treatment, or adopting another, according to the effect produced ; and frequently it may be right to take away a moderate quantity of blood in the first instance, and to have recourse to an opposite mode of treatment almost directly afterwards.

In order that I might bring the subject before you in its simplest form, I have hitherto referred merely to the question of blood-letting. But of course this involves much other treatment. Where blood-letting is proper active purgatives will be proper also, as well as saline and diaphoretic medicines ; and every thing in the shape of stimulating liquors and food should be avoided. Where blood-letting, on the other hand, is improper, though aperient medicine may be required, very active purgatives should be avoided. The patient should be allowed such diet as his stomach is capable of digesting ; and he should have wine, or ale, or even brandy or gin—the quality, as well as the quantity, of the stimulus varying according to the character of the symptoms, and his previous habits. I say his previous habits ; for it is essential that you should always inquire what these have been, and act accordingly. It is rarely safe to deprive a dram-drinker, for any considerable time altogether, of his usual stimulus ; and the effect of a judicious exhibition of it is very remarkable, not only in arresting the progress of mortification, but in abating the violence of the inflammation which leads to it. Decoction of bark, quinine, and other tonics, may be useful under certain circumstances ; but I must say that the longer I live, and the more I see of these cases, the less is my faith in such remedies, while inflammation and mortification are going on : and I am satisfied that they often do great harm, by loading the stomach, and interfering with the digestion of food. At a later period, however, when the progress of the mortification is stopped, and the sloughs are beginning to separate, I have no doubt that they are eminently useful. The repeated trials which I have made, and seen made, of ammonia, have not left on my mind any more favourable impressions of this remedy than those which I entertain of bark and quinine. It is a temporary stimulus ; but alcohol, prudently administered, is much better : and my observation leads me to suspect that large doses of ammonia, if persevered in for a considerable time, tend to depress the vital powers, and lessen the chances of recovery. Opium is useful under certain circumstances : as where there is severe pain ; or where the inflammation and mortification depend on the operation of a specific poison.

I have already had occasion (with a view to explain the pathological phenomena of mortification) to advert to the effects of incisions made through the skin into the cellular membrane, when the cells of the latter are exceedingly distended with serum. Whether the explanation which I then ventured to offer of the mode in which this serous infiltration operates in producing mortification be or be not correct, there can be no doubt that the evacuation of the serum, and the consequent relief of tension, will go far towards preventing an extensive mortification in all cases, and will prevent it altogether in a great many. It is not, however, always necessary for this purpose that we should make scarifications or incisions. Mere acupunctures are not unfrequently sufficient. I have on many occasions requested the house-surgeon of this hospital to make punctures where this serous infiltration of the cellular membrane was going on, every morning and evening, or whenever he had the opportunity of doing so ; and it often has happened that nothing more was required. But of course this simple practice is useful only in an early stage of the disease—where there is that state of things which may lead to mortification, but where mortification has not actually taken place. Where sloughs of the cellular membrane have begun to form, or where an infiltration of pus has begun to follow the infiltration of serum, mere punctures of course will be insufficient. Incisions or scarifications will then be required ; and they should be of sufficient extent to allow the serum and pus to escape freely, and to relieve the tension of the skin. But they should not be more than this : first, because such painful operations are a great shock to the nervous system of a person in vigorous health, and a very great one indeed to one who is weakened by previous disease : secondly, because this shock is not given to the system once for all, as, if the inflammation spreads, it may be necessary that the incisions should be repeated : thirdly, because in proportion to the extent and depth of the incisions, is the danger of hæmorrhage ; the occurrence of which, to any considerable extent, is sufficient to prevent the patient's recovery. In making the incisions, you should always bear in mind that it is of vital importance that there should be as little hæmorrhage as possible ; and here you will find the advantage of having some active and intelligent assistants, who will carefully watch your lancet or scalpel, and whenever they see a vessel beginning to bleed make pressure with the finger on it. Ligatures may be sometimes required ; but not in general. The divided vessels under these circumstances bleed profusely in the first instance, but they soon contract, and the

pressure of the finger for a few minutes is usally sufficient to stop the hæmorrhage altogether.

The foregoing observations apply to all cases in which inflammation of cellular membrane has already begun to terminate in gangrene, or threatens to do so, whether the inflammation be phlegmonous or erysipelatous, or that peculiar variety of inflammation which produces carbuncle. The effect of scarifications in preventing the further progress of mortifications of the skin in all these cases is very remarkable : but under certain circumstances they produce a still greater benefit to the patient. Whenever putrid matter is pent up round a slough of the cellular membrane, the system is, as it were, poisoned. The sulphuretted and carburetted hydrogen gas evolved during the decomposition of dead animal matter, seem to pass, in part at least, into the circulation, and produces the most dangerous symptoms. The incisions, which relieve the tension of the skin, allow these noxious gases to escape, and the relief which this affords to the patient is most remarkable. I might, if it were necessary, enumerate a great number of cases in illustration of what I have just observed. One, however, will be sufficient : and this I am tempted to relate, because the subject is one of great importance, and because a particular instance may serve to impress it more on your minds than a mere general observation. I was called some few years since to see a gentleman, who appeared to be actually on the point of death. His extremities were cold : his pulse barely perceptible. It was doubtful whether he was sensible or not. He made, on being roused, several imperfect attempts to speak, but could say nothing intelligible. Below the right hypochondrium there was a considerable tumor; the skin being of a dark red colour, on the verge of mortification. I said to myself this gentleman ought not to be allowed to die without it being ascertained what this tumor is. On examination with the fingers I perceived a sort of emphysematous crackling, and only an imperfect fluctuation. On making a free incision, I discovered underneath the discoloured skin what might be called a quagmire of slough. A small quantity of putrid matter escaped. But there escaped also such a quantity of noisome and offensive gas, apparently sulphuretted hydrogen, that I could scarcely bear to remain in the room. The stench pervaded the whole house, and even could be perceived in the garden round it. Within two minutes after the performance of this operation, so trifling in appearance, but so important in reality, the patient looked up, and said quite distinctly, " What is that you have done which has made so great a

difference in my feelings ?" At the same time the pulse returned at the wrist, and from this moment he recovered without any further unfavourable symptoms. After a few days sloughs came away, probably of muscle, cellular membrane, and peritoneum, in a confused mass ; and with them a gallstone of moderate size—explaining, to a certain extent, at least, the origin of the disease.

The cases in which you will most frequently have occasion to resort to the employment of scarification are those of diffuse cellular inflammation of the extremities, whether it be phlegmonous or erysipelatous, and those of carbuncle. But there is another class of cases, which occur after injuries, and often after slight injuries of the scalp, in which the same treatment will be required ; to which, before I conclude this present lecture, I am tempted to draw your attention. *First*, because they will serve to illustrate the observations which I have already made ; and *secondly*, because the disease is one with which you ought to be made acquainted, but which, as far as I know, has not been distinctly described by surgical writers. Here, as in cases of erysipelas of the skin, there is a rigor followed by an attack of fever preceding the local symptoms. The latter shew themselves in the form of pain in the neighbourhood of the wound or contusion, and an œdematous swelling of the scalp, without any redness of the skin. The swelling pits on pressure. It spreads over the whole scalp to the forehead, and sometimes over the whole face, the skin still retaining its natural colour, or even appearing paler than natural. The progress of the swelling is accompanied by pain in the head, and a continuance of febrile symptoms. In some cases, the disease, after having continued for 10 or 12, or perhaps 14 days, begins to subside ; the serum which caused the œdematous swelling being gradually absorbed without any further mischief. In other cases suppuration takes place underneath the scalp, with extensive sloughing of the cellular membrane, and this is followed by sloughing not only of the scalp above, but of the pericranium underneath. I have known the latter destroyed to such an extent as to lay bare a large portion of the bone of the cranium. If you would prevent all this great mischief, you must by one method or another relieve the tension caused by the œdematous effusion into the cellular membrane. Simple acupunctures are often sufficient for this purpose, provided that they are repeated once or twice daily for several successive days. Where a sufficient quantity of the serum does not escape by the punctures, large openings are required, and incisions must be

made through the scalp, and the subjacent textures, quite down to the cranium. These must be repeated from time to time, as the disease extends from one part of the scalp to another. The appearances observed when these incisions are made explain in some degree the seat and nature of the disease. There is a slight effusion of serum immediately underneath the scalp : but the great effusion, and that on which the tumefaction chiefly depends, is underneath the tendon of the occipito-frontalis muscle ; and here the effusion is in some instances so extensive, that I have known the tendon to be separated as much as half an inch, or even more, from the pericranium. A large quantity of serum immediately escapes on the incision being made, the tension is of course relieved, and the destruction of the parts is prevented. I suspect this disease to be a form of erysipelas, although the skin is not usually inflamed, as every now and then it assumes the character of true erysipelas as soon as it reaches the face.

Let us now suppose that mortification has taken place to a certain extent ; that the progress of it is arrested ; and that the system survives the shock ; what further local treatment is required ?

Indeed, I have little faith in any. The separation of the slough is a natural process. It is usual to apply stimulating, or as they are called digestive ointments ; solution of chloride of soda ; stale beer poultice, and other things of the same kind. But my own experience would lead me to believe that the process of separation will go on just as fast with the simplest treatment, such as that of a bread and water poultice, or a linseed poultice, or wet lint with a piece of oiled silk over it. The constitutional treatment at any rate is of much more importance than any topical applications. Bark may generally be given with advantage : but the discreet administration of wine and a nourishing diet is of more importance still. Of course no general rule can be laid down. You must study the existing symptoms, and act accordingly.

COLOURLESS GLOBULES IN THE BUFFY COAT OF THE BLOOD.

Mr. ADDISON presents his compliments to the Editor of the MEDICAL GAZETTE, and would be obliged by his giving the accompanying communication a place in the next number of that Journal.

Great Malvern, Dec. 10th, 1840.

When blood is drawn from the arm, coagulation usually takes place in from five to ten minutes ; the whole mass in that period becoming a soft solid. As this jelleying or solidification proceeds, the surface puts on various appearances in health and disease : it may be red and homogeneous, or red with a curdled flocculent aspect, variously patched with purple or buff; sometimes there is a clear transparent fluid swimming above those portions containing the red globules, and occasionally this is superseded by an opaque dirty yellow fluid, which entirely obscures all the red portions of the blood.

When the surface of the coagulum is patched with purple or buff, the blood is said to be sizy ; when the clear oily-looking fluid swims at the surface, and the red globules are subsiding entirely from it, the clot will be buffed and cupped ; and when the dirty yellow opaque fluid occupies the upper portion, the buffy coating will be very dense and thick.

After standing some time the coagulated blood separates from the sides of the vessel in which it is contained, and the serum begins to exude from the coagulum : this exudation goes on for some time, and at length the clot is formed, which continues to contract its dimensions for at least eighteen or twenty-four hours.

It will be convenient, practically, to make a distinction between the coagulum and the clot : the former contains the whole of the constituents of the blood, and is formed generally in the short period before specified. The clot is the coagulum freed from the serum, and contains only the spontaneously solidified materials with the globules.

The clot, or crassamentum, in health, is altogether red, and is usually considered as consisting of two parts : the fibrine, or coagulable lymph, which gives it solidity, and the red globules. During pregnancy, in rheumatic and other inflammatory diseases, the clot exhibits two distinct portions; the lower red, and consisting of the same materials as in health, and the other yellow whitish, or buff-coloured, forming the inflammatory crust, and consisting of coagulable lymph free from any red globules. There can be no doubt but this inflammatory crust is an important character, having some in-

fluence or share in the cause of many diseases; being thicker, tougher, and more completely free from red globules, in those disorders of a serious inflammatory character. It is therefore of great importance to understand its real nature.

CASE I.—J. B., a man aged 60: ill with acute rheumatism; pulse from 65 to 70, feeble. V. S. to 12 oz.: blood drawn into three cups. In a quarter of an hour the first portion had a purple surface, streaked with red; the surface of the second was entirely a dirty yellowish buff, without any visible red globules; the third was similar to the first.

On gently dipping the point of the finger on the surface of the second portion, and before the coagulation had taken place, a clear colourless drop adhered to it, which, when transferred to a piece of glass, and examined by a common lens, against the light, was found to contain an immense multitude of clear colourless globules.

CASE II.—G. R., a man aged 52: ill in bed with pleuritis. V. S. to 16 oz. In five minutes the whole surface of the blood presented an opaque, shreddy, or flocculent appearance: no red particles were visible except a few round some bubbles of air. The following morning the clot was covered by a thick, tough, buffy coat; and in the cupped centre was a jelly-like matter of looser consistence. This patient was bled again the following day: blood just the same. Before the coagulation had proceeded, and while the upper portion was yet fluid, I took up three or four tea-spoonsful quite free from any red globules, and placed them in another cup: in a short time it was coagulated; and after some hours a tea-spoonful or more of clear serum had separated, leaving a tough buffy coagulum. Hence it is obvious that the first change in inflammatory blood is its separation *into two fluid* portions; the *upper* colourless, or of a yellow buff colour; the *lower*, red. The next change is the coagulation of both these portions. After this the serum separates, part exuding from the upper *buff* portion, and part from the lower *red* portion.

CASE III.—J. H., aged 45: ill with acute rheumatism. V. S. to 16 oz. The blood had all the characters of Case II.

In five minutes a thin pellicle or film had formed on the surface, which, in another five minutes, became thicker and more stringy: underneath this was a clear colourless portion still fluid. On dipping the point of the finger in the surface, and transferring a colourless drop to a piece of glass, an immense multitude of separate, distinct, and colourless globules (evidently lymph, or altered blood-globules, free from any colouring matter) were seen floating in the clear liquid. In this case the clot evidently contracted its dimensions, or continued to diminish in size, for twenty-four hours.

If a small portion of fresh blood is examined by the lens, or by a low power in the microscope, the red globules are usually found congregated and entangled together in ragged confused masses; and this may be seen even by the eye alone, the blood appearing curdled. On the other hand, the colourless globules of the buffy coat do not appear so; they remain much more separate and distinct; and when they do coalesce, they form strings, films, or lines.

In this case I placed several drops of this clear coagulable liquid on the glass: in a few minutes coagulation commenced in streaks and films, all of which were evidently composed by the aggregation of the globules. After this four or five teaspoonfuls of the same fluid were placed in a clean cup, which, by the following morning, had separated with a tough buffy clot and some clean pale serum; the former weighed 717·5 grains; the latter 677·5 grains, or 51·5 per cent. buffy clot, and 48·5 serum. This is a large proportion of serum, and shews the strength or firmness of the coagulation by which a larger proportion of serum was squeezed out than would have been the case from a clot with the red globules. The form of the clot in buffy blood is generally contracted and concave, and of a less diameter than the lower red portions.

CASE IV.—M. J., a woman, aged 38, very ill with quinsy. V. S. to 14 oz.: blood drawn into two cups. In about eight minutes there was a considerable quantity of clear liquid swimming like oil on the surface of the blood first drawn, and through this a quantity of flocculent tufts, just like curdled soap, of a dirty yellowish buff colour, could be

seen, and these quite obscured the red portion of the blood.

On dipping the point of the finger into the clear liquid, it somewhat disturbed the coagulating process, and a thin gelatinous film adhered to it, together with some of the still fluid portion : both were placed on a piece of glass and examined by the lens (a Coddington) against the light, when a great number of the same colourless globules could be seen, and the coagulated film appeared to be composed entirely of these globules adhering together. Here the clot did not attain its smallest dimension till the end of eighteen or twenty-four hours.

On the following day I bled the patient again, when the blood displayed the same appearances. Half a teaspoonful of the clear or colourless liquid swimming on the surface was placed on a piece of glass. On examination by the lens an immense number of the same globules were found floating in it. In about five minutes the coagulation commenced by the formation of numerous opaque streaks and films, which were evidently composed by the aggregation of the globules. In a short time the whole was jellied, and some serum separated. During this change the coagulum becomes opaque, and its composition cannot then be detected.

From these experiments it is evident that inflammatory or buffy blood has two kinds of globules ; the heavier red globule sinking to the bottom, and forming the lower portion of the clot, and the colourless lighter globules swimming at the top.

Müller enters pretty minutely into the cause and appearance of the inflammatory crust, but makes no mention of any globules to be found in the fluid from which it is formed. On the contrary, he distinctly states that the fibrine of the blood is really dissolved in the liquor sanguinis, and that it does not exist in the blood in the form of globules *.

I am still pursuing my investigations on this subject : in the meantime I hope this brief communication will be the means of drawing attention to the subject—now that we are fast reverting to a " modified humoral pathology."

* Physiology, pp. 124, 128.

MIDWIFERY CASE.

To the Editor of the Medical Gazette.

Sir,

If you imagine the following statement will be read with interest by the medical public, perhaps you will find it a place in your weekly publication.

I was summoned some days since to attend Mrs. ——, aged 27 years, and the mother of two children, and on my arrival found her in labour, but very weak and languid, having suffered from ill health during the greater part of her pregnancy. Having ascertained that the parts were fully dilated, and that it was from mere want of uterine action that the labour was not completed, I gave the patient ℈i. of the secale, but did not rouse the uterus to efficient action to complete labour : therefore, having waited a proper time, I repeated the dose, and expulsion of the child and placenta was soon accomplished ; but no sooner had this taken place than violent sickness came on ; syncope to an alarming extent ; cold perspirations, &c. I administered brandy, ammonia, and various stimuli, and after two or three hours she was sufficiently recovered for me to venture to leave her, giving strict directions, in case of return of symptoms, to apprise me, as I was not living far distant. I left her about two o'clock A.M., and saw her again at nine, when I found the sickness had not returned, and that she had rallied considerably ; but the symptoms were these :—Great pain in the head, with giddiness ; a full staring eye, and to a great extent unconscious of what was passing around her; breathing humid; pulse small and quick ; and continued and violent pain or cramps in the lower extremities. Regarding the symptoms as the result of the ergot, I cautiously emptied the stomach and bowels, and then gave every three hours nitro-muriatic, or, according to the present nomenclature, nitro-hydrochloric acid, taking the precaution to render the room dark. Having met with a nurse, who had good sense and good nature, I gave strict injunctions to keep the house perfectly quiet. I saw the patient again in the evening, and found her much improved : bowels relieved twice ; the brain evidently returning to its accustomed functions, and the cramps in the legs

better. I have seen her daily since, and she is now convalescent. In her former pregnancies and labours she had been in good health, and labour had generally terminated in three or four hours, and her previous medical attendant had never required to give her any thing to assist her labour. There could be nothing unusual in the ergot, for I have used some from the same parcel repeatedly; therefore I conclude there must be some peculiarity in this individual more than mere derangement or common irritability of stomach.—I am, sir,

Your obedient servant,
ALFRED CRABB.

March, Cambridgeshire,
Nov. 23, 1840.

POISONING WITH BINOXALATE OF POTASS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case of poisoning with binoxalate of potass, which was attended by my father and myself, of sufficient interest for a place in your journal, I shall feel obliged by its insertion.—I am, sir,

Your obedient servant,
JOHN JACKSON, M.R.C.S.

30, Church Street, Spitalfields,
Dec. 7, 1840.

A female, of about 20 years of age, took on the morning of the 13th of November, 1840, some binoxalate of potass, which she had previously dissolved in some hot water. The quantity taken was, as nearly as could be ascertained, about an ounce. About an hour and a half after having swallowed it, she was found by the servant lying on the floor quite faint, having been previously very sick. On being visited, as soon as the nature of the poison had been ascertained, ʒiv. of Mist. Cretæ were administered, with the view of neutralizing the acid of the salt, if any remained on the stomach. At this time she was in a state of extreme depression; the pulse being so feeble that it could scarcely be felt; the skin cold and clammy: and the face and lips pale, with continued rigors affecting the whole body. She complained of a scalding sensation in the throat and stomach, of pain in the

back, and of great soreness of the eyes, with dimness of vision. The conjunctivæ of both eyes were a good deal injected, and both pupils were dilated, though the eyes were exposed to a pretty strong light, as the patient was placed opposite to a window. Immediately after the administration of the Mist. Cretæ she was well wrapped up in warm blankets, and bottles filled with hot water were applied to her feet. She also took occasionally some ether and tincture of opium in camphor mixture. The state of depression continued for a about an hour after these means had been adopted for its relief. At the end of this time reaction began to take place, and in a short time was fully established; the pulse becoming full and quick; the skin hot; and the countenance flushed. She now complained of throbbing pain in the head, and of great thirst. The scalding sensation, which at the commencement was felt in the throat and stomach, now extended more or less over the abdomen, being accompanied by tenderness on tolerably firm pressure being made. Eighteen leeches were now applied to the abdomen, and followed by warm fomentations. After the abstraction of blood by the leeches, the faintness recurred, which rendered necessary the readministration of a stimulant. Some carbonate of ammonia was given, and the patient rallied again. The abdominal tenderness, though diminished, still existed, being accompanied by constant sickness. A mustard cataplasm was now applied to the scrobiculus cordis, and some calomel and opium were administered every three hours.

Nov. 14th.—On being visited this morning she expressed herself much easier, having slept a little during the night. The abdominal tenderness being almost entirely gone, and her bowels not having been open since the day previous to that on which she took the poison, some carbonate and sulphate of magnesia were given every four hours. It was necessary to omit this medicine once during the day, in consequence of a return of the fainting, which was relieved by the administration of some ether and tincture of opium.

15th.—She states that she passed a tolerably good night, the bowels having been freely opened. From this time, until her leaving London, in two days after,

she rapidly improved, the only symptoms remaining being those indicative of irritation of the mucous membrane of the alimentary canal, to relieve which demulcents and opiates were given with success. At the time of her quitting town she seemed quite well, with the exception of debility.

The above case is interesting in two respects. In the first place, as far as I am aware, instances of poisoning with binoxalate of potass are seldom met with, a circumstance the more to be wondered at, as the salt is extensively used as a decolorizing agent by those who prepare straws for the manufacture of bonnets, &c. The individual who is the subject of the above account was engaged in a business of this sort. In the second place, though the symptoms were in the main very similar to those which have been observed in cases of poisoning with oxalic acid or its salts, yet in some particulars they were essentially different. The injection of the conjunctivæ, the dimness of vision, and the dilated condition of the pupils, which existed during the state of depression, and which gradually disappeared after the establishment of reaction, are circumstances which are not adverted to at all by Dr. Christison, in his account of the effects of oxalic acid and its salts, and which, therefore, I presume, have not been previously noticed. There was in this case no tendency either to tetanus or coma, both of which symptoms were observed by Drs. Christison and Coindet, in their experiments with the salts of oxalic acid.

REMARKS ON THE

MORTALITY OF PUERPERAL WOMEN IN GREAT TOWNS.

To the Editor of the Medical Gazette.

SIR,

IN the paper on Uterine Hæmorrhage by Mr. Adams*, the following observation occurs:—"According to Mr. Farr the proportion of deaths from child-bed is 71 per cent. greater in towns than in the country. It would be important to know whether abnormal implantation of the placenta be one of the causes of this greater mortality. For this reason,

* MED. GAZ. No. 6, Oct. 30, 1840, p. 199.

as well as many others, it would be much to be desired that medical statistics were more cultivated."

There can be little doubt that the cause of this greater mortality in towns than in the country is owing to the existence of lying-in hospitals in the former; and there is no subject more deserving of attention than an investigation into this subject. Dr. Lee observes at p. 114 of his work on the Diseases of Women, 1833, " I cannot conclude this important subject without pointing out the urgent necessity which there exists for a full investigation of the means calculated to prevent the occurrence of puerperal fever, or uterine inflammation, in lying-in hospitals, where its dreadful fatality has been recorded by all writers since the foundation of these institutions. From the Registers of the British Lying-in Hospital, the Maternité at Paris, the Dublin Lying-in Hospital, and the tables of M. de Chaleauneuf, it is proved that the average rate of mortality greatly exceeds that of institutions where individuals are attended at their own habitations; and if it should ultimately appear that all precautions are unavailing in diminishing the numbers attacked by the disease, it becomes a subject deserving the most serious consideration, on the ground of humanity, whether lying-in hospitals should not be looked upon as injurious rather than beneficial to society. From what has fallen under my own observation in the British Lying-in Hospital, and other similar institutions in this metropolis, where the utmost attention is paid to ventilation and cleanliness, and where the wards are not over-crowded with patients, I cannot hesitate to express my decided conviction, that by no means hitherto discovered can the frequent and fatal recurrence of the disease be prevented in lying-in hospitals, and that the loss of human life thereby occasioned completely defeats the objects of their benevolent founders."

Dr. Ferguson has come to nearly the same conclusion, for at page 103 of his work it is stated respecting the influence of hospital air upon the production of the disease, that "On this head we have abundant evidence of the disease being most fatal in hospitals, as these receptacles are now managed. Neither the skill, the comfort, the careful dieting, and even the assiduous

nursing which are lavished on its in- mates, diminish the mortality to a level with that attendant on the out-door population."

If these be facts, for whose benefit then, may I be permitted to inquire, are such institutions kept up ? Certainly not for the advantage of the poor women, who have little idea on enter- ing the wards of a lying-in hospital that they are to be plunged in an at- mosphere loaded with putrid and con- tagious miasmata, and that they are to encounter dangers to which they would not have been exposed in their own comparatively comfortless homes.

The Statistical Society would, in my opinion, render a great service to hu- manity by instituting an inquiry into the mortality of lying-in hospitals.

I am, sir,
Your obedient servant,
A. B. G.

CASE OF HERNIA.

To the Editor of the Medical Gazette.

Sir,

I HAVE read with interest the remarka- ble case of Hernia published in your number for November 27, in the reports of the Aberdeen Infirmary ; and solicit the favour of your publishing the fol- lowing case, which occurred in a patient of mine, and which I think will go far towards explaining the production of the ligamentous band which proved the cause of strangulation in the case of A. R., the sailor ; appearing to the writer to be altogether inexplicable. I transcribe the case from my note-book.

1832, March 7th : Lucy Darville, aged 21, thin and spare, her parents healthy and strong, has not been in good health for two or three years, but able to get about, and in good spirits generally. She had taken a walk of three miles, and before returning home was seized with pain in the side of the abdomen, about the left iliac region. It was very acute. She began to vomit, and for the first three days I know little more than that she is described by her mo- ther to have vomited almost incessantly. Previous to this attack her bowels had been relaxed, and, attending to a verbal account of her illness, on one of the early days, an aperient draught and an astringent mixture had been sent. The

latter was taken, the former omitted. No motion of bowels taking place, the vomiting continued, with tension of the abdomen. Purgatives, fomentations, bleeding locally and generally, blisters and warm baths, were all had recourse to. Sometimes the abdomen was tense, but never very tender, and for a case of enteritis, which I supposed it to be, (not being able to discover a hernial tumor), I was surprised at the little complaint of pain.

The retching having subsided one day, began again. She lived from the attack fourteen days, and died, having had no motion, except the emptying of the lower bowels by the injections.

When bled, she very soon became faint, and upon every occasion I failed to procure as much blood as I had wished, on account of the collapse that followed the opening of the vein ; still it was observable that the fainting pro- duced no good. During her illness, opiates were given, castor oil, elaterium, colocynth, gamboge, calomel, senna, saline medicines, and antispasmodics.

I could not but suspect that there was something peculiar in this illness, and the idea of an internal hernia occurred to my thoughts.

I felt an anxious desire, after the fatal termination, that the doubts which had existed during life should be as much as possible solved by a post- mortem examination.

Appearances on examination.—A large mass of intestine presented itself in the iliac region, of very dark colour in one point, giving way to the pressure of the finger, and letting out some of its con- tents. Leaving, for the present, a more particular examination of this part, I turned to the upper part of the cavity, designing to trace the course of the in- testinal canal from the stomach down- wards ; in doing which, I found the upper surface of the liver adhering so firmly to the contiguous parietes that a separation was effected with great difficulty. Half a dozen scybala, the size of a bantam's egg, were contained in the intestine, very firm in texture, some of them covered with purulent- like mucus. Reaching that part of the intestine which was in a morbid state, I was struck by a curious, and, at first, unintelligible appearance ; viz. a liga- ture, a cross, a doubling of the canal, including all the discoloured part, to the extent of about seven or eight inches in

length, having very much the appearance of a digastric muscle, the size being for a small extent that of a piece of whipcord, enlarging into a fleshy substance each way laterally. Carrying the finger along the course of this band, I discovered it to be a ring formed by an opening in the mesentery, which had produced the strangulation, and thus were accounted for the appearances and the fatal termination, without throwing any light which could have rendered the case more curable had it been understood. The included intestine contained a pint or more of yellow feculent fluid, and was so meshed with the ligature, that I conceive the mass had been thus pressed upon for some time.

Accident, or some morbid process, must have produced an aperture in the mesentery, through which the duplicature of the intestine passed; and in proceeding, and enlarging subsequently, stripped from itself the membranes of which the structure is formed. The circumferent portion of the ring, not being turned quite through, thus assumed the form of a cord.

The valuable contributor to your journal of the article alluded to, will, I think, scarcely doubt that the two cases were strangulated mesenteric hernia; his own, at least, suggesting very powerfully, as is justly observed, the importance of a little hesitation as to establishing the general rule of returning a hernial sac unopened.—I am, sir,

Your obedient servant,
NATHANIEL RUMSEY, M.D.

Henley-on-Thames, Dec. 2, 1840.

MEDICAL GAZETTE.

Friday, December 18, 1840.

HEALTH OF THE POOR IN LARGE TOWNS.

MISS EDGEWORTH has observed with great truth, that one half of the world does not know how the other half lives. It is pleasant, therefore, to see that the number of those philanthropists is on the increase, who serve as interpreters between the several halves of society and explain to the lords of hill and dale, that the poor of real life are not the poor of a poem or a melodrama, and that much of what appears tolerable in their state is a gilded fallacy. Mr. Slaney, on whose speech we commented in our last volume*, belongs to this noble class, and endeavours to awaken the slumbering rich to a consideration of the neglected poor. He has lately published another pamphlet on the same subject, which is now lying before us †. Mr. Slaney is perfectly aware of the difficulty of the task which he has undertaken. The busy and the politic look at every thing through coloured glasses; they

" narrow their mind,
And to party give up what was meant for mankind."

So that even if they can tear themselves awhile from Parliamentary tactics, or the absorbing interests of the Bank parlour, *cœlum non animum mutant*, they change the scene of contest, but not the passions which animated it.

On the other hand, the hereditary possessors of wealth are loath to look at the subject at all. One man wears blue spectacles, and another shuts his eyes; query—which of the two is most likely to see things of their real colour ? These opulent and powerful classes, says Mr. Slaney, are usually generous, and liberally open their purses to known cases of misfortune. But " an attempt to show them that the state of things is not so bright or safe as they have always deemed it, is considered almost as an injury ; their passions and prejudices, their hopes and wishes, lay [lie] all the other way, and how

* Art. Physical Condition of the Working Classes, MED. GAZ. April 10, 1840.
† Reports of the House of Commons on the Education (1838), and on the Health (1840), of the poorer classes in large towns ; with some suggestions for improvement, by Robert A. Slaney, Esq. M.P., Chairman of both Committees.

few are resolute enough to be con-vinced in spite of all these!"

Tell them, in fact, of the Rookery, and its lodgers; of the human sties filled with beings little above the condition of the beasts; of the satire on the rulers of the world, more bitter than Juvenal ever wrote, implied in the thronged cellars of Manchester, and the depopu-lating fevers of Glasgow — and they will tell you, that you are a *mauvais sujet*, and ask whether you have signed the Five Points!

Many of them, indeed, think that misery means the elegant distress of a romance; the word immediately recalls to their imagination a merchant forced to lay down his carriage, and retire to a cottage *orné* on the banks of the Wye; but not a room in an Edinburgh wynd, and its occupier living on three meals a week. Unseared by these mis-apprehensions, Mr. Slaney calls every ones attention to the important ques-tion—shall we remedy the evil while it is yet time, or shall we await an " in-crease of crime, disease, and discontent, and outbreaks from time to time, more and more difficult to suppress?"

The two reports which Mr. Slaney has reprinted in his pamphlet show that during the last forty years the rural population of England has in-creased about 40 per cent., while that of many great towns has increased from 80 to 120 per cent.; and that in these towns " no adequate provision is made for the proper education of the children, no due regulations are enforced for the health and comfort of the poorer classes, and no sufficient means placed within their reach to enable them to provide against the trials that beset them!"

The first remedy suggested is a good practical education based on religious principles. But, adds Mr. Slaney, edu-cation is not confined to schools, and the filthy wretched homes of many of the indigent destroy the good effect of the instructions received without.

Habitations damp, dirty, and unven-tilated, where the first elements of health and comfort are wanting, and where gloomy discontent alternates with unwholesome exhilaration, are not schools of virtue.

It is not in the squalid abodes of indigence that content and industry are to be learned, or that the stripling is formed into the citizen. Despair increases the evils by which it was produced; and destitution is naturally allied to that *shiftlessness*, of which Cobbett says that it is an evil little short of the loss of eyes or of limbs[*]. It is to want in this extreme that we may too often apply the saying of the poet:

"Credi mihi, miseros prudentia prima reliquit ; Et sensus cum re consiliumque fugit."

The first thing, therefore, is to im-prove these miserable homes; they are *incompatible*, so to speak, with the les-sons learned at school.

A check is wanted on those ignorant or avaricious builders who run up rows of houses in the worst manner, and in the worst situations. Good drainage and ventilation should be compulsory, and the legislature should interpose between those who are actuated only by the thirst for gold, and their un-happy victims. They should be taught that to stifle their humble fellow-citi-zens in turn-again alleys is not among the legitimate applications of the right to do what they will with their own[*].

---

[*] Cottage Economy, sec. 166.
[†] To teach this benevolent lesson a bill " For improving the Dwellings of the Working Classes," was brought in and printed 17th July, 1840. " It is applicable only to houses under £30 per an-num. Its principal provisions are,—
1. To forbid the building in towns of a certain population of cellar dwellings, unless with an open area adjoining.
2. Houses not to be built in courts and alleys without a thoroughfare at each end, feet wide.
3. Houses not to be built back to back, or with-out a clear space of yards between.
4. Opposite rows of houses to have a certain space between.
5. Houses built after the Act, without drains, &c., not to be occupied.
6. Housewardens to be appointed by rate-pay-ers, vestries, or guardians of poor, to enforce these provisions."—Slaney, p. 7. Note.

A drainage Act, the establishment of Boards of Health, and a general Act to facilitate and enforce local improvements, are also recommended by the committee. The expense of these ameliorations will, of course, be objected by some economists ; but where the results to be attained are so great, and comfort as well as health are the reward of the outlay, we think this objection light as air, and scarcely worth a formal refutation.

Mr. Slaney, indeed, hopes that the cost will be repaid by the improvement in the character of the people, and consequent saving of sums now uselessly or hurtfully squandered. He supposes, for example, that " the outlay in drunkenness and the use of spirituous liquors injurious to health (after every allowance for reasonable conviviality) is above fifteen millions per annum throughout the kingdom.

This would be a large fund to draw upon ; but we doubt whether Mr. Slaney has made sufficient allowance for conviviality, or even for the sober consumption of ale and beer in shop and market, farm and mansion. He says, that according to the returns to Parliament, 30 millions of gallons of spirits are annually consumed, which are retailed at about 10s. per gallon, and 450 millions of gallons of ale and beer, which are valued at between 20 and 30 millions sterling; so that the two together are worth about £40,000,000 ; and, therefore, he considers $\frac{3}{8}$ of this as superfluous.

We shall not dwell much on the report of the committee on health; partly because their recommendations are touched upon in Mr. Slaney's preliminary remarks ; and partly, because most of their facts and suggestions, though new in the *salons dorés* of the opulent, are sufficiently familiar to medical practitioners. Yet as each great town seems to have some special variety

of unhealthy arrangement, we may cite Dr. Duncan's account of the courts in Liverpool : " Very few have an entrance wider than four feet, and that is by an archway built over it ; the width is from nine to fifteen feet between the rows; there is one only six feet. The backs of the houses in one court are built against the backs of houses in another court ; at the further end there is generally an ash-pit between two privies ; they are in the most abominable state of filth."

The committee mention the injurious custom of burying the dead in the midst of populous cities; the importance of an ample supply of water ; the necessity of public walks near great towns ; an inspection of the lower lodging-houses ; and public bathing places.

Practitioners of physic can hardly do a greater service to the community than by pressing these topics on the attention of the opulent. Those who have been accustomed to think of Glasgow only as the emporium of Scotland, the residence of princely merchants, must learn the painful truth " that penury, dirt, misery, drunkenness, disease, and crime, culminate in Glasgow to a pitch unparalleled in Great Britain *;" and those who speak of London only as the metropolis of the world, should be taught to know, at least by description, the topography of Bethnal Green.

GANNAL PROCESS OF EMBALMING.

A LARGE number of the members of the profession, and others, assembled on Wednesday in the Theatre of Anatomy, Little Windmill Street, to witness the opening of a body which had been preserved for upwards of two years by a new method of embalming, termed, the *Gannal Process.* The discovery was made fourteen years ago by M. Gannal, an eminent French chemist. He has since that period continued to

* Slaney, page 46.

direct much of his attention to the sub-
ject ; and the process, as now improved
by him, while it is ready for application
at any time, and at a moderate expense,
is said to " preserve the body for an
unlimited period from incipient decay,
without alteration in its appearance,
or the presence of the slightest efflu-
via :" nay, it has the effect of arresting
putrescency after it has actually com-
menced. Mr. Gregory Smith, before
proceeding to uncover and open it,
stated that he had been present, though
not taking any actual part, at the em-
balming of the body, on the 9th of
November, 1838, by M. Gannal himself,
who visited this country for that pur-
pose. It has since been under Mr.
Smith's charge, and exposed to various
degrees of temperature at different times.
The man died on the 5th of the month,
and signs of decomposition had begun
to manifest themselves on the abdomen
and lower part of the neck, when, on
the 9th, M. Gannal threw into the left
carotid, with a common injection sy-
ringe, a large quantity of acetate of
alumina. In about half an hour after,
the greenish appearance on the abdo-
men neck and belly became less evi-
dent, and within three days was no
longer observable. The subject now
presented a waxy, and rather full but
firm appearance. In this condition it
was left until the 14th, when every part
of it, except the face and hands, was
invested first with a covering of linen,
then a coating of lead, and over that
was put a thick envelopment of ban-
dages, not less than 200 yards alto-
gether having been used by M. Gannal
for this purpose.

Between the folds of bandage were
sprinkled some aromatics, and no other
odour than that which they emitted
was perceptible during the examina-
tion. Over the face and hands, which
were left uncovered by the bandages,
was a thin coating of wax.

When these coverings had been suc-
cessively removed, the body presented
generally the waxy appearance de-
scribed above, and had rather a dark
tinge ; but the arms, one especially,
which had become partially dry, were
nearly black, as were also both feet,
and part of the right leg, where a sore
had existed at the time of death.

The abdominal muscles were now
divided, and they seemed to be easily
cut. These having been reverted, and

the abdominal and thoracic cavities
laid open, the different viscera pre-
sented a dark appearance, but seemed
perfectly fresh ; thus the intestines
were entire, and could be separated with
ease, while the broad ligament of the
liver was natural to the feel. The state
of the muscles was inspected in various
parts of the body, and though they
had generally speaking become dark-
coloured, yet in some parts they re-
tained their natural tinge. The brain
too was examined. Here the dura
mater was at one part dark and par-
tially decayed, and the substance of the
brain generally was softened, though
the medulla oblongata was of natural
consistence. The softening might arise
from the state of the brain before death,
seeing that the man is reported to have
died of epilepsy.

We may observe that the knife used
in making the examination did not
seem to be in the least corroded, as it
is apt to become after cutting a body
preserved by the oxymuriate of mer-
cury.

There were in the theatre, besides
the body of a child, various specimens
of animals preserved by this method,
which had not been protected against
changes of temperature, and yet ap-
peared to be perfectly fresh. Among
these were a dog, a cat, a rabbit, and
several birds. In all the viscera had
been left, nor does M. Gannal in any
case deem it necessary, before using the
injection, even to clear out from the
intestines any fæculent matter which
may be present in them.

In 1835 the Academy of Sciences of
Paris, and in 1837 the Academy of
Medicine, having fully investigated the
subject, expressed in strong terms their
sense of the value and importance of
the discovery. So also did the mem-
bers of the Institute : and the process
is now adopted in many of the greatest
anatomical schools in France, besides
being much used by private individuals
for embalming persons deceased.   It
has been suggested that the discovery
might be advantageously employed 1
cases of adventitious death—and o'e
case is already on record where it hd
led to the detection of a murder.

M. Gannal has obtained a patent n
France, and Mr. George Smith, of
John Street, Oxford Street, has taen
out an English patent for the inven-
tion.

PRESENTATION OF PLATE TO DR. FORBES.

DR. FORBES is known to our readers as the translator of Laennec, and the able editor of a Quarterly Review. At Chichester he has merited the additional fame of a skilful physician, and a good fellow-citizen.

On Tuesday, the 8th of December, as we learn from the Brighton Herald, a farewell dinner was given to Dr. Forbes, at the Dolphin Hotel, Chichester, at which plate to the value of nearly £300 was presented to him. The chair was filled by William Charles Newland, Esq., supported by Admiral Thompson, and about sixty other gentlemen. After the Chairman had presented the plate on behalf of himself and the other subscribers, Dr. Forbes thanked him for this mark of their esteem in a very agreeable and manly strain. He neither assumed to himself all the praise implied in so distinguished a gift, nor did he wholly reject it; but was rather inspired by the genial consciousness that so great a chorus of approbation could not be founded upon error.

The plate was presented " in testimony of his character, and in gratitude for his zealous and indefatigable exertions in behalf of the Chichester Infirmary."

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.
Dec. 8, 1840.
SIR B. C. BRODIE, Bart., in the Chair.

On the Structure of the Entozoa belonging to the Genus Cysticercus. By GEORGE GULLIVER, F.R.S. F.Z.S. Assistant Surgeon to the Royal Regiment of Horse Guards. Communicated by Dr. Clendinning.

AFTER observing the great importance of the cystworm as one of the very few parasites that infest the muscular fibre of man as well as that of animals used by him as food, the author refers to a notice which he gave to the Zoological Society in March last, " On certain oval corpuscles obtained from the cysticercus;" adding that the object of the present memoir is to explain the nature, situation, and extent of these bodies, and to give some illustrations of other points in the anatomy of the worm, which he believes have hitherto either been imperfectly elucidated or altogether neglected, since nothing has yet been added to the observations published by Dr. Knox, in 1836, which are more accurate than the compilations which have since appeared.

Mr. Gulliver then adduces many reasons drawn from the structure, composition, and situation of the ovæ corpuscles, to induce the belief that they are in fact the ova of the entozoon. They are said to occupy the neck or true body of the worm, while the bladder-like part or caudal vesicle is destitute of them, and throughout pervaded by spherules infinitely more minute in size, and totally different in other characters: for the ova have a granular interior with a calcareous shell, while the spherules of the vesicle are not affected by acids.

In a description of the configuration and arrangement of the hooklets, the author shews that the two sets, though alike in form, are quite distinct in size, and arranged alternately: and that each claw has a blunt lateral process, which may be mistaken for a distinct body or ovum; and he remarks incidentally that, although Rudolphi appreciated the importance of the tentacles in the arrangement of some of the entozoa, an accurate account of the structure and disposition of these parts has never been given, though necessary to a discrimination of many genera and species of the cystoid order, which have not yet been clearly characterized.

The memoir is illustrated by several drawings, executed by Mr. Liddall, exhibiting the struture of the ova, as well as that of the tentacles,—body, caudal vesicle, and cyst of the parasites.

Observations on Chorea. By JOHN WEBSTER, M.D. Consulting Physician to the St. George's and St. James's Dispensary.

St. Vitus's dance was little known to the ancients, although Pliny and Galen are thought to have alluded to it; and it is still doubtful if the epidemic which prevailed so extensively in Germany in the 14th century was chorea, or the disease called Raphania. The most accurate description of St. Vitus's dance is that given by Sydenham and Dr. Hamilton. This complaint prevails among the poor, the badly fed and manufacturing town population of England; the higher and middle ranks being comparatively more free from its attacks. Girls are more subject to it than boys, and of 21 cases treated by Dr. Webster 16 were in females, and but 5 in boys, or nearly 3 to 1.

Even when fatal, a much larger proportion of girls become victims to chorea than boys, as proved by the valuable report of the Registrar-General for 1840, which states that 20 females died of the disease, and only 4 boys, or 5 to 1, being the highest average in regard to the two sexes which the report contains. A very large number of the fatal cases occurred in the central and manufac-

turing districts of England, including the metropolis, and very few deaths in the more agricultural parts, whilst the northern counties, the purely agricultural and maritime districts, exhibited not a single fatal casualty, excepting one at Lancashire. The symptoms of chorea are so well known that no description of them was considered necessary by the author ; and the treatment he found most successful consisted in active purging by aloes, jalap, and similar remedies, varying them according to circumstances ; next the administration of tonics, such as Peruvian bark, ammonia, and camphor ; and lastly the proper regulation of the ingesta, which was always found of the greatest importance, for if that point was neglected more purging was required, and the case thereby protracted. When the head appeared affected, leeches and blisters were useful ; and if the uterine action also became implicated in the disease, then leeches and blisters to the loins, with the hip-bath, and that added to the purgative remedies, were found to be of essential service. Of the 21 cases treated by Dr. Webster, only 1 proved to be fatal ; but as in this instance the patient died of a fever which supervened to the St. Vitus's dance, and as the body besides was not examined, the author, from personal observation, could not bring forward any new fact regarding the etiology of chorea, although he expressed his opinion to coincide with those authors who consider the spinal cord and its membranes to be the primary seat of this singular disease.

No discussion followed the reading of Mr. Gulliver's paper.

At the conclusion of that by Dr. Webster, Dr. Wilks said that he had been led, by considerations founded on both physiology and pathology, to the conclusion, that chorea depended essentially on an affection of the cerebellum. In support of this, he alluded to the experiments of M. Magendie, which showed that certain injuries of the cerebellum, in animals, were followed by a loss of the directing power naturally possessed by the will over the voluntary muscles ; and, in particular, to an experiment by that physiologist, which he had himself seen him accidentally perform, in which one of the crura cerebelli being divided the rabbit immediately lost all voluntary influence over its muscles, and began to rotate its body. He observed also that some cases of chorea which he had seen appeared highly favourable to this view. In one that had occurred at St. George's Hospital, a girl had been attacked with chorea soon after having fallen on the back of her head ; all the usual remedies were employed without success ; but the disease was ultimately removed by the repeated application of leeches and

counter-irritation to the region of the cerebellum. Since that time Dr. W. had constantly treated chorea on the principles founded on the opinion he had been thus led to form, and with pretty constantly successful results.

Dr. Webster was aware that various authors had ascribed different parts of the nervous system, as the essential seats of the disease, marked by the convulsions of chorea. He regretted that he had not been able to perform any inspections of those who had died of the disease, and was, therefore, not in a position to form a decided opinion.

Dr. Addison having asked what Dr. Wilks considered to be the exact nature of the affection of the cerebellum, which gave rise to chorea, Dr. W. said " it might be an affection marked by no palpable lesion ; he believed, also, many different affections of the cerebellum might give rise to chorea, in the same manner as Dr. Abercrombie had shown that there were many different morbid conditions of the brain which were marked by the same symptoms ; as for example in apoplexy, in which it was often observed that the same symptoms occurred in cases where blood was effused, in others where serum only was effused, and in others where no effusion at all had taken place. In the case to which he had particularly alluded, and which occurred after a fall, Dr. W. imagined that a condition of inflammation of the cerebellum must have existed.

Dr. Addison then said that the idea of the cerebellum being the essential seat of the disease in chorea seemed to him entirely disproved by the fact that in the cases which proved fatal that organ was not found appreciably altered, while in the cases where the cerebellum was actually diseased, no choreal symptoms occurred. He had never seen a case of fatal chorea in which the cerebellum appeared diseased ; but he had seen many where from disease of the internal ear, or from other circumstances, acute inflammation had occurred in and about the cerebellum, leading to thickening of its membranes, effusion of albuminous matter, and even suppuration, and the formation of abscess — in which, in short, every circumstance that could produce irritation of the cerebellum had existed—and yet in none of these had any chorea occurred. He might apply the same observations with regard to the spinal cord, which was assumed to be the seat of the disease. He had had the misfortune to be able to examine several cases of chorea that had terminated fatally in his own and his colleague's practice ; but, after the most careful investigation, the only thing that was found remarkable was, the total absence of any appreciable lesion in the nervous centres. On the other hand, cases constantly occurred in which the spinal

cord was importantly diseased, but in which no chorea existed; and he believed he might appeal to the experience of surgeons, that injuries of the spinal cord are seldom or ever followed by symptoms of this kind. He believed it would be found that in this disease, and all those related to it, which are marked by sposmodic action of the muscles, the seat of disease, whether such as to produce appreciable lesion or not, was not so much in the medullary matter of the cord as in its membranes. So convinced was he of this, that it had become with him a matter of diagnosis, and, whenever he saw a case presenting, with other signs of disease within the vertebral column, convulsive action of the muscles, he at once considered the affection to be seated in the membranes of the cord, and not in its substance; whereas, if there existed paralysis of the muscles, he always conceived the nervous substance, and not the membranes, to be diseased. He thought attention had been given too exclusively to the nervous substance : to the neglect of the remarkable structure of the pia mater, and the other membranes which could not but exercise an important influence in the functions of the nervous system.

In confirmation of this opinion of Dr. Addison respecting the influence of diseases of the membranes, Mr. Davis related two cases, one of choreal affection, the other of epilepsy, both of which had occurred in consequence of local injury of the head, and both of which had been benefited only by the application of remedies to the part injured,— means which had produced complete cure in both.

Dr. Copland confirmed the author's statement as to the frequency of chorea among the poor of towns, by the fact that in the Manchester Infirmary there were seldom less than from twenty to thirty patients suffering from this disease. He wished to state his claims to the original idea of this affection being dependent on the spinal cord; as early as 1832 he had published his belief that it was the result of irritation, caused by disorder of the digestive system, and propagated through the ganglionic and vagus nerves to the spinal cord, from which it was again *reflected* to the nerves of the voluntary muscles. It was not till the following year that the same idea was brought before the Society by others.

The President said his observations had not led him to believe that chorea had any particular locality in the nervous system. In one case that had terminated fatally, he had found a cyst as large as a hazel-nut attached to the pineal gland; yet he should be far from thinking that that part was the seat of disease in chorea, though, in this case, its affection was, undoubtedly, the original cause of the symptoms. In another case,

the cortical substance of the brain was in a peculiar state, and quite red by the turgidity of its vessels, and no other apparent disease existed; in a third, the chorea was consequent on a prick of the finger; yet it was not probable that the part evidently diseased, in either of these cases, was the constant seat of the disease in chorea. He thought, also, it was erroneous to speak of the motions in chorea as involuntary; they seemed to him to be the results only of wrongly-directed will; the motions often commenced with such as were evidently voluntary, as picking the lips or fingers, and those gradually increased to real choreal movements. It was the same with hysterical affections of the muscles; in these cases the patient evidently willed the movements, but willed them at the wrong times, her mind not having sufficient control over her will to guide it aright; and so, in hysterical paralysis, the power of the muscles was not lost, but the will was not rightly exerted over them, and the patient was paralytic rather because she would not, than because she could not move.

In illustration of the occasionally local origin of chorea, Dr. Kingston related a case, in which, after injury of the elbow in a young girl, a violent and long-continued, constant, involuntary motion, had existed in the arm.

The discussion, which was throughout carried on with unusual vivacity, was continued till beyond the usual time of adjournment.

LIVERPOOL MEDICAL INSTITUTION.

THIRD MEETING.

Dr. Vose in the Chair.

Mr. Long related the following case of tubercle in the cerebellum :—

Whilst attending a lady, in February last, I was requested to see a servant who was suffering from sick headache; she had nausea, and occasional slight vomiting; her bowels were constipated, and tongue slightly furred; a disagreeable bitter taste in the mouth; pain in the occipital region extending to the vertex, and a perfectly quiet pulse.

I ordered an aperient, which evacuated the bowels freely, and then directed small doses of blue pill to be taken at bed-time, and a mild aperient each morning. In a few days the tongue became perfectly clean and moist; the disagreeable taste had disappeared; but the vomiting and headache persisted, having still the characters of that form of headache usually denominated sick headache.

I ordered her to bed, with the intention of examining her more carefully. I found the abdomen quite soft, without the slightest degree of tenderness in the epigastric region, or elsewhere. I then inquired into the state of the uterine system: her age was forty ; the catamenia were regular as to time, and healthy in quantity and quality. She informed me that for upwards of a dozen years she had, at intervals, suffered from attacks similar to that which she now experienced, and that at times the pain in her head was so severe as to confine her to bed; that these attacks frequently came on at the menstrual period, but, if they occurred prior to it, were always aggravated by it ; that at first they were easily removed by a brisk aperient, but had progressively become more obstinate ; and that the attack under which she was then labouring had existed a fortnight before I saw her.

She described the headaches as commencing usually during the night, or towards morning, and when very severe being always attended with vomiting, which occurred most frequently after eating, but frequently without any assignable cause ; in fact, it was the obstinacy of the vomiting which drew my attention more particularly to the case ; for medicines and treatment directed by this particular symptom were of no use whatever.

Taking into account the healthiness of the uterine functions, the quietness of the pulse, the natural state of the tongue, the freedom from pain or tenderness in the epigastric region, and the persistence of the vomiting and periodical headache, I felt little doubt but that these phænomena owed their origin to the cerebro-spinal system ; in effect, on making pressure between the occiput and atlas she experienced an acute pain extending from this region to the vertex, and immediately vomited.

I directed leeches to be applied below the occiput ; they produced marked relief. I repeated them, and the headache and vomiting ceased ; she slept soundly during the night, which she had not done for weeks before, and was able to go about the house as usual. At this period I did not remark any peculiarity in her gait, except that she moved about cautiously, as if afraid of shaking her head.

In a few days the symptoms began to return. I directed a blister to be applied to the same region. This checked them at once ; she improved, was able to go out, and stated that although she did not feel quite well, yet that she was in her usual state of health. In this state she continued, and at my urgent solicitation applied a second blister, but could not be prevailed upon (being relieved from her distressing symptoms) to persist in the treatment I had laid down for her.

Towards the end of March she went into the country, and consulted a practitioner there, who was of opinion that all her ailments resulted from a " change of life," and that the leeches and blisters had been injurious. He recommended some medicines, which she took ; the effect, however, not bearing out the opinion she had received, but her headache and vomiting recurring, she returned to Liverpool, and I was requested to see her in consultation with a physician of this town. I found her much worse. The headache and vomiting were as bad as at first, with occasional hiccup, and now and then slight difficulty of deglutition. In attempting to walk she staggered like a drunken person, and supported herself by holding a chair, or placing one hand against the wall. In sitting down she was some time before she could steady herself. At times partial convulsive movements occurred. These were peculiar ; the muscles at the back of the neck first became rigid, the head being drawn backwards, and then twisted to the right side, and then convulsive movements of the muscles of the face on the same side commenced. These convulsive movements were sometimes accompanied by a tremor of the whole body. The menstrual secretion was still regular and healthy ; the tongue quite clean, but tremulous ; the bowels easily moved by medicine ; the pulse slow, but otherwise natural ; the temperature of the body below the natural standard.

The plan of treatment adopted included slight irritation of the nape of the neck by means of lunar caustic, and she continued under our care until the middle of May, the convulsive twitchings increasing in severity, the headache, unsteadiness in walking, and vomiting persisting. It is worthy of remark that the convulsive twitchings and accompanying phenomena had for the last week or two assumed an intermittent character, so that she had what she called a good day and a bad day ; the good day was only so, however, when compared with her bad day. This always commenced with headache during the night, then vomiting, then convulsive twitchings of the neck and right side of the face, and then a tremor of the whole body. During her bad day she was confined to bed ; during her good day she sat up or walked about in the unsteady manner I have described. She was once seen by one of the family, when attempting to walk in the garden, to roll completely over. Her sister also informed me, and was corroborated in her statement by her fellow-servants, that she had frequently a tendency to fall forwards, and would have done so had not she or they caught her.

She went to reside with her sister in town from this period until the evening of the 28th May (about a week). I heard nothing of

her. On the evening in question I was sent for, and found her seated in a chair, dead. She appeared to be asleep, so that I had some difficulty in persuading her friends that she was actually dead. Her sister informed me that during the preceding week she had been rather worse than usual; that the convulsive twitchings had extended to both arms, both being equally affected; that, on the morning of the day on which she died, she felt better than usual, but expressed a strong conviction that she should not recover. In the evening her headache commenced, the convulsive twitchings succeeded, she complained of sickness, a basin was held before her, she opened her mouth as if to vomit, and expired. She had passed her usual catamenial period eight days.

I examined the body eighteen hours after death, and was assisted by Mr. Ellison. There were no external signs of scrofula. Nothing unusual was found in the membranes of the brain, or in its substance. A considerable quantity of colourless fluid escaped from the lateral ventricles; the arachnoid investment of both choroid plexuses was considerably distended by fluid underneath, presenting a hydatid-like appearance. The pia mater investing the cerebellum was much more minutely injected than could be accounted for by the effects of mere gravitation, particularly as the pia mater investing the posterior lobes of the brain was not similarly injected. The external configuration of the cerebellum was natural. Its whole substance and surface were rather softer than usual. The inferior vermiform process was occupied by a tubercle the size of a common marble, of a somewhat irregular figure, extending about a quarter of an inch into the right lobe. The nervous tissue immediately surrounding it was softer than the rest of the cerebellum. The superior surface of the right restiform body, just where it plunges into the cerebellum, was much softer than the left. The medulla oblongata, the pons varolii, and the nerves arising from them were perfectly healthy. We were not permitted to examine into the state of the spinal cord, or any other part of the body. The tubercle was hard, and when cut into presented granules of concrete pus, and appeared to me to be contained in a fine cyst.

Summary of the symptoms.—Senses unaffected; intellectual faculties entire, except that the memory seemed at times impaired; catamenia regular, and no derangement of sexual functions; periodical headache extending from the occiput to the vertex, of twelve years' standing.

Pain on pressing the occipital region; vomiting without epigastric tenderness; clean but tremulous tongue; occasionally slight difficulty of deglutition; rigidity of the muscles of the neck, with convulsive twitchings drawing the head to the right side; twitchings of the muscles of the right side of the face, extending subsequently to both arms; want of command over the lower limbs, with tendency to fall forwards.

Lesions found after death: tubercle in the inferior vermiform process of the cerebellum, extending into the right lobe; softening of the cerebellum, particularly around the tubercle; injection of the pia mater investing the cerebellum; softening of the right restiform body; fluid in the lateral ventricles of the brain.

1. The points worthy of notice are the rarity of tubercles of the cerebellum. Thus Louis and W. Lombard found tubercles in this organ twice only in 450 tubercular adults.

2. The length of time these productions may exist without giving rise to serious symptoms: a case is mentioned by Dr. Abercrombie in which a tubercle of the cerebellum evidently dated its commencement at least five years prior to death.

3. The intermittent phenomena caused or induced by a permanent change of structure, or new production, depending probably upon the intermittence of the lesions which exist around it; and, consequently, the existence of a new production may give rise to no phenomena, so long as the surrounding tissues are unaffected by it, and remain in a state of integrity.

4. The non-appearance of the menstrual discharge at its usual period—eight days prior to death; the aggravation and extension of the symptoms during this period; the existence of a considerable quantity of serum in the lateral ventricles: though a question may arise whether death was caused by the vessels relieving themselves by this effusion, or whether it was produced by syncope.

5. The softening of the right restiform body, and the remark of Rolando, " That injury of one of the restiform bodies produced convulsions, with curving of the body of the animal to the injured side;" there being in this particular a coincidence.

6. The want of accordance between the case I have related and the case related by Mr. Serres, which induced him to place the seat of sexual impulse in the middle portion of the cerebellum (on this point I was particularly anxious, and purposely delayed its consideration for this place). Eighteen years ago she had a son, who is now alive; since that period she has had no intimate male acquaintance, although she has not shunned their society; and during the whole of my attendance I did not perceive the least symptom of any amorous propensity, and her sister assured me that since her mishap she is certain she had none.

I may mention here that Mr. Montault has related a case of a tubercle an inch in size occupying the whole vertical thickness of the middle portion of the cerebellum. The individual was paraplegic, and addicted to women; but in this case there existed other disease of the brain, and the lumbar vertebræ were diseased; whereas M. Guerard mentions a case where a tubercle an inch and a half in size existed at the upper surface of the cerebellum, and in the middle line; the substance of the cerebellum around the tubercle to the extent of two lines was softened; the spinal cord was sound. This individual was weak, particularly in his lower limbs, and staggered in walking. It is added it would be impossible to say that there was any marked symptom referring to the genital organs. The case rather seems to favour the opinion of M. Magendie, who, it is stated in the Journal Hebdomadaire, ascertained, by direct experiment, that when an injury was inflicted upon the middle portion of the cerebellum the animal remained undecided in its movements; or considering the cerebellum as a whole, without reference to its middle portion, it seems to favour the opinion of M. Flourens and M. Bouillaud, that in it resides the faculty of combination of the movements; and coincides with the cases related by Lallemand, Gall, and Guerard, the individual staggering in walking, and having a tendency to fall forwards.

7. The accordance of the symptoms in the case I have related with the cases of disease of the cerebellum related by Andral, these being thirty-six cases of disease of various kinds, and of variable extent, and eleven cases of abscess.

Thus we find the intellectual faculties affected in 5; the senses in 6; the motor powers in 30; the tongue, in the thirty-six cases, 2; headache in 35; vomiting in 17.

With respect to derangements of the motor powers they are stated to have been various; but amongst them we find several in which paralysis affected especially the lower limbs; whilst it is noted, however, that involuntary contractions of a greater or less number of muscles is a more common phenomenon than paralysis: in a great number all the body was agitated by convulsive movements, at intervals, in other particular muscles, as those of the neck, drawing the head backwards, or to one side. He also mentions the facts stated above, that some individuals had a sort of uncertain gait, staggering like a drunken person, and having a tendency to fall forwards.

I may here mention two cases, one by Andral. Convulsive movements occurred, and always commenced by a powerful agitation of the head, which was drawn backwards as in a variety of tetanus. Some days the convulsions were confined there; but at other times became more general, and almost all the muscles of the body were affected: they augmented in frequency and intensity, extended to the respiratory muscles, and the patient died in a sort of asphyxia. An encysted abscess, the size of a pullet's egg, existed in the left lobe of the cerebellum. The second by M. Recamier. Frequent convulsive movements existed, commencing always in the muscles of the neck. In these attacks all the body was agitated, and the head drawn backwards. An encysted abscess, the size of a pullet's egg, existed in the left lobe of the cerebellum.

With respect to the headache, it is remarked by Andral that it was generally seated in the occipital region; was mostly intense, and in several cases assumed a periodical or intermittent character; and that when vomiting occurred it was in all sympathetic, and one of the predominant symptoms, not occurring as a simple complication, but being certainly connected with the disease of the cerebellum.

Dr. Abercrombie remarks, that where periodical headaches and paroxysms of vomiting occur in indurations of the nervous centres, the prominent morbid appearances are found in the cerebellum, and that the uneasiness in the head is more permanent and fixed than we should expect to find in a dyspeptic case, and the uneasiness is increased by causes which would probably be beneficial in dyspeptic headache; such as activity and cheerful company.

He also notices that in cases of paraplegia tumors and indurations often exist in the cerebellum or tuber annulare; but that the cases on this point are unsatisfactory, in consequence of attention not having been paid to the spinal cord.

Diseases of the central organs of the nervous system are involved in great obscurity, and must be so so long as we are ignorant of the functions of their separate parts, so long as we have a difficulty in ascertaining the precise amount of a lesion, or of conveying to another a precise idea of it when ascertained; for a degree more or less of an injury may make a vast difference in the amount or kind of symptoms produced; or a disorganization or change of structure in a part endowed with a special function may, according to its extent or locality in that organ, in one case alter, in another, weaken and destroy its functions, or call into action another part with which it may have a direct or secret influence. I think, however, that sufficient may be gathered from the above remarks to enable us, in certain cases, if not to diagnosticate diseases of the cerebellum, at least to enable us to state with some degree of probability that disease of this organ does exist.

REPORT

BY THE

ROYAL COLLEGE OF SURGEONS OF EDINBURGH,

On the proposals of Messrs. Warburton and Hawes for the amendment of the laws relating to the medical profession in Great Britain and Ireland.

Adopted unanimously, 12th December, 1840.

THE Royal College of Surgeons of Edinburgh having been unsuccessful in a series of attempts, during a period of more than twenty years, to obtain from Parliament a legislative remedy, founded upon broad and general grounds of public advantage, for the inequalities of education and of privilege which affect the medical profession in this country, rejoice to find that there is at length a prospect of this subject being brought fairly under the consideration of the legislature, with such an amount of support from the profession and from the public as to insure the attainment of some measure of practical good.

The progressive improvement in the courses of study prescribed, and in the minuteness and accuracy of the examinations instituted, by the different Boards to which the power of licensing is at present committed—an improvement in which the College have at all times taken a very prominent and leading part—has hitherto constituted the chief security to the public for the possession of a well-educated body of medical practitioners, and for the advancement of medical science itself.   Under this system, there has risen up in Great Britain and Ireland a large body of highly instructed medical practitioners, who feel aggrieved by the disabilities and inequalities of privilege to which they are subjected; who are conscious that their importance in the community entitles them to a remedy; and who are, with good reason, determined to urge their claim to that remedy, as being due, not merely to their own interests, but to those of the public at large.

Some years ago, such a degree of improvement in the system of granting medical qualifications by means of the existing incorporated bodies, as would have secured to the holders of those qualifications equal education and equal privileges throughout the United Kingdom, was all that the most sanguine medical reformers desired to effect. But an anxiety has recently been manifested, and very loudly and generally expressed, to accomplish those and similar objects by means of a general representation of the medical practitioners of this country. While the College have not hitherto given any

encouragement to this project, they do not view it with any particular apprehension; and seeing how much importance is attached to it by professional men of the highest character, they are willing to hope that a representative body, chosen by the practitioners of the healing art, if properly arranged, and accompanied by effectual checks for securing the community against the influence of partial views and interests, might work beneficially both for the profession and the public.

It is a gratifying proof of the just appreciation of the importance of this subject by those who are not of the medical profession, that two members of the House of Commons, Mr. Warburton and Mr. Hawes, have each promulgated a plan of medical reform, and that their several proposals evince an enlightened acquaintance with the nature of the evils to be remedied, which could only have been acquired by a great sacrifice of time and labour.   In both of these proposals are contained many valuable suggestions; and in both, as might have been expected, there are matters which seem to the College to require reconsideration.

The subject of medical legislation may be considered, as it respects the interests of the public, those of medical practitioners, and those of medical incorporations.

I. The interests of the public call for the following provisions :—

1. That all persons who receive a legal recognition as practitioners of medicine, should be previously subjected to a uniform and efficient system of education and examination.

2. That the public should have an opportunity, by means of a system of registration, of distinguishing those who have received this public recognition from those who have not.

3. That the public should be permitted to select their medical attendants, from among the number of those who are thus recognized, unembarrassed by any exclusive privileges of particular classes of medical practitioners.

II. When the subject is considered with a more immediate reference to the interests of medical practitioners, all of these conclusions appear to be confirmed.   The following expressions of Mr. Warburton on this subject appear to the College to be just and apposite :—

" The legitimate means of discouraging unqualified practice appear to be the following :—

" 1. Uniformity of system in respect of medical instruction and examinations, and uniformity of professional privileges founded thereon; so that the public may see and know that when a man has passed his examination, the state considers him a fit person to practise *ubicunque gentium.*

" 2. Registration of all who practise,

distinguishing the qualified from the un-qualified, that the public may be informed by the state what practitioners are to be confided in.

3. " Employment by the state, and by all public institutions, of none but the qualified.

4. " Punishment, as for fraud, of all per-sons who practise, assuming a professional title which does not belong to them." (See Mr. W.'s Letter to Dr. Maunsell, in the Dublin Medical Press, No. XCVI., p. 300.)

Besides these four methods of protecting the qualified practitioner, and discouraging the unqualified, another has been much agitated by medical reformers, viz. the establishment of a system of penalties against the latter for practising medicine without a license. In regard to this, Mr. Warburton says in another letter (Dublin Medical Press, No. XCVI., p. 301), " I have no faith in the efficacy of heavy penalties, when sought to be enforced against obscure people." This seems a sound opinion : it is conformable to the actual practice of this College, which has for a long period desisted from prosecuting those who have infringed its exclusive privileges, and has had no cause to regret its abstinence from this prac-tice ; there being no town in which ignorant pretenders to medical skill are less numerous and less respected than in Edinburgh. There is much reason to fear that prosecu-tions will be found to fail in accomplishing the object proposed. They may render the unqualified more cautious in practising on public credulity, without making them less successful ; they may even impart to their pretensions a degree of fame and of impor-tance, which those pretensions would never acquire without such assistance ; and they may have an unfavourable impression on the character of the qualified, who will be more likely to stand well with the unprofessional part of the public, if they have the magna-nimity to despise this species of artificial protection, and to rest their claims to public confidence solely upon their professional talents and qualifications. There cannot, of course, be any objection to their endeavour-ing to strengthen these claims by acquiring those honorary distinctions which univer-sities and other public bodies are in the practice of conferring.

III. But the subject of a reform in the laws affecting the profession must also be considered in its bearings on the interests of the existing Medical Incorporations. These incorporations have been objected to on the following grounds : 1. Their exclusive rights of examining and licensing the prac-titioners in certain districts, which have the effect of disqualifying from practising, within those limits, well educated men who have obtained a qualification elsewhere ; 2. The disparity in the conditions required of those

who are admitted to examination by the different boards and Universities, both as regards the length of the period of study, and as regards the number of branches of in-struction prescribed by their several cur-ricula ; and, 3. The very different degrees of rigour with which the examinations for licenses or degrees are conducted by the different Boards. The College have no hesitation in expressing an opinion which they have long entertained, and often promulgated, that the exclusive rights and restrictions referred to under the first of these heads, are altogether unsuited to the present state of the pro-fession. The only justification of them which has ever been proposed is based upon the disparities specified under the second and third heads. Great irregularities in regard to education and examination un-doubtedly exist, and constitute the plea for the obnoxious inequalities of privilege ; and it will certainly be expected of medical reformers that when they propose to abolish this last species of inequality, they will, at the same time, be prepared to admit the necessity of taking effectual means for the abolition of the two former also. About inequality of education, no great difficulty would now be experienced. An imperative system, sanctioned by some public authority, could easily be introduced and made appli-cable to every part of the United Kingdom. The Colleges of Surgeons of London, Edin-burgh, and Dublin, in a conference which they held in London by delegates, during the discussion in Parliament of the Irish Charities' Bill, came to an understanding as to what should constitute the *minimum* of study, without evidence of having gone through which no one should be admitted to examination by any board. The joint reso-lutions of these bodies were afterwards ac-ceded to by the Faculty of Physicians and Surgeons of Glasgow. A similar scheme was resolved upon by the University of Edin-burgh, and the Colleges of Physicians and Surgeons of Edinburgh. By a comparison of these plans, and of those of other licens-ing boards, a uniform system of education could without any serious difficulty be ad-justed.

But uniformity in the degree of rigour and minuteness in conducting examinations is by no means so easy of attainment, and indeed, nothing better than an approximation to such uniformity can be expected. The object is undoubtedly of the greatest impor-tance to the interests of the public, and no scheme of professional reform would deserve the name, if it did not attempt to secure as great a degree of uniformity in examination as can be attained. There are only three methods which occur to the College by which the object may be accomplished. The *first* of these is the plan proposed by Mr.

Warburton, and consists in intrusting the business of examining and conferring professional qualifications to a single board, appointed by a medical council in each of the three divisions of the Kingdom. It is further provided, that the examinations shall be conducted according to a set of bye-laws enacted by a Medical Senate for the whole Kingdom, and shall be under the immediate inspection of the Councils, and of the Senate. The College cannot but feel that the rights of the existing Boards to grant licenses applicable to their respective bounds, though proposed to be retained under this scheme, would be virtually abrogated, since no one would waste his means in acquiring the minor privilege, when the more extensive one applicable to the whole of the British dominions was made accessible. This proposal, therefore, if carried into effect, would altogether supersede, and indeed destroy, a number of establishments created at great cost to the public and the profession, and containing within them most if not all of the elements requisite for the successful performance of the functions hitherto intrusted to them ; establishments, of some of which it may safely be averred, that they have discharged their functions with the greatest liberality and disinterestedness. To destroy the powers of these boards, and thus to cut off from the incorporations appointing them those funds which are at present applied to purposes of great public utility, would be a gratuitous injury to the public interests, and the attempt would, in all probability, encounter such opposition as would be fatal to it in Parliament. The College readily acknowledge that if the laudable object which Mr. Warburton seeks to accomplish could only be attained by means of this proposal, the privileges of the incorporations, conferred solely for the public weal, could never be permitted to stand in the way of it. But the College are of opinion that either of the other two methods yet to be commented on would be preferable as a means to the proposed end.

The second plan for assimilating examinations is that of Mr. Hawes, which, like the former, provides a senate for the whole kingdom, with power to make by-laws for regulating education and examinations ; and a medical council in each of the three divisions of the kingdom, with power to select a board of examiners for carrying these laws into effect under the superintendence of the council and senate. Thus far there is a coincidence between the two plans. But there is this very important difference, that Mr. Hawes' plan provides that the bye-laws "shall not be good and valid unless they require that, previous to the final examination of any person desirous of obtaining a diploma of qualification to practise the Art of Medi-

cine, he shall produce a diploma, certificate, or letters-testimonial, of having taken a degree in medicine, or of having passed an examination in medicine or surgery before some university, college, hall, or other persons legally entitled to grant a diploma, certificate, or letters-testimonial, at the time of the passing of the act." This proposal secures the continued existence of the present machinery for granting professional qualifications, and avails itself of that machinery by making it imperative for a first stage of examination, but makes a second trial necessary before the Board appointed by the council. This examination, which is obviously intended to operate as a check on any laxity on the part of the existing Boards, and to equalize their proceedings, would certainly effect these objects to some extent, but by a procedure which is open to some objections.

The college conceive that a third scheme might, without much difficulty, be devised, which, leaving the immediate conduct of the examinations in the hands of the existing Medical Boards, would, at the same time, place them under the superintendence of the senate or councils, proposed to be instituted, acting through the intervention of assessors specially appointed by them for the purpose. Such a conjunction of local examinations with general superintendence would possess the twofold advantage of avoiding any infringement of the privileges of existing institutions, and of, at the same time, removing all apprehension or suspicion of the examinations being conducted inefficiently by any Board, or with less strictness by one Board than by another. To many of the members of the College it appears that this conjoint method of testing the candidates' qualifications, by examiners appointed by the existing institutions, and assessors nominated by the senate or councils, might be rendered at once more easy of execution and more efficient, by taking advantage of the system of examining by written questions, now pursued in many institutions, in judging of the claims of candidates to degrees and other honours.

The examinations might either embrace all the subjects in the curriculum at one sitting, or separate sittings might be given to the departments of medicine, surgery, and midwifery ; and it would be necessary that those Boards which do not examine on all the subjects in the curriculum should make an arrangement for co-operating with other Boards, in the same place, which might examine on those subjects to which their own examinations do not extend ; so that every part of the course of study might be included in the examinations. The fees payable to these Boards should be uniform and moderate ; and the proceeds, after defraying the expenses of the examinations on a scale approved of by the councils, should be applied, as they

have for many years been applied by this College, to purposes of public and professional utility.

In concluding these general remarks on the subject of the proposed reform, as it respects the interest of the public, of medical practitioners, and of the existing medical institutions, the College is fully aware that when these three views are contemplated with the eye of an enlightened liberality, they must be found to be coincident. The College can aver, with truth, that they have pursued no corporate ends to the public injury ; that they have sought to raise the standard of medical acquirement in this school by an enlarged system of education, proportioned to the wants of the age ; that they have refrained for a very long term of years from making additions to the cost of their diploma ; that their examiners have submitted to be greatly underpaid in order to enable the College to maintain their ground without such additions ; and that their entire accumulations have been expended in erecting their Hall, and in purchasing and maintaining a Museum, to the accommodation of which the greater part of the building is devoted, and which is accessible to the public, and most beneficial to the medical school. Having made such use of their present privileges, the College conceive themselves entitled to claim the credit of disinterestedness in any advices which they may offer in reference to medical legislation ; and they do most fully and unequivocally admit the supremacy of the public interest in all that relates to this most important subject. Let the medical incorporations be compelled to submit to all such regulations as the welfare of the public requires : let their privileges, in particular, altogether cease to be exclusive and local in their character ; but let not an apparatus, so capable of being beneficially employed, be gratuitously and inconsiderately annihilated.

[The College then proceeds to examine and comment upon the proposals of Mr. Warburton and Mr. Hawes.]

UNIVERSITY OF LONDON.

SECOND EXAMINATION FOR THE DEGREE OF BACHELOR OF MEDICINE, NOV. 1840.

Physiology and Comparative Anatomy.—Richard Quain*†, University College ; John Paddon†, University College ; Edwin Wing, School of Physic in Ireland.

Surgery.—John Charles Bucknill†, University College ; Thomas O'Meara, Mercers' Hospital, Dublin ; Thomas Williams, Guy's Hospital, and Webb Street ; Richard Quain, University College.

* To each of these gentlemen has been awarded a University Medical Scholarship of £50 a year, for two years.

† To each of these a gold medal of the value of £5.

Medicine.—Thomas O'Meara*†, Mercers' Hospital, Dublin ; John Douglas Strang†, University College ; John Charles Bucknill, University College ; Edwin Wing, School of Physic in Ireland ; Thomas Williams, Guy's Hospital, and Webb Street.

Midwifery. — John Douglas Strang †, University College ; Richard Quain, University College ; Thomas Williams, Guy's Hospital, and Webb Street.

Structural and Physiological Botany.—John Douglas Strang, University College.

EXAMINATION FOR THE DEGREE OF DOCTOR OF MEDICINE, NOV. 1840.

Anthony French Carpenter, M.B. Lond.

MYODIATOMY.

To the Editor of the Medical Gazette.

Sir,

As every thing in science that is likely to outline a day should have a name, and that the operation of dividing muscles for the cure of deformities arising from their contracted condition seems to have taken rank amongst the practical operations of the day, will you allow me to suggest to the profession the propriety of adopting the term myodiatomy, to designate this operation generally.

I am not aware that it has been before applied, if so will you make it more known, and throw this behind the fire.—I am, sir,

Your obedient servant,

T.

CHARLES HENRY ADAMS

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XIV.

Treatment of Inflammation, continued. Recapitulation. Bleeding: purgatives: mercury: antimony: digitalis: colchicum: opium.

Local remedies. External cold: external warmth: counter-irritation.

AFTER pointing out to you, yesterday, the necessity of guarding your patient, as much as possible, from all stimulants or sources of irritation, both internal and external, the avoidance of which constitutes what is called the *antiphlogistic regimen*, I began to speak of the *remedies* of inflammation.

Now the great remedy in acute and dangerous inflammation is blood-letting; and when this remedy is used at all, it should be used freely, and so as to produce a decided impression: and its efficacy will always be the greater, in proportion as it is applied in the earlier stages of the inflammation. The objects of the abstraction of blood are twofold: to lessen the force of the heart's action is one object; to empty the gorged capillaries of the part inflamed is the other. We effect the first of these objects, or both of them at once it may be, by making an orifice with a lancet, in the trunk of some convenient vein or artery, and allowing the blood to escape; we accomplish the second by making little incisions with a scarifier through the skin as near the inflamed part as we can, and forcing the blood through these little wounds by the pressure of the atmosphere: *i.e.* we take off the pressure from the part

scarified, by placing over it a glass cup, from which the air has been in a great measure exhausted, and then the unbalanced weight of the atmosphere upon the surrounding surface forces out the blood; or we suffer leeches to scarify the skin, and to suck out the blood. These two modes of drawing blood, from the trunks of the blood-vessels on the one hand, and from the capillaries on the other, we call, respectively, general bleeding, and topical bleeding.

I say the main point to be achieved in general bleeding is so to manage the operation as to make a decided impression, as quickly as possible, upon the pulse or the heart: and to do this we place our patient in an upright position, and make a free orifice in the vein of one or both arms.

And when the force of the general circulation has been thus abated, it will in many cases be proper and necessary to take away blood from the capillaries also, in the neighbourhood of the suffering organ: this is almost always safe and good practice: there can seldom be any reason for abstaining from it, except when the general bleeding has brought the patient so low that the abstraction of a few more ounces in any way might be hazardous. But the employment of local depletion presently after general is *then* especially indicated, when the *local* symptoms remain unrelieved; when, although the indirect symptoms which manifest themselves through the medium of the system at large have been moderated by the general bloodletting, yet the direct symptoms belonging to the part, and disturbing its functions, the pain, for example, or the labouring breath, or the stupor, have not undergone a proportional improvement. Under such circumstances, the unloading the oppressed capillaries by means of leeches or cupping will often be attended with the happiest effects.

I mentioned that the most common way of performing general blood-letting in this country is by venesection; and that the

veins chosen, as the most suitable for that purpose, are the cephalic and basilic veins at the bend of the arm : but that when, from accidental circumstances, blood cannot be obtained easily and abundantly from those veins, any other large and superficial blood-vessel may be opened. It matters little which, in my opinion, so far as regards the effect of the *abstraction of blood* upon the disease. Some persons are fond of opening the temporal artery when the inflammatory disease is situated in or about the head : and certainly, when we see this vessel starting from the surface like a cord, and tortuous from its fulness, and visibly throbbing, we feel tempted to give vent to the blood which is distending it. But arteriotomy is not so easily managed as phlebotomy. It is sometimes difficult to get the blood to flow properly ; and it is sometimes difficult to stop its egress when we wish to do so; and sometimes there are after-consequences which are far from being pleasant : little aneurismal tumors are apt to arise. It is, besides, desirable to avoid the necessity of bandaging the head, in order to restrain the farther efflux of blood from the artery. Other practitioners recommend opening the external jugular vein in head cas s, especially in children, whose veins in the arm are small. This is a plan which I have very seldom adopted, and which, I am bound to tell you, I do not much like : 1st. because I think it is seldom necessary ; 2dly. because I think it is often unsafe.

It is seldom necessary : for in children we can always get as much blood by topical bleeding as will be equivalent to a general blood-letting. And it is unsafe in two ways : 1st. It is not always an easy matter to stop the bleeding from the jugular vein, especially in a struggling and unmanageable child : and the difference of a few ounces of blood may be a *fatal* difference. Here also any compression of the neck, to stay the hæmorrhage, might affect injuriously the cerebral circulation. 2dly. There is a distinct and peculiar danger attending the incision of this vein, that, namely, of admitting *air* into it. You perhaps are aware that if air enters a large vein near the heart, and passes on to that organ, it kills outright. If you open the jugular vein of a horse, and blow forcibly into it towards the heart, the animal drops down dead. The celebrated Dupuytren was performing some operation about the neck, in the course of which he cut across one of the veins there situate : some bubbles of air rushed in at its open mouth, with an audible clucking noise, and, in an instant, his patient expired. The same frightful accident has occurred in operations performed in this country, and in America. I was told very lately that in one of our metropolitan hospitals it was thought right, for some reason or other, to bleed an adult patient by

opening his jugular vein : the opening was made very near the clavicle, so that pressure between the orifice and the heart was difficult to effect. Of course the blood soon leaves the portion of the vein nearest the heart ; and whether by some suction power of the heart itself upon the veins, or how, one scarcely knows, but air rushed in, and the patient was presently a dead man. Perhaps misadventures of this kind may be capable of being prevented by using great caution in such cases : but as it is the etiquette for physicians to direct but not to perform these manual services towards the sick, and as, therefore, I should incur all the responsibility, and at the same time be able to ensure none of the necessary care, I confess that I am shy of recommending venesection to be made in that particular place.

Whether, all other things being the same, the abstraction of arterial blood be more effectual in restraining inflammation than the abstraction of venous, is more than I can tell you.

When topical bleeding is employed with the view of disburdening the turgid capillaries, either in chronic inflammation, or in acute inflammation as an auxiliary to general bleeding, it would seem most expedient to get as near to the part affected as we can. To apply, for example, our cupping-glasses or our leeches to the temples, or behind the ears, or just below the occiput, in inflammatory affections of the head ; to the chest and præcordia, when the lungs or heart are the seat of the disease ; to the surface of the abdomen, in inflammation of the liver, or stomach, or intestines, and so on. And this is the plan which I have almost always adopted ; and with such satisfactory results that I have felt little inclination to try any other. But many persons do believe that local bleeding is more useful when it is performed at some distance from the affected part : they would put leeches, for instance, on the insteps, to relieve an inflamed throat ; and they attribute the benefit that ensues to what is called *revulsion :* they suppose that the suction of the leeches solicits the blood, as it were, to that quarter, and diverts it from the vessels of the part that is inflamed. It seems to me that the revulsive influence of *topical* bleeding would be greater in the neighbourhood of the inflamed part than far from it. I know, however, some very practical men who have been much struck with the results of this distant blood-letting, which they had seen practised in the Parisian hospitals. Leeches are also sometimes applied at a distance from the seat of the inflammation, on another principle—that of drawing the blood directly from the veins which communicate with the diseased part. In abdominal affections, in inflammation of the liver or intestines, the French are in

the habit of applying leeches in great numbers to the verge of the anus: because, they say, the blood is then abstracted from the very veins through which it is returning towards the already overloaded organs. It is right that you should be aware of these opinions, and of this practice. I can say but little of it from my own knowledge. I can well believe, however, that it is good and useful practice: but in this country we should find it difficult to persuade many of our patients to submit to have leeches planted round the anus: and I have seldom been disappointed of the benefit I expected from topical bleeding, when it has been employed at the surface as near the part inflamed as possible.

Purgatives.—The *evacuation* next in importance to blood-letting, is purging. This is an expedient which in cases of violent inflammation, or high general fever, should scarcely ever be omitted. To keep the bowels what is called *open*, forms indeed a part of the antiphlogistic *regimen;* but in acute inflammatory diseases, active purging is of very great service. These two points are gained by it. The stomach and intestines are freed from accumulated fæces, or other matters, which, by their bulk or their acrimony, might prove irritating: and at the same time depletion is carried on by means of the serous discharge which is produced from that large extent of mucous membrane. There are some cases of inflammation in which the operation of purgative medicines is of especial service; as in inflammatory affections of the head, either external or internal, of which part these medicines assist or cause the depletion in a very sensible manner. We have an illustration of this in the paleness of the face, which often, during health, accompanies the action of a brisk cathartic. The usefulness of repeated purgatives is less distinctly seen in inflammations situated within the thorax; although in these cases also they are often highly beneficial. They are efficient remedies too in all inflammatory conditions of the liver. But when inflammation has fastened upon the stomach or bowels themselves, although it may be indispensable that they should be unloaded of their contents, which are often composed of irritating ill-digested food, and of morbid secretions, no less irritating and hurtful, the propriety of going beyond this point is extremely questionable. I believe that much harm is often done by pressing the inflamed alimentary canal with active purgatives. But to all these points I shall have occasion to return.

Mercury.—Next to blood-letting, as a *remedy*, and of vastly superior value upon the whole, in serious inflammations of various kinds, to purgation, is *mercury.* This mineral is really a very powerful agent in controlling inflammation; especially acute,

phlegmonous, adhesive inflammation; such as glues parts together, and spoils the texture of organs. It is of the greatest importance that you should accurately inform yourselves concerning the various effects of mercury upon the system: the changes it produces; the changes it arrests or prevents; the cases in which it does good; the cases in which it does harm; that you should learn, in short, how to wield a very potent, but a two-edged weapon.

If we inquire what mercury does when it is administered to a person in health, we find three very marked effects following its internal use. They vary, indeed, in different cases, and under different circumstances: but we know that the employment of mercury under any of its usual forms of exhibition is often followed by increased watery evacuations from the intestines; or by an increased discharge of bile; or by an increased flow of saliva; that is to say, it determines (as the phrase is) to certain secreting organs—the mucous membrane of the bowels, the liver, the salivary-glands; it augments their natural secretion; and in this augmentation of secretion is implied an increased afflux of blood to the secreting part. It is probable that mercury has a similar influence on most or all the secreting surfaces of the body, altering the condition of the capillary circulation throughout. And an explanation of its curative power in inflammation has been drawn from this fact: it has been supposed that mercury thus tends to *equalize* the circulation; that by causing the blood to be distributed in larger quantity than common upon *several* surfaces at the same time, it obviates, *pro tanto,* its excessive congestion or accumulation in any one organ. Whether this hypothesis in respect to the *modus operandi* of mercury be true or not, I will not pretend to say; but it certainly is not an unreasonable hypothesis.

If you push this remedy in healthy persons, other effects ensue: inflammation is actually *produced:* the gums become tender, and red, and swollen, and at length they ulcerate; and in extreme cases, and in young children especially, the inflamed parts may perish: the cheeks, for example, sometimes slough internally. Not only the gums, but the throat and fauces, become red, and sore, and sloughy.

Now you will do well to observe what is the *character* of the inflammation thus produced. It is superficial, spreading, erysipelatous: it leads to ulceration without any distinct occurrence of suppuration: the ulcers enlarge. Of the three processes which I formerly pointed out as going on in different degrees, at the same time, in an ulcerated surface, that of absorption is vastly predominant; and you will find that persons in

whom this local affection, this condition of the parts within the mouth, has been produced, get rapidly thin : their fat disappears : they become emaciated. That is, the absorption of the old materials throughout the body exceeds the deposit of new matter. Patients who are kept under the influence of mercury grow pale as well as thin : and Dr. Farre, who has paid great attention to the effects of this drug, remedial and injurious, holds that it rapidly destroys red blood ; as effectually as it may be destroyed by venesection. As an example of this he was in the habit of relating in his lectures the case of a lady who was attacked with hematemesis : her gastric system and her liver were gorged with blood. " Her complexion," said the Doctor, " was composed of the rose and the violet. Under a course of mercury she was blanched, in six weeks, as white as a lily."

There are still other, occasional, effects of the continued introduction of mercury into the system : a peculiar eruptive disease ; a peculiar condition of the nervous system : but with these I do not now meddle ; they will come under our more particular consideration hereafter. At present I am desirous to place such facts before you as may help you to determine in what cases mercury is a fit remedy for inflammation : in what cases it would be improper to give it. The facts I have already mentioned shew that it has a loosening effect upon certain textures; that it works by pulling down parts of the building.

But the great *remedial* property of mercury is that of stopping, controlling, or altogether preventing the effusion of coagulable lymph ; of *bridling adhesive inflammation* : and if we, in our turn, could always bridle and limit the influence of mercury itself, it would be a still more valuable resource.

From the little I have now said you will readily understand in what description of cases mercury is likely to be useful. In common adhesive inflammation, whether of the serous or the cellular tissues ; whenever, in fact, you have reason to suppose that coagulable lymph is effused, or about to be effused, and mischief is likely to result from its presence then you may expect much benefit from the proper administration of mercury ; as an auxiliary, however, to blood-letting, not as a substitute for it.

On the other hand, mercury is likely to be hurtful in those forms of disease " where the morbid action approximates to its own action." In cases of erysipelatous inflammation having a disposition to gangrene ; in scrofulous diseases ; in inflammatory complaints attended with general debility, and an irritable condition of the nervous system,

or a manifest tendency to take on a typhoid character.

When we have to contend with acute inflammation, and desire to prevent or arrest the deposition of coagulable lymph, our object is, after such bleeding as may have been proper, to bring the system as speedily as possible under the specific influence of mercury. How may this best be done ? and how are we to know that it has been achieved ?

I will answer the last of these questions first. We know that the whole system has been brought under the specific influence of mercury, as soon as its effects become even slightly perceptible in the gums and breath of the patient ; and in adults we can't be sure of it before. The gums grow red and spongy ; the patient complains that his gums are sore ; and that he has a metallic taste, a taste like that of copper, in his mouth : and an unpleasant and very peculiar foetor, easily recognised again when it has been once perceived, is smelt in his breath. These symptoms are enough : you need not in general look for any more decided affection of the mouth, such as ulceration of the gums, swelling of the glands beneath the jaw, and of the tongue, and a profuse flow of saliva. Formerly, when it was believed that the material cause of the disease was carried out of the body with the saliva, the mercurial treatment was continued with the view of producing the discharge of many ounces, and even of a pint or two, in the twenty-four hours : but all that is requisite is that the gums should become distinctly tender, and that the mercurial foetor should be unequivocally manifest, and that these symptoms should be kept up for a certain time.

Now this is best effected, usually, by giving some form of mercury in equal and repeated doses, by the mouth. For urgent cases calomel is the best form in which it can be administered : two or three grains, given every four or six hours, will generally suffice to touch the gums in the course of thirty-six or forty-eight hours. If it acts as a purgative its specific effect upon the whole system will be postponed by that circumstance ; and it then becomes expedient to combine it with just so much opium as will prevent its passing off by the bowels. A quarter of a grain of opium with two grains of calomel—or a third of a grain of opium with three or four grains of calomel—will generally be sufficient to restrain the purgative operation of the latter. When a speedier effect is desirable we give larger doses ; such as five or ten grains every three, or even every two hours : or we combine mercurial inunction with the exhibition of calomel by the mouth. It is impossible to lay down any precise rule that will fit all cases.

Blue pill, or the hydrargyrum cum cretâ,

may, in certain cases, be preferable to ca-
lomel; but they must be given in larger
doses. Some practitioners believe that a
combination of blue pill and calomel acts
sooner, and answers better, than a propor-
tional dose of either, given alone.

This mode of giving mercury, so as to
affect the system at large, is eminently useful
in many instances of acute phlegmonous in-
flammation, after bleeding has been carried
as far as the circumstances of the case will
warrant. I repeat that it must not be
allowed to supersede blood-letting. Previous
bleeding renders the body more readily sus-
ceptible of the influence of mercury; and
the operation of the mercury comes in aid
of the salutary effect of the abstraction of
blood. The two remedies accomplish by
their joint power what neither of them could
accomplish singly.

It is important to know that different
persons admit of, or resist, the specific
agency of mercury in very different degrees:
so that in some patients the remedy becomes
unmanageable and hazardous; while in others
it is inert and useless. It is most grievously
disappointing to watch a patient labouring
under inflammation which is likely to spoil
some important organ upon which it has
seized, and to find, after bleeding has been
pushed as far as we dare push it, that no
impression is made upon his gums by the
freest use of mercury. Such cases are not
uncommon; and unfortunately they seem
most apt to occur when the controlling
agency of mercury is most urgently required.
On the other hand, there are persons in
whom very small quantities of mercury act
as a violent poison; a single dose producing
the severest salivation, and bringing the
patient's existence into jeopardy. This his-
tory was told to Dr. Farre by a medical man,
under whose notice it fell. A lady, whom
he attended, said to him, at his first profes-
sional visit to her, "now, without asking
why, or speculating about it, never give me
mercury, for it poisons me." Some time
afterwards she met with the late Mr.
Chevalier, and spoke to him about her
complaints; and he prescribed for her, as a
purgative, once, two grains of calomel, with
some cathartic extract. She took the dose;
and the next morning showed the prescrip-
tion to her ordinary attendant. "Why (said
he) you have done the very thing you were
so anxious to avoid; you have taken mer-
cury." She replied "I thought as much,
from the sensations I have in my mouth."
Furious salivation came on in a few hours;
and she died, at the end of two years, worn
out by the effects of the mercury, and having
lost portions of the jaw-bone by sloughing.

Another medical man informed me that he
knew a person so susceptible of the influence
of mercury, that when his wife had rubbed

a very small quantity of white precipitate
ointment upon her neck for some cutaneous
affection, after sleeping with her his gums
were tender for three or four days, and slight
salivation took place. This did not happen
once only, but three several times. On one
occasion this same man took two blue pills,
as preliminary to a common purge, and he
was salivated profusely for six weeks. Cases
similar to these occur now and then to most
medical men: we cannot tell beforehand in
whom such effects are to be looked for; but
it is never prudent to neglect any warning
which the patient gives of his own previous
experience on this point. You will generally
find that where the affection of the gums and
salivary organs goes on to a troublesome or
distressing extent, it has supervened upon
the employment of a very moderate quantity
of mercury.

So distressing are these effects of mercury
upon the mouth sometimes, that I may
pause a moment to tell you what I know
about the mode of remedying them. You
will constantly be called upon to do some-
thing for the relief of this disease (for so we
must call it), which you yourselves, or some
of your brethren, have with the best inten-
tions inflicted. I have tried all sorts of
expedients, and I have asked a great number
of my friends what are the best means to
adopt in such cases: but I never could get
much satisfactory information from them.
Some thought purging was the best thing.
Others recommended alum gargles; or gar-
gles made of the chloride of soda; and these
last certainly have one good effect, that of
correcting the fœtor. Others believed that
sulphur, which has long been prescribed in
such emergencies, was really of use; and
some advised that the patient should be as
much as possible in the open air: a few
commended iodine. All admitted that they
knew of no certain remedy. Neither do I.
But there are two expedients which I am
confident are often of very great use in
checking the violence of the salivation, and
in removing the most distressing of its ac-
companiments. If there be much external
swelling, treat the case as being, what it
really is, a case of *local inflammation:* apply
eight or ten leeches beneath the edges of
the jaw bones, and wrap a soft poultice
round the neck, into which the orifices made
by the leeches may bleed; and I can promise
you that, in nine cases out of ten, you will
receive the thanks of your patient for the
great comfort this measure has afforded him.
When the flow of saliva, and the soreness of
the gums, form the chief part of the griev-
ance, I have found nothing *so* generally
useful as a gargle made of brandy and
water; in the proportion of one part of
brandy to four or five of water. This last
piece of practice I learned from the present

apothecary to the Middlesex Hospital: I have tried it over and over again; and I tell it to you as a thing worth remembering. These little points are by no means to be despised. A very fashionable and successful physician, now dead, used sometimes to say when he met others of his brethren in consultation, " It is all very well to speculate about the exact situation, and the precise nature of the disorder, but the question with me is, ' what is good for this, that, or t'other thing ?' " A wise physician will seek to concombine with an accurate knowledge of disease, and settled principles of treatment, those practical expedients and minor appliances which are picked up by casual experience ; which could never have been reasoned out ; and which sometimes constitute nearly all that we can do for the benefit of our patient.

But to return to mercury as a remedy against inflammation. It is of great service in many cases of *chronic* inflammation; and I may repeat here the observation I formerly made when speaking of blood-letting—that the treatment must *keep pace*, as it were, with the disease. When textures have been slowly altered by a gradual deposition of coagulable lymph, we should gain but little by suddenly or speedily salivating our patient. The lymph, if it can be dispersed at all, must be *gradually* taken up again : and mercury, given with the view of promoting its absorption, must be slowly and gradually introduced into the system ; and when at length its specific influence is felt, it must be sustained for a considerable length of time.

You must not expect any good, but the contrary, from the exhibition of mercury in scrofulous inflammations ; and where the scrofulous diathesis is well marked, you should be cautious in giving mercury at any time. But I am certain that many men are *too* scrupulous on that head ; and that, through over tenderness of your patient's constitution, you may risk his life, by withholding mercury because he shows tokens of scrofula. You may recollect my stating that scrofulous persons are not exempt from attacks of *common* inflammation ; and in some such cases the probable aggravation of their general ill health is not to be put in competition with the immediate danger from the local inflammation. I have again and again seen scrofulous patients benefited by moderate salivation ; which, if it proved injurious at all to their general condition, was certainly less injurious than the unchecked local complaint would have been.

Antimony.—There are some other remedies for acute inflammation which, in this general account of its treatment, I must briefly notice. Antimony is one of them ; and a very valuable remedy it is in some forms of inflammatory disease. Antimony,

properly administered, subdues the action of the heart and arteries, producing nausea, paleness, and sinking of the pulse, and frequently great relief to the local symptoms. You bring the circulation into that state into which it may be brought by free bloodletting. But when the violence of the inflammatory symptoms recurs again and again, you cannot again and again employ the lancet : and if you do so employ it as at length to extinguish the inflammation, you reduce your patient to a state of pitiable, and even perilous, debility. Now you may continue or repeat the depression of the circulation by means of antimony, without any dread of such subsequent weakness. Antimony, as far as my own observation goes, is admirably suited to cases of active inflammation, in which mercury would either be not so useful, or could not be brought to bear. It is in inflammation of the mucous membrane of the air passages that antimony is so signally beneficial. You will see a patient labouring for breath, unable perhaps to lie down, with a turgid and livid countenance from imperfect arterialization of the blood. He has been ill but a short time; it is an acute affection ; and upon listening at his chest, you hear that peculiar wheezing sound which we call *sibilus*, in every part of his lungs. I shall have to describe this sound, and its causes, and its meaning, in a future part of the course. You give such a patient repeated doses of antimony; he becomes sick, vomits perhaps, but he feels nausea; his pulse becomes less forcible, his face grows pale, and he can breathe again. The nausea is not a pleasant sensation ; but the want of breath is a far more distressing one; and that is greatly mitigated. Perhaps a free secretion takes place from the congested membrane, and then the patient is easy and safe. Now you could not effect this change so quickly and readily, or so conveniently, by mercury, and perhaps not at all. Bronchitic affections are very common in children, in whom it is usually difficult to induce the specific influence of mercury.

On the other hand, antimony does not appear to be nearly so valuable a remedy as mercury, when serous membranes are inflamed.

The French and Italian physicians place much reliance upon antimony for the cure of inflammation ; and they seem to know little or nothing of the remarkable agency of mercury upon that disease. For my own part I do not see how any useful *comparison* can be made between these two substances in respect to inflammation, considered generally, as we are now considering it. There are some particular forms of inflammation to which the one remedy is better suited, and

there are others in which the other is most effectual. I must content myself with having adverted to these distinctions for the present.

As to the form in which the antimony should be exhibited, I apprehend that we shall all come at last to freshly dissolved tartar emetic. The antimonial powder is of very uncertain strength ; and the antimonial wine contains too much spirit to allow of its being given in large and frequently repeated doses. It is a curious circumstance, that although vomiting and purging are apt to be produced by the first two or three doses, they usually cease when the same quantity is persevered with. *Tolerance* of the remedy is produced. But although these unpleasant primary effects cease, the curative agency of the antimony appears to continue. When you desire to obtain its full influence in a short time, you may dissolve a grain of the tartar emetic in two ounces of hot water ; and give a fourth-part of the solution every half hour. If the patient becomes pale and sick, you pause a while and allow him to recover himself ; and if the inflammatory symptoms return, you repeat the medicine. It sometimes acts violently upon the bowels, and then it will be necessary to add a few drops of laudanum to each dose.

Digitalis.—Digitalis is another powerful medicine, from which much was at one time hoped as a remedy for active inflammation ; but those hopes have been in a great measure disappointed. It is not a manageable remedy in such cases. Its singular property of retarding the circulation, of bringing down the number of the heart's pulsations, and abating its force, led to the expectation that it might render the use of the lancet unnecessary ; that it might check the inflammatory process without permanently reducing the strength of the patient. But if you give moderate doses of digitalis, its peculiar effect upon the pulse comes on at very uncertain periods, and may be postponed until it is too late to be of any service. If, on the other hand, you give it in such quantity as speedily to affect the heart's action (which is what we want in acute and serious inflammation), then you are never secure against what may be called its poisonous effects : deadly faintness, frightful syncope, and even death itself. Most practitioners can tell of cases in which patients, who were taking full doses of digitalis, have suddenly expired ; and when the remedy has appeared to have had more to do with the fatal event than the disease. There are practitioners, however, and I know one of them, who affirm that digitalis may be given, after due depletion, and in acute inflammation, in very large, and I should say startling doses, with the very best effects— doses which range from half a drachm to half an ounce, and even six drachms of the officinal tincture. I confess to you that I

should be very unwilling to sanction this mode of using digitalis. I never attempt to employ it with the view of knocking down acute inflammations—to which alone you will observe that my present remarks apply. Digitalis is often of great service in other complaints ; but I am not at present discussing the remedial virtues of digitalis, or of any other drug, except so far as they relate to the cure of recent and active inflammation.

Colchicum. — Colchicum is a remedy which is often prescribed in inflammation. It is a most valuable remedy in certain *specific* forms of inflammation. But for repressing common phlegmonous inflammation we have much more certain and better remedies. For this purpose colchicum is, I believe, a very unimportant medicine.

Opium.—I have formerly been asked, by students attending here—and therefore I anticipate the question now—respecting the utility of *opium* as a remedy in inflammation. Certainly opium, like most of our powerful medicines, may do much good, as it may do much harm, in different inflammatory diseases ; and it is not very easy to point out clearly, in a general view of the treatment of inflammation, the rules for its administration by which we must be guided in different cases. Yet there are a few general observations which I may make now on this subject.

The administration of a full dose of opium has been strongly recommended after that free and effective bleeding which I have already described. It prevents the rekindling of the inflammation which is apt to result from irritation of the nervous system— a kind of irritation, you will remark, which the copious abstraction of blood is calculated to produce ; or to augment, if it finds it already existing. The opium soothes this nervous irritability ; and it must be given, when given at all, in doses that will have that effect. It is best adapted to those cases in which a natural irritability is inherent in the constitution of the patient—to those in which such irritability has been acquired by bad habits of life—and to those in which the local disease is attended with much *pain*, which is in all constitutions a source of irritation.

However, this is a remedy which requires to be used, in inflammation, with great caution and discrimination. In cases of active inflammation within the cranium, its propriety is very questionable. It is apt to confuse both the patient and his physician, who is unable to say, after a full dose of opium has been given, how much of the stupor that follows is owing to the disease, and how much to the drug. It is a very ticklish remedy in pectoral inflammations. I believe that by the free use of opium I

saved the life of a relation of my own, an old lady, who was in danger of being worn out by the cough and bronchial affection which attended the influenza. On the other hand I have certainly known more than one person, labouring under extensive and severe bronchitis, so effectually quieted by a dose of the same medicine, that they never woke again. As a general rule I should say that you should be very careful how you venture upon opium in inflammatory diseases that tend to produce death by *coma*, or *apnœa*. If there be any unnatural duskiness of the face, if ever so slight a tinge of purple mingles itself with the red colour of the lips, this is an appearance which should warn you against opium. It shows that the blood is imperfectly arterialized; and imperfect arterialization of the blood, as I hope you all know now, either results from, or conduces to, a state of coma.

On the other hand, it is, *cæteris paribus*, in cases where the tendency is towards death by *asthenia*, that the use of opium, as a remedy for inflammation, is most serviceable. It has a capital effect often, after free bleeding, in cases of peritonitis, and of enteritis. It probably does good in various ways : by quieting the nerves — by sustaining the faultering action of the heart—by keeping the inflamed parts at rest. There are some frightful accidents in which we can expect little from blood-letting, but in which the judicious employment of opium affords some glimmering of hope. I allude to those cases of intense and general peritonitis which arise upon the escape of irritating substances into the cavity of the belly ; the contents of the intestines, from ulceration, or from external injury ; urine from rupture of the bladder ; and so on. If there be any hope for such cases, it is to be found in the continued exhibition of opium in considerable doses. But upon all these points I shall go more into detail when we come to consider individual diseases.

External remedies.—A very few remarks, in respect to external remedies in cases of inflammation, will terminate both this lecture and what I have to say, thus generally, of the treatment of inflammatory complaints.

Cold.—The application of external *cold* will aid us very powerfully, in certain serious cases of inflammation ; and especially in cases of inflammation within the cranium. It is really wonderful what a sedative and soothing effect this expedient frequently has in allaying delirium, the result of active inflammation of the brain and its membranes. Thin folds of linen, kept constantly moist and cold, by cold water, are placed upon and around the shaven head. We often apply ice in the same way. But I need not go at present into any detail on this subject : I

will only observe, that we have a most excellent and simple guide as to the probable usefulness of cold applications to the head, in the *sensations* of our patients. It is very lucky that it is so. As long as the cold cloths, or the bags of ice, are pleasant and grateful to the patient, so long we sedulously continue to apply and renew them : as soon as the patient dislikes them, they had better be intermitted.

Cold applications to the *chest*, and to the *belly*, in active inflammation of parts situated within those cavities, have been praised by some practitioners ; but I believe are very seldom employed. I have no personal experience either of their utility, or of their hurtfulness. I confess that I should not like to use them. I should think that the effect of the cold, in driving the blood from the cutaneous vessels, and accumulating it in internal parts, would be likely to be injurious. We shall see, by and by, that the contents of the skull are differently situated, in this respect, from those of the thorax and abdomen.

Warmth.—The totally opposite measure, applying *warmth* to the surface, is of very great service in many cases of internal inflammation : especially in inflammations of the abdominal organs. We speak of cold *lotions*, and of hot *fomentations*. These last are managed in various ways, which I do not at present enter into. They seem to do good by determining to the surface ; they promote perspiration ; they mitigate pain, and persuade to sleep.

In cases of *external* inflammation, sometimes cold and sometimes warm applications are found to be of use. In this matter also the sensations of the patient afford the best criterion. Both of them tend, in different circumstances, to promote resolution. We have an illustration of the beneficial agency of cold applications for this purpose in the treatment of recent burns and scalds, particularly when the injury is superficial, and the skin has not been destroyed. Probably there is scarcely any one present who has not experienced the relief given to the *pain* of a burned finger, by dipping it in cold water ; and the return of the pain upon taking the finger out again. The cold may be so constantly applied that the pain will cease to recur when the application is at length suspended. Dr. John Thomson relates a case in which a burned arm was kept immersed in cold water for two days and two nights incessantly ; and the inflammation was thereby wholly prevented. I have known this expedient fail, however. A nurse in the Middlesex Hospital fell as she was carrying a pail of hot water upstairs, and in her fall thrust one of her arms into the scalding liquid. Without loss of time she plunged

the same arm into cold water ; but after a while was obliged to desist ; the cold immersion bringing on severe rigors.

In erysipelas, I am persuaded that warm fomentations not only afford more comfort, but are more effectual and safer than cold lotions.

Independently of their occasional influence in promoting *resolution*, warm applications, warm soft poultices for instance, are often used with the view of forwarding *suppuration*. Hence this rule. Whenever resolution of the inflammation is *possible*, but suppuration is *likely* to ensue, warm applications are the most proper : because under their use we have an equal chance of obtaining resolution, with less hazard of retarding, or rendering untoward, the process of suppuration, in case resolution does not take place.

Counter-irritation. — *Counter-irritation*, by means of blisters, sinapisms, irritating ointments, setons, issues, or moxas, is often very beneficial. It probably operates by attracting blood into the neighbouring parts, and in the same degree diverting it from the inflamed part. It is most serviceable in chronic inflammations, and towards the decline of those which are acute. It is particularly adapted to scrofulous affections. There is an objection to the use of counter-irritation during the height of the inflammatory fever, on account of the increase of general irritation which it would then occasion. Neither in local inflammation should counter-irritation be applied *very* near to the inflamed part. Blisters are not proper, therefore, at least in the early stages of the disease, in acute inflammation within the cranium ; but they are sometimes applied in such cases, with advantage, to the lower extremities. Blisters to the chest, however, in thoracic inflammation, and to the belly in abdominal, are often not only perfectly safe, but of the greatest use, as will, I trust, be apparent, as we go on.

NEW OPERATION FOR LATERAL CURVATURE OF THE SPINE.

To the Editor of the Medical Gazette.

Sir,

As the new operation for lateral curvature of the spine, which you did me the honour of inserting in your journal of 27th ult., appears to have excited some interest in the profession, and to have directed attention to a branch of surgical practice which has long been neglected, a few further observations on this important subject may not, perhaps, be deemed unacceptable.

The result of the operation above alluded to has in every respect realized my most sanguine expectations. The spine, which previous to the operation suffered a deviation of at least three inches from the mesial line of the back, involving the six superior dorsal vertebræ, is now reduced to within half an inch of its natural situation, the right shoulder has fallen on a line with its fellow, and the muscles on the *concave* side have acquired a considerable increase in bulk. The breathing, which before the operation was difficult and impeded, is now perfectly free, the chest expanded, and nearly restored to its natural shape. Amongst the changes that have taken place in the state of the back, the sacro-costalis and longissimus dorsi muscles on the *concave side*, which before were scarcely perceptible, can now without difficulty be traced from their origin to where they pass beneath the trapezius and rhomboid; evidently shewing an increase of activity, and a corresponding development of muscular structure.

On the Monday following the above, Nov. 30th, I operated on another lad, 16 years of age, who had been affected with lateral curvature upwards of four years : the convexity in this case was towards the left side, and extended from about the fifth to the tenth or eleventh dorsal vertebræ, being precisely that condition of curve which I have described as the second stage of this complaint. There was considerable excurvation of the ribs on the right side ; those on the opposite being much depressed. The left shoulder was slightly elevated, and the right hip projected ; the chest had undergone great alteration in shape, and the functions of the lungs were impaired. The sacro-costalis muscle on the *concave* side was much larger than its fellow, and was seen passing from its origin up to the centre of the curve—evidently a counteracting agent to any further deviation of the spinal column, and which from thus acting had suffered considerable enlargement.

This operation was performed in a manner precisely similar to the former, and the results have been just as satisfactory. I should remark that the lad was left-handed, and although his occupation was light, being that of a cigar-maker, yet he had been in the habit of lifting heavy weights occasionally with his left hand.

The displaced vertebræ, with the ex-

ception of two, have in a very gradual manner regained their situations; the ribs are losing their rounded or barrel-like form, and the back itself now scarcely bears any trace of deformity. He has increased in height since the operation.

My next case was a delicate female of six-and-twenty, who had been affected with lateral curvature of the spine ten years; her occupations were sedentary. She regards the curvature as a consequence of close application to a piece of embroidery she was anxious to complete when about 15 or 16 years of age. From the habit of sitting some hours at a time before the frame, with the right hand above and the left beneath, a lateral inclination was given to the spine, which in a very short time increased to the extent it was when she applied to me. On examining the back I found the deviation to extend from the fifth cervical to the seventh dorsal vertebra on the right side, not in the form of a simple lateral curvature, but directed outwards and backwards—*postero-lateral.* The ribs formed a most singular appearance, being flattened at the sides, with their angles projecting in the shape above mentioned, much in shape like a mower's scythe, whilst the points of the false ribs appeared almost protruding through the abdominal integuments. The spine below the seventh dorsal vertebra was perfectly straight; the left side was much contracted, but scarcely any projection of the hips. By bending the body forwards I could distinctly trace the sacro-costalis muscle, stretched like a tense cord through its whole course, and the longissimus dorsi, as far as the greatest point of the convexity of the curve, was full and firm; beyond this it was lost.

The trapezius and rhomboid muscles of the left side differed materially from the preceding cases, for beyond the point alluded to scarcely any trace of muscular substance existed. The same appearances were exhibited on the left side as I have witnessed in the generality of these cases, and the muscles appeared thin and weak throughout their whole extent.

Reflecting on this case I found no difficulty in satisfying my mind as to the side on which the division of muscles should be effected. The trapezius and rhomboid muscles had never been

thrown into considerable action, nor was it at all apparent that they had any influence in producing the curve; on the contrary, they were attenuated and weakened.

On Saturday, Nov. 28th, she underwent the operation. Directing the patient to bend forward, I passed a narrow curved bistoury beneath the external edge of the sacro-costalis muscle, on a line with the last dorsal vertebra; and carrying it inwards and downwards until it reached the transverse process, I depressed the handle, and gradually withdrew the bistoury, making a complete section of the muscles without wounding the integuments, a powerful retraction took place, leaving a space of at least half an inch between the divided edges. Immediately on withdrawing the bistoury a gush of blood followed, which was easily suppressed by pressure. Up to this time the patient has not had a bad symptom: the wound suppurated, a circumstance I should by no means regard as unfavourable, inasmuch as it prevents too early an union of the divided surfaces: it has now healed. Although I operated on this case by the urgent request of the young lady, yet I did so with faint hopes of success. I am happy to say the results have far outstripped my expectations: the displaced vertebræ are gradually moving towards the mesial line of the back; the left side much less contracted; and the ribs no longer form that projection in front of the abdomen. She has increased an inch and a half in height since the operation.

In the subsequent treatment of these cases I have employed extension by means of pulleys, the head being made a fixed point, whilst cords were attached to a circular band round the hips. This cannot be ventured on till the seventh or eighth day after the operation: in my first case I recommended it on the fourth day, but was compelled to discontinue it.

The position in which the patient lies should be a matter of great moment for the first three days subsequent to the operation: the prone position is the best: after that period it should be changed, and a folded pillow placed in apposition with the dorsal curve, and in such a manner that the patient lying on her side, with the upper and lower portion of the trunk bending over it,

the intercostal muscles on the opposite side are kept upon the stretch, and the ribs separated from each other. The patient should then be induced to grasp with his left hand a rope suspended from the ceiling, and at such a distance from the body as to keep the rhomboid and trapezius on the stretch, and at the same time endeavour to bring the arm to the side: by this latter movement these muscles are thrown into a state of activity. This should be repeated frequently during the day.

I must beg leave to correct an error I have fallen into in my former letter. In alluding to the case, I observed, that in the curvatures that are met with amongst young children and delicate females, the muscles on the *concave* side acquired an increase of action, whilst those on the opposite suffered a loss of power. I am now convinced that this increase of thickness, which is sometimes observed, has no effect whatever in producing the curve, but, on the contrary, is the result of a continual effort to draw the spine towards the mesial line of the back, as was instanced in the second case I operated on. A lateral inclination is first given to the spine, either by certain occupations of life, in which the trapezius and rhomboid become inordinately acted upon, or by certain bad habits acquired in the siting or standing posture: the sacro-costalis and longissimus dorsi, below the convexity, become shortened, as a secondary result, and in conjunction with the above mentioned muscles resist every attempt to reduce the spine to its original position.

I can easily conceive, were these muscles (the sacro-costalis and longissimus dorsi) free in their whole extent, from their origin to their insertion, lateral curvature might be induced by approximating their points of attachment, bearing the same relation to the spine that a string does to a bow: such not being the case, it must be assumed by the abettors of this doctrine that the muscles acquire an irregular power of contraction, that a predominance of muscular power exists in their external division, whilst the internal, attached by means of strong tendons to the tranverse processes of the vertebræ, are in a passive or weakened condition. Mr. Bamfield, in alluding to this subject, has observed, that he has never met with a case in which the shorten-

ing was on the concave side of the curve, but that by dissection he has always found these muscles smaller and weaker.

As to the situation of the primary curve, there can be no doubt in the minds of those who have had an opportunity of seeing these cases in their earlier stage, the dorsal vertebræ being in a majority of cases the first to suffer displacement.

I am happy to find from Mr. Laycock's communication last week, that he has adopted views similar to myself respecting the class of muscles to be divided: it would be interesting to know the result of his late operation. Respecting our priority of claim, I am unwilling to arrogate to myself any unmerited position, not forgetting the old latin adage " Palmam qui meruit ferat."—I am, sir,

<div style="text-align:right">Your obedient servant,
G. B. CHILDS.</div>

ON THE TREATMENT

OF

CERTAIN DISEASES OF THE BRAIN,

By E. COPEMAN, Esq.

[*For the Medical Gazette.*]

</div>

THERE appears to have been of late a considerable though gradual change in the views of some eminent members of our profession respecting the pathology and treatment of certain disorders of the brain and nervous system. The subject, it cannot be denied, is one of the greatest importance that can occupy the attention of the medical world; and it seems desirable to place upon record any facts that may tend to elucidate the real nature, and proper treatment, of maladies so frequently terminating in death. For a long time it has been held that apoplectic and paralytic seizures are caused by pressure upon the brain or spinal marrow, or by organic and incurable disease of those nervous centres; and this doctrine of congestion, and pressure from loaded vessels, or consequent serous effusions, has led to the almost indiscriminate practice of free blood-letting, as the most likely means of saving the patient. In my own limited experience I have several times observed that

bleeding in apoplectic and paralytic attacks has been followed by very unsatisfactory results; and the excellent remarks published by Drs. Holland, Griffin, and others, have convinced me that it is safe and right to employ other means of relief, and better not to rely upon the indiscriminate use of the lancet.

The following cases are offered under the idea that they may, in some slight degree, confirm this opinion, and contribute towards throwing light upon this very imperfectly understood branch of the science of medicine.

Case I.—*Apoplexy occurring three times in the same individual.*

On the morning of the 18th of January, 1839, I was summoned in haste to a gentleman residing at a short distance from my house, who had been attacked with slight vertigo, and confusion of thought, whilst dressing. He was advanced in years, being upwards of seventy, and had spent great part of his life in India; he was low in stature, corpulent, and short in the neck. He had long been accustomed to high living, and had been the subject of chronic inflammation of the air passages. Not many months before the present attack I removed two polypi from the nose, and, until within a very short period, he had profuse muco-purulent discharge from one nostril.

I found him complaining of giddiness, and his conversation was incoherent—pulse excited, but not very full; tongue furred; slight pain in right temple. I immediately drew about sixteen ounces of blood from the arm, and administered purgative medicines. He was slightly relieved by the bleeding, but in the course of the day he almost lost the power of expressing himself, his memory failed, and he was scarcely able to stand alone. I requested a consultation, and in the evening met an experienced practitioner from Norwich, who advised cupping: this was performed in his presence, and before many ounces of blood could be drawn, the patient had a convulsive start, became faint, and it was feared a paralytic seizure was at hand. The cupping was immediately discontinued, and he was removed to a warm bed. He took

Pil. Hyd., gr. v. at night, and had a blister applied behind each ear.

19th.—His mental faculties very much confused; quite unable to express himself intelligibly. Slept tolerably during the night; pulse languid; tongue furred; bowels open.

Capt. Haust. Salin. t. d.

20th.—In much the same state. He made frequent attempts to speak, and ap-

peared to know what he wanted, but I could not make out a word. It seemed to me that he might be speaking Hindostanee, or some Indian language that he had been accustomed to in former days; but his lady, who had also lived in India, could not at all understand him.

Ordered a large blister to the nucha, and Haust. Salin. t. d.

21st.—Slept well. Pulse soft and languid; bowels acting. Has taken no food, except gruel and thin broth, at present.

Cont. Haust. Salin.

24th.—No particular alteration occurred till this morning, when he made me understand that he felt sick, and had pain in the forehead. He could not recollect the name of any thing or person—for instance, the name of the gentleman who met me in consultation on the 18th—but he had some slight remembrance of the circumstance.

A blister to the temple. Blue pill and rhubarb at night.   Draughts as before.

25th.—Pain removed from the forehead. Bowels free; tongue cleaner; pulse soft. More generous diet allowed.

It is not necessary to enter into all the details of this case; suffice it to say that as his general health improved he regained the power of language; the first indication of this, which I observed, was his asking me, at one of my visits, for some water, in Latin: he could not then recollect the English name of it. He each day improved in this respect until he could speak tolerably well. His memory, however, remained feeble; his eyesight, particularly in the right eye, was imperfect, as if the retina were partially paralysed; and owing to this failure of sight, coupled with an incapability of directing his attention to any particular object for even a very short time, he found it impossible to write, or to attend to any business whatever. His hands also were tremulous, and the whole muscular system weak and unsteady, perhaps from not being sufficiently controlled by his debilitated brain.*

Several months elapsed before he appeared to be much stronger; but at length his eyesight was restored, and his faculties in general became more perfect. His digestive organs were kept in order by small doses of blue pill and rhubarb, and saline draughts. In July he left home on a visit of some weeks' duration to some friends in a distant

* Dr. Marshall Hall, in a memoir on the Nervous System, published in the twenty-second volume of the Medico-Chirurgical Transactions, observes that in cerebral paralysis the irritability of the muscular fibre becomes augmented for want of the application of the stimulus of volition; and that the cerebrum is the exhauster, through its acts of volition, of the muscular irritability.

county; and on his return might be said to have quite regained his usual state of health.

The impression, at the time, as to the nature of the attack, was, that it was a case of threatened apoplexy, mitigated by the early adoption of antiphlogistic measures; that effusion had taken place, and that the gradual amendment in the patient's health was probably consentaneous with the absorption of the effused fluid, and consequent removal of pressure from the brain. From what I have witnessed in the subsequent attacks about to be related, I now believe it to have been nothing more than sympathetic functional disorder of the brain, from disturbance of the digestive organs; and that the slow recovery was owing to the debility caused by abstraction of blood.

On the 5th of November, in the same year, my attendance was suddenly required by the same gentleman under the following circumstances:—About three hours after a heavy dinner, he appeared to his family to be a little confused in his speech, asking for the same things several times over, and then forgetting what he had said. I was quickly on the spot, and found his manner hurried and confused; his tongue furred; his pulse languid and feeble. His friends urgently requested me to bleed him, but considering the state of the pulse, I recommended in preference a purgative dose of medicine, and with some difficulty persuaded them to allow the bleeding to be deferred for the present. He took directly a calomel powder and a strong senna draught. About half an hour afterwards I was again summoned in a great hurry: after having taken his medicine he had been assisted up stairs, but as soon as he had seated himself in his easy chair he groaned, and fell forwards insensible upon the ground. I found him lying on the floor in profound apoplexy. Stertorous breathing; cold skin; face covered with cold perspiration; great insensibility; pulse very small and feeble; no convulsive movements. Some remarks were made reflecting upon my not having bled him on my first visit, inferring that if I had done so I might probably have prevented the fit; and in accordance with the wishes of the attendants I now opened a vein, but, as might be expected from the state of the pulse, not more than an ounce flowed. We then put his feet in hot water, applied strong hartshorn and aromatic vinegar to the nostrils, and endeavoured to make him swallow a little brandy and water, for I thought he was rapidly sinking, and would not live half an hour. The hartshorn at length caused a convulsive sigh, and by applying it most assiduously he was roused sufficiently to open his eyes, and raise his hand to his nose as if to prevent the further application of the stimulus; it was however persevered in, and shortly after he showed signs of returning consciousness; in a few minutes he became sick, and vomited the largest quantity of ingesta I ever saw rejected from the human stomach. The vomiting continued at intervals for a quarter of an hour, and roused him still more, so that he was able to recognise persons in the room, and to make inquiries as to what had been the matter; he said he felt very weak and ill, and we soon got him into a warm bed. An hour afterwards he was able to answer questions readily, and expressed himself extremely desirous of getting sleep. Gave a small quantity of brandy and water.

6th —Slept comfortably in the night; pulse quiet; skin perspiring; tongue furred; no complaint of languor and sickness. Took blue pill and rhubarb and senna draught during the day, which acted freely on the bowels. Could bear but very little muscular exertion; breathing easy; slept frequently during the day.

7th. — Passed another good night, and awoke refreshed. Took a little tea and toast. No sickness nor headache.

Cont. Haust. Sennæ.

The next day he was down stairs, conversing cheerfully with his family; took gruel, meat, broth, and pudding. Kept bowels free with senna draughts. I continued to see him daily till the 12th, when he was so well that I discontinued my attendance. Ten days afterwards I called again, and found him remarkably well, able to walk about his grounds, and to take drives in his carriage without fatigue. No dimness of sight or paralytic affection occasioned by this attack.

On the 30th of May, 1840, about eight o'clock in the morning, this gentleman had another fit. He was seized with giddiness as he was coming down stairs, and shortly after he fell back in his chair insensible, his head dropping forwards upon his chest, and his face covered with cold perspiration; breathing stertorous, with discharge of frothy saliva from the mouth; loss of muscular power in the limbs; skin rather cold; pulse languid and labouring. A very few minutes elapsed before I arrived, and his lady pressed me much to bleed him forthwith, having already prepared bandage, basin, &c., for the purpose; but my experience of his former attacks, and a knowledge of his having been at a dinner party the evening before, determined me not to bleed; and although the number of hours which had elapsed since food was taken seemed to point out that vomiting was not so likely to afford relief as in the second attack, which occurred soon after a meal, yet I resolved to empty the stomach; and having applied strong hartshorn to the nose to rouse him, managed to pour down his throat a draught of senna, containing a

scruple of Ipecacuan powder. His feet were put in hot water. In about a quarter of an hour he appeared gradually to regain his consciousness, and asked in a hurried manner whether he had been ill. He said he felt sick and must go to bed, but he was not allowed to move. He soon began to recognise his attendants, and asked them what was the matter. Whilst sensibility was thus returning, and before vomiting commenced, a curious phenomenon occurred. He was sitting with his head resting upon his hand, and his elbow supported by the arm of the chair; and whilst in this position he had frequent twitches of the trapezius muscle, pulling the head towards the shoulder. I observed at the same time similar convulsive movements, synchronous with the former, of the rectus externus oculi, turning the eye towards the outer canthus*. After he had vomited these twitches ceased, and the powers of the brain seemed much restored: he vomited a second time, and then appeared perfectly sensible of every thing that was passing; breathing became natural; took some aperient pills and senna draught, and lay in a recumbent posture on a sofa. The medicine soon acted powerfully upon the bowels, and in a few hours he was sufficiently recovered to read a letter written in a rather illegible hand. In a few days he was quite well, and has remained in good health to the present time.

CASE II.—*Hemiplegia cured without bleeding.*

Mrs. S., a farrier's wife, æt. fifty-eight years, thin, but active and industrious, experienced a numbness in her left hand whilst preparing dinner for her family, which prevented her holding what she was using at the time. This occurred about noon, on the 23d of January, 1840, and was quickly followed by darting pains in the right temple. Feeling very unwell, she managed to get up stairs into her bed-room, and almost immediately lost her speech and the use of the left leg and arm. She had for some weeks previously felt occasional pain and numbness in the left forearm, which she considered to be rheumatism, and scarcely worthy of notice. I saw her at 3 P.M., and found her sitting in a large easy chair, with the following symptoms:—left cheek partially paralysed, and mouth drawn to the opposite side; articulation very imperfect; pain in right temple, but less severe than at first; left arm hanging by her side quite

* This occurred during nausea, and before the brain had regained its natural powers. Was it not produced by the state of the stomach influencing the spinal accessory, and the sixth nerve, through the medium of the par vagum and great sympathetic? It ceased as soon as the brain recovered, and the equilibrium of the nervous system was restored.

powerless; left leg imperfect in its movements, but not quite paralysed; pulse feeble and indistinct; skin cool, with a tendency to shivering; nausea, and a sensation of faintness. Before I saw her she had swallowed with difficulty a little wine and water, and felt the better for it. The first question was, " Won't you bleed her as soon as possible?" I did not feel disposed to accede to this: but, from the depressed state of the system and cold surface, in preference administered a little more warm wine and water, and got her into a warm bed, with the head and shoulders a good deal raised.

Applic. Empl. Lyttæ Ampl. Nuchæ.

R Magn. Sulph. ʒvj.; Inf. Sennæ, ʒvj.: Dec. Aloes, c. ʒij.; Tr. Jalap c. ʒij.; Tr. Hyos. ʒj.; Syr. Rhamni, ʒss. M. cochl. larg. iij. 2dis horis donec alv. bene respond.

11 o'clock P.M. — Rather drowsy, but easily roused; breathing quite natural and easy; pulse 72, and soft; skin warm; speech less imperfect; left leg less powerless; pain in the forehead intermitting; says she feels more comfortable in every respect; blister drawing; bowels not yet relieved.

Cont. Mist.

24th. — 7 A.M.   Slept quietly several times for about an hour, without dreaming; had taken all the mixture, and swallowed the last dose without difficulty; skin warm; pulse 72; bowels acted powerfully three times; vomited once; can move the leg freely, and, to my astonishment, moves the forearm in the directions of flexion, extension, and rotation, to some considerable extent. I had intended to apply leeches to the right temple this morning, but the pain had so much abated that I postponed it for the present. Takes gruel, tea, and milk.

R Magn. Sulph. ʒss.; Dec. Aloes, c.; Inf. Sennæ, aa. ʒij.; Tr. Hyos. ʒj.; Aquæ, ʒij. M. Cochl. larg. ij. 4tis horis.

9 P.M.—Much inclined to sleep, but quite sensible and collected when awake; pulse 60, regular, and soft; skin moist; can lift the left arm out of bed, and, when sitting up in bed, can raise her hand to the top of her head, but says the elbow feels heavy; urine scanty.

Cont. Mist.

25th. — Found her dressed and sitting up in an easy chair; can walk about the room, and move the arm almost without difficulty; no vertigo; pulse 72; bowels open; no drowsiness; very little distortion of the mouth.

26th.—Rather more pain in the temple, for which a blister was applied behind the ear.

Cont. Mist.

27th. — Blister drawn well, and pain in forehead removed; tongue milky; complains of slight numbness at the ends of the fingers, and feels languid.

℞ Inf. Gentian; Dec. Aloes, c. aa. ʒiv. M. Cochl. larg. ij. t. d. To take mutton broth with bread.

29th.—Improving; sits up several hours, and walks about the room.

Cont. Mist.

31st.—Complains of languor and faintness; tongued furred; pulse quiet.

℞ Quinæ Sulph. gr. viij.; Acid. Sulph. dil. ʒss.; Inf. Gentian, c. ʒviiss.; Syr. Zingib. ʒss. M. Cochl. larg. ij. t. d.

Feb. 2d.—Bowels not sufficiently relieved; ordered a wine glassful of the first aloetic mixture every morning; tongue covered with yellowish fur, but has proper taste, and relishes food; can move the limbs freely; no distortion of the mouth. To remove the fur from the tongue and improve the secretion, to take a small dose of blue pill and rhubarb every night, and continue the quinine mixture.

14th.—Tongue clean.

Sumat. Pil. noct. ter in hebdom. Cont. Quin.

Gets down stairs daily.

May 4th.—This patient has been gradually improving, and is now able to resume her duties as mistress of the family. The left arm is still weaker than the other, and will not bear prolonged exertion; but she can sew, &c. with considerable facility.

August.—Health good; takes no medicine but an occasional aperient.

Case III.—John Took, æt. sixteen years, a strong farming lad, was taken suddenly ill after a club feast on the 6th of June, 1840. My assistant saw him at 10 P.M. He was alternately drowsy and delirious, and could not be made sensible of what passed around him. Pulse small; extremities cold; head and face hot and flushed. Ordered purgatives, and mustard poultices to the feet. Next morning more flushed in the face, and comatose, but pulse still very small and compressible. Could not be made to swallow his medicine; and was very boisterous when roused. This was the report given me by my assistant, who thought he ought to have bled him, but was afraid to do so from the state of the pulse. I recommended a large blister to the nape of the neck, and a purgative clyster. At night I went to see him, and found that after the blister had been on a few hours he fell asleep, and had remained quite quiet till about an hour before I arrived, when he became sensible, dressed himself, and said he did not recollect anything about being ill. When I saw him he was down stairs in a chair, and talked cheerfully

and rationally. Skin warm, especially about the head; although he said if he went near the door he was inclined to become chill. Pulse rather full. Drew about eight ounces of blood from the arm, and gave aperients. Next day much better; no disturbance about the head; bowels well relieved.

9th.—Out for a walk when called upon, his friends stating that he was quite well again.

Case IV.—A young man was attacked on the 10th of June, 1840, with the following symptoms:—He had been employed all the previous day and night serving customers with beer, &c., at a public house where a club feast had been held. He dined with the club, ate heartily, but did not drink much beer. Early in the morning he was employed to cart faggots, but felt unwell, and was sick before he began. After working a short time he was seized with pain in the back and the pit of the stomach, and was obliged to be carried home. A surgeon, who chanced to be near, bled him and gave him salts. I saw him about an hour after the bleeding: he was become very drowsy; face flushed; pulse round and soft; surface warm; breathing easy. Attendants said he had complained much less of pain since the bleeding; but when I roused him he complained of pain in his stomach. I requested him to rise up in bed, which he did very slowly, and with difficulty; but when up could make a full inspiration without pain. Fell into a doze again as soon as left to himself. I thought it possible that his drowsiness might be the consequence of fatigue, and therefore did not repeat the bleeding. In about two hours his father came to tell me he was quite insensible, and could not speak; was very hot, and frequently rolled his eyes about.

Ordered a large blister to the pit of the stomach, and senna and salts every three hours.

11th, A.M.—Still very drowsy, and difficult to rouse. Skin warm; pulse feeble. Warm bath, after which the bowels acted for the first time.

12th.—Sensorium much oppressed; eyes frequently half opened, turned upwards, and moved from side to side. Pulse large, and inclined to double beat: perspiration profuse about the head and face: bowels not open. Cut his hair off, and applied vinegar cloths to the head. Roused him sufficiently to make him swallow half an ounce of castor oil, the taste of which greatly displeased him, and he afterwards complained of being sick.

Empl. Lyttæ Ampl. nuchæ. Mist. Sennæ 4tis horis.

13th.—Answers questions much more readily than yesterday, and says he is quite free from pain. Blister drawn well. Head cool, still covered with wet cloths: pulse 72,

regular. Still doses when left alone. Bowels not open.

Adhib. Enema. Pil. purgant. ij. 4tis horis.

15th.—Bowels well relieved. Convalescent.

CASE V.—Mrs. W, æt. fifty-eight, a lady of nervous temperament, and rather full habit, the mother of a large family, was seized, whilst at work in her garden, on the evening of the 14th of June, 1838, with numbness and loss of power in her left leg, which, after a few minutes, increased so as to oblige her to fall to the ground. The day was warm, and she had exerted herself sufficiently to cause profuse perspiration. With a little assistance she was soon sufficiently recovered to walk into her house, and upstairs to bed; but on the following morning, finding that the numbness of the limb remained, she requested my attendance. Two rhubarb pills had been taken, and had acted freely on the bowels.

I found her in a state of high nervous excitement, with partial paralysis of the left arm and leg; the left side of the face was also slightly affected. Pulse frequent and jerking; tongue rather foul: no pain in the head, or intolerance of light. Ordered a composing draught, and saw her again in a few hours. No headache: pulse steadier, but full. Limbs in same state.

Venæsectio ad ʒxvj.; and small doses of calomel and opium every four hours.

16th, 10 A.M.—Complete paralysis of the left side; but no headache, or symptoms of inflamed brain. Skin perspiring: sensation in the affected limbs perfect: complains of sickness.

8 P.M. More nervous excitement, and pulse jerking. Slight power of closing the fingers of the left hand. Had some sleep since the morning. Her son, a medical practitioner, came to see her, and advised more bleeding.

V. S. ad ʒxvj. Sumat. Calom. gr. j.; Extr. Col. c. gr. iv. 4tis horis.

17th.—No amendment in the state of the limbs; left side of the face paralyzed; pulse quiet; bowels not open.

Haust. Sennæ 4tis horis.

Stomach irritable, but very little vomiting.
P.M.—Bowels acting freely, and has had some sleep.
18th.—Bowels very open; more depression than yesterday; no return of power in the paralyzed parts.

Applic. Empl. Lyttæ Nuchæ.

19th.—Bowels acted freely in the night. Strong mercurial factor in the breath, and

ulceration of the lining membrane of the mouth.

Omit Pil. et utat. Garg. Chlor. Calcis.

22d.—Has taken a little meat broth, and enjoyed it; no power in the paralysed limbs; got some comfortable sleep in the night.

25th.—Mouth still sore; bowels act daily without medicine; appetite improved; takes milk and meat broth.

28th. — Can move the thumb and fore-finger of the left hand, and draw the leg a little up in the bed.

30th.—General health improving; more movement in the fingers of the left hand; takes meat broth freely.

Nothing more of importance occurred for some time. As the general health improved, the state of the limbs improved also; and in course of time the patient could walk across the room with little assistance, and could use the forearm sufficiently to amuse herself with knitting. She paid great attention to diet, and rode out frequently in her carriage.

On the 9th of December, 1838, I was called in again, on account of pain and of heaviness in the head. Tongue furred; appetite failing; occasional chills followed by heat; bowels not so much open as usual; pulse excited, beating 120 in a minute; no giddiness; no tinnitus.

R Magn. Sulph. ʒss.; Inf. Sennæ, Dec. Aloes, c. aa. ʒij. M. 4ta. part. 4tis horis. Pediluvium.

10th.—Bowels well relieved; head better; pulse 108 in the morning, 98 in the evening; no alteration in the state of the limbs.

Cont. Mist.

11th. — Head still uncomfortable from heaviness, but not painful; pulse 96.

Cont. Med. et applic. Hirud. iij. pone utramque aurem.

12th. — Head better; pulse 90; bowels relaxed; tongue cleaner.

Applic. Hirud. iij. pone utr. aurem; Cont. Mist.

14th.—No uneasy sensation in the head. No further treatment required at present.

Several times during the next year this lady had attacks of nervous excitement and disordered stomach, and was occasionally bled to the amount of a few ounces, which generally afforded temporary relief; but the state of the limbs remained much as usual until the 6th of December, 1839, when, after having ascended a steep flight of steps, chiefly by her own exertions, she suddenly perceived a difficulty in speaking, and in a few minutes her articulation became very imperfect, and the paralytic limbs more feeble than before. Pulse frequent and jerking; mouth more

drawn to one side. She was bled to eight or nine ounces, and took senna draughts. In the evening she felt better, and the bowels had acted freely. The blood was remarkably tenacious and sizy, and adhered to the fingers like glue*.

This attack was followed by more debility both of body and mind. When depressed more than usual, Spirits of Ammonia and Camphor mixture afforded relief, and a light bitter tonic was prescribed for general use.

In May 1840, the mental powers of my patient were much diminished, and her memory much impaired. There was an appearance of languor and listlessness which I had not seen in so great a degree before, but I acertained from the family that it had been gradually increasing for several months, and they all observed how much she was altering for the worse.

On the 18th of June last this lady and her family were thrown into the greatest affliction by the sudden death of her husband. He was devotedly attached to his family, and equally beloved by them : he had been her constant attendant and nurse ever since the commencement of her illness, and died in the act of dragging her about in a small hand carriage. It was impossible to anticipate the effect such a severe shock would have upon her in her debilitated condition, but I feared it would be more than she could bear, and that she would sink under it. The immediate effect was to stupify her : she sat by the corpse unmoved, and could not be made to believe that he was really dead. She witnessed the sorrow and distress of her children, but give vent to no expression of feeling herself for many hours. She gradually, however, became convinced of the melancholy truth, and, strange to say, has since considerably rallied from her previous state of mental inactivity, and is now altogether better than she had been for months. She appears to feel that she is now required to make more exertion, and has, to a certain extent, been wonderfully enabled to do so.

From the cases above narrated, and from others of a similar nature, I have been led to draw the following inferences :—

1. That apoplectic and paralytic affections may take place in an extreme degree without organic disease of the brain.

2. That they often occur from other causes than pressure on the brain.

3. That bleeding, so far from being always necessary, is in many instances prejudicial.

* Boerhaave mentions a thick glutinous blood as a cause of apoplexy.

4. That the effort of vomiting is not so prejudicial in these diseases as is generally supposed.

5. That counter-irritation, both external and internal, is a valuable means of affording relief to the symptoms immediately succeeding the attack.

1. Apoplectic and paralytic affections may be severe without there being organic disease of the brain.

In case 1, the first attack seemed to be the result of effusion and pressure on the brain : but it is clear that the 2d and 3d attacks, although much more severe at the commencement, could not have depended upon such a cause, or recovery would not have been so rapid and perfect. It is probable, therefore, that the first as well as the others arose from disorder of function, and not from organic disease. For the same reasons, the case of Hemiplegia (No. 2) must have arisen from functional disturbance of the brain, and not from effusion of blood or serum.

" I have met with many instances in which it has been proved that not only a general derangement of the functions of the nervous symptoms producing apoplexy, but also partial effects of a similar nature, causing hemiplegia and paralysis, may take place, without any visible change of structure in the brain."
—Abernethy on Local Diseases.

2. These diseases often occur from other causes than compression of the brain.

In the second attack, case 1, what are generally considered symptoms of compression were very marked : but had pressure been the cause of them, how could recovery have taken place so rapidly, and relief have been afforded immediately on the stomach rejecting its contents ? This leads me to make a few remarks on the effects of pressure on the brain. I have often witnessed pressure on the brain from external violence without the symptoms attributed to compression. In the 18th volume of the Medical Gazette, a remarkable case is reported by Mr. Johnson, where a boy presented himself at the Norfolk and Norwich hospital with the thick part or screw of the breech pin of a gun firmly impacted in the frontal bone, the part which fastens on the stock projecting like a horn. The

patient had no symptoms of compression till the pressure was removed by the extraction of the foreign body. In the same report are two other cases of fracture of the skull with depression to the extent of the thickness of the cranium, without symptoms of compression.

A little boy in my neighbourhood fell from a horse, receiving a severe wound in the forehead, and another at the back part of the head, where the cranium was fractured and depressed to the extent of the thickness of the bone. He was stunned by the blow at first, but soon recovered, without symptoms of compression, and without the depressed portion of bone being raised. He now enjoys good health, the pressure on the brain still remaining.

A child was affected with congenital hydrocephalus; the head gradually enlarged, until, at the age of 8 months, it had attained the following dimensions, viz.:—Circumference, 24½ inches; from ear to ear over the top of the head, 15¼ inches; width between the frontal protuberances, 4¼ inches.

At the age of 13 months the size of the head was as follows:—Circumference, 26 inches; from ear to ear over the top of the head, 18 inches.

During the whole period referred to, this child had never been really ill. The appetite was good, and its senses unimpaired. Bowels were regular and healthy, and at the age of seven months had cut two teeth without difficulty. At the time of the last measurement of the head, I find the following report in my case-book :—" The child is much the same as to general health, its faculties are still tolerably perfect, its temper is cheerful, and it knows its attendants perfectly well. The body is more emaciated. About a week after this the child died suddenly with slight convulsions, but had not previously been worse than usual."

It is thus beyond a question that pressure upon the brain may exist to a greater extent than can be imagined to occur from loaded blood-vessels, without apoplectic or paralytic symptoms being produced. Compression is not the only cause capable of producing those symptoms, and I am inclined to believe that such a cause does not exist in a majority of the cases of apoplexy that present themselves.

3. *Bleeding, so far from being always necessary, is in many instances prejudicial.*

I am much inclined to the opinion that apoplectic and paralytic seizures are frequently diseases of debility, especially in persons advanced in years; and that the brain does not well bear defraction of blood in addition to the shock of the attack.

Celsus says, " Si omnia membra vehementa resolute sunt, sanguinis detractio vel occidit, vel liberat," and again, " Post sanguinis missionem, si non redit et motus et meus, nihil spei superest."

Hippocrates says that bleeding, except it relieves, kills. Boerhaave mentions a *cold phlegmatic* cause of apoplexy. Galen says " Paralyticorum parvus pulsus, languidus, tandusque est. Nonnullis rarus quoque, aliis creber, sed nonnihil inordinatè intermittens. Est enim parvus et tardus, *quia morbus est frigidus :* languidus, quod *facultas infirmior.* Comitialium et attonitorum pulsus sunt similes." " Quorum trium morborum, frigidus, crassusque : aut omnino viscidus humor est causa."

In all cases of apoplexy or paralysis, in which the cause is dubious, " and such, on the first examination of them, the majority of them will probably be, it seems right to try the effect of correcting disorder of the digestive organs, with a view to alleviate nervous irritation, before we proceed to those severer methods, which the belief of the existence of organic or vascular disease in the brain would induce us to institute. For if blood-letting and counter-irritation be employed, in order to diminish vascular action ; or if mercury be used to some extent, in order to induce the absorption of deposited substance; these measures must aggravate that disorder of the general health, upon which, in many instances, the nervous affection depends."—*Abernethy on Local Diseases.*

In the first attack, case 1, bleeding was carried to some extent, and the recovery was very tedious, a diminution in the functions of the nervous system remaining for a considerable time. In the 2d and 3d attacks, in which bleeding was not resorted to, the recovery was rapid and complete.

In the case of hemiplegia (case 2) the patient was several times in the course of her illness affected with

symptoms indicating debility, which were relieved by tonics; and I am much inclined to think, if bleeding had been practised, the cure would have been more tedious and less perfect.

In case 5, in which bleeding was several times resorted to, the paralysis has become permanent, and frequently the general powers of the body have declined. The excitement caused by the heavy loss the patient sustained in the death of her husband, has produced amendment in her condition.

In case 4, in a young subject, bleeding was followed by coma, but whether as a consequence or not I cannot pretend to determine, as I did not see the state of the patient before he was bled. I merely record the fact. In case 3, the boy had recovered from the symptoms of disordered brain *before he was bled*, although probably according to the general opinion he was in circumstances especially demanding abstraction of blood.

4. *The effort of vomiting is not so injurious in these diseases as is generally supposed.*

The 2d and 3d attacks in case 1, were very much benefited by it, and no prejudicial effect followed.

5. *Counter-irritation, external and internal, is a valuable means of affording relief to the symptoms immediately succeeding the attack.*

By *internal counter-irritation*, I mean irritation produced through the medium of the stomach and bowels, by emetics, purgatives, or nauseating medicines. I well remember, during my apprenticeship, being sent to visit a poor woman in Norwich, who had been taken in a fit. I found her apoplectic; and owing to a suspicion of her symptoms having been occasioned by taking laudanum, (which however was afterwards proved to have been unfounded,) a fellow pupil and myself proceeded to empty her stomach by means of the stomach-pump. The stimulus caused by the introduction of the tube, and injection of water into the stomach, roused her from her state of insensibility, and she quickly recovered. As a proof of the occasional good effects of external counter-irritation, in addition to what appears from the cases above recorded, I shall briefly refer to a circumstance which occurred at the Norfolk and Norwich hospital, during my residence in that institution. A man who had

been the subject of general dropsy, and in a very weak condition, became insensible, and had all the symptoms of serous apoplexy. No bleeding could be practised on account of the debility present; neither, to the best of my recollection, could he be made to swallow anything. The physician under whose care he was placed ordered blisters to be applied in succession, I might say, almost all over the body. On the back of the neck, on both arms, both thighs and legs, soles of the feet, and I think on the top of the head. In two or three days the patient regained his senses, and recovered from his apoplexy.

A question of great importance remains to be discussed, namely, whether there are symptoms generally present in cases of apoplexy and paralysis, which, by strict observation, may enable us to distinguish clearly between those which require bleeding, and those which would be better treated without it. I frankly confess my inability to answer it satisfactorily, and find that others have also failed in doing so. If I may be allowed to give an opinion, I should say that bleeding is unnecessary or prejudicial where the patient is 60 years of age or upwards; where the pulse is feeble, very frequent, intermitting, slow, or large, and inclined to double beat, (I have always found a pulse with double beat indicative of a state of system best relieved by diffusible stimuli,) where the respiration is laboured and accompanied with *cold* perspiration; where there is great mobility of the nervous system with weak muscles, whether the body be thin or *corpulent;* when the attack comes on soon after a full meal, or after great bodily or mental fatigue.

A quick, wiry, resisting pulse, flushed countenance, warm perspiration, noisy breathing, and a tendency to spasmodic muscular contraction, occurring in persons of an earlier age, seem to point out a necessity for resorting to abstraction of blood; but I believe there will be less danger in not bleeding in any case, than in always having recourse to it, where there are *some* circumstances indicative of the propriety of its employment.

I am fully aware that the observations that I have offered upon this most interesting subject are very imperfect, and, from my limited experience, cannot be conclusive either as regards the

nature or the treatment of the diseases
under consideration. My own mind,
however, is strongly impressed with
the truth of the inferences I have drawn,
in opposition to the more prevailing
opinions of the day. If they be correct
I shall be glad to find them confirmed
by those who, from more extended ex-
perience, can form a better judgment ;
and if erroneous, I trust I may, from
the same source, receive such instruc-
tion as may enable me to treat in the
most effectual and best manner, those
cases that may in future be submitted
to my charge.

TREATMENT OF CYNANCHE.

To the Editor of the Medical Gazette.

Sir,

Allow me to place before the readers
of your valuable journal, a few more
cases of cynanche tonsillaris, treated by
guaiacum. Permit me at the same time
to correct an error of considerable im-
portance which occurs in the *recipe*
given in my former communication on
the subject, that appeared in the Me-
dical Gazette of 30th October last :
you have there inserted "Tr. guaiac,"
instead of " Pulv. guaic."   Now, if
any person should prescribe the me-
dicine according to the recipe as it
appeared, I have not the slightest doubt,
but that owing to the small quantity of
the drug which would be exhibited,
they would fail to obtain the beneficial
results which it has produced in my
hands.

Before relating the following case, I
would take the opportunity to express
my thanks to Dr. Badeley, of Chelms-
ford, for his confirmatory remarks re-
garding the use of the remedy under
consideration, and also for the flatter-
ing manner in which he takes notice of
my paper, in his communication to the
Medical Gazette of Nov. 13th.   I
regret that his success has not been
equal to that which I have experienced.
I am inclined to think this is owing to
the small dose of the guaiacum which
he orders : the *recipe which he gives* is
not more than half the strength of my
prescription : consequently it cannot be
expected to have the same effect.

Before I employed guaiacum in the
treatment of these cases, I was in the
habit of using the means which Dr.
Badeley recommends, viz. free scarifica-

tions of the tonsils, leeches to the throat,
emetics, purgatives, diaphoretics, and
in some instances general depletion,
with considerable benefit, but by no
means with universal success. I have,
however, found that by the use of
guaiacum alone I am able to effect a
cure, with greater celerity and certainty,
and with much less annoyance and pain
to my patients, than by the means above
enumerated.

I find that profuse perspiration gene-
rally follows the use of the medicine.
In some cases nausea is excited, parti-
cularly if I prescribe the powder, as I
sometimes do. Purging has also been
occasionally produced, but in many in-
stances so very little effect occurred in
this respect that I have found it neces-
sary to administer purgatives in order
to procure free discharges from the
bowels

Case I. June 16th, 1837.—Henry
Sterling, æt. 28 years, a stone-mason,
of a stout habit, sanguine temperament,
complains of headache and severe pain
of throat, increased on deglutition : is
unable to swallow anything, from the
acuteness of the pain.   Right tonsil
very much swollen, of a deep red colour ;
the uvula is also inflamed ; tongue white
and furred ; thirst ; pulse 98 ; skin hot ;
was seized with pain of throat about one
o'clock this morning.   He has been
labouring under a slight attack of bron-
chitis for four or five days.   Has taken
of his own accord two ounces of sulph.
magnes. which is now operating.

> The tonsil was freely scarified, and 12
> leeches ordered to the throat, and an
> emetic of Ipecacuanha and Tart. Anti-
> mony administered.

17th.—Ten leeches, bled well ; the
emetic operated freely ; he had consi-
derable mitigation of pain and other
complaints for nearly three hours, when
they returned with their former vio-
lence, and have continued since. Pulse
120.   Right tonsil presents the same
appearance as at noon yesterday : that of
the left side is also inflamed.

> R Pulv. Guaiac. ʒiij. ; Mucil. G. Arab. ;
> Syrup. Simpl. ʒij. ; Aq. Cinnamon,,
> Aq. Puræ, aa. ʒiv.   M. et solve.
> Capt. ʒij. 4ta. q.q. h.

18th.—Had only taken two doses of
his medicine when pain and difficulty
of swallowing began to subside; these
complaints are now nearly gone. Head-
ache completely relieved; tonsils much

less in size; redness almost gone; tongue cleaner; has taken some breakfast; skin covered with a profuse perspiration; pulse 66. No dejection since yesterday afternoon.

Cont. Mist. Guaiac. et Habt. R. Pulv. Jalap., gr. xxv.; Submur. Hydr. gr. viij. M.

19th.—Complaints gone; right tonsil slightly enlarged; bowels freely moved.

This is the first case in which I employed the guaiacum, and the result was so flattering, that I resolved to have recourse to it in the next that came under my notice, which shortly occurred and forms the subject of

CASE II. June 29th, 1837. — John Stewart, æt. 48 years, a cotton spinner, of a relaxed frame, dark complexion, complains of severe headache and pain of the throat; pain is greatly aggravated on attempting to swallow; face flushed, tonsils highly inflamed, and so much enlarged as almost to meet in centre of throat; tongue furred; pulse 117; bowels said to be regular; was seized yesterday forenoon. Has been frequently attacked in a similar manner; on these occasions he has been bled both locally and generally; has had blisters applied. These means were sometimes attended with relief, at others they failed to procure the slightest benefit.

Habt. Pulv. Guaiac. ʒss. 6ta. quàque horà, ex decoct. Avenæ. q.s.

30th.—Pain of the throat greatly better; can swallow with tolerable ease; headache gone; tonsils less red and swollen; pulse 96; feels sick and inclined to vomit; has had two loose stools.—Cont.

July 1st.—Has no pain of throat to-day; takes food and drink with the greatest freedom; pulse 70; tonsils natural here, but rather enlarged; nausea still continues; bowels freely moved. Intermit. medicament. This man has had several attacks since the above, in all of which he has been cured by the use of the mixture prescribed.

CASE III.—August 21st, 1839, John Hamilton, æt. 39 years, a carpenter, of stout make, low stature, and dark complexion; has both tonsils very much inflamed; cannot swallow his food from excessive pain of throat; complains of severe headache; pulse 120; skin hot and dry; tongue furred. Was seized last night as he was coming home from his work. Had a similar attack about

three years ago, when I bled him from the arm, applied leeches to his throat, and made very free scarifications of tonsils with considerable benefit; but in spite of these means suffocation eventually occurred.

R Pulv. Guaiac. ʒiij.; Mucil. G. Arab. Symp. Simpl. aa. ʒij.; Aq. Cinnamon. Aq. Puræ. aa. ʒij. M. et solve Capt. ʒii. 6ta. q.q. hor.

22d.—Is much better; inflammation of tonsils much reduced, but they have not resumed their natural appearance; has taken his dinner with very little annoyance from throat; pulse 86; has had four large dejections.—Cont.

23d.—Is quite well.

Intermit. Medicament.

CASE IV. Sept. 30th, 1839—John Hart, æt. 24 years, a stout farm servant; has both tonsils much inflamed, he has great pain of throat, particularly on deglutition; headache; tongue furred; skin hot; pulse 108; bowels said to be regular. Was seized 36 hours since, after exposure to cold.

Habt. Pulv. Guaiaci. ʒss. ex decoct. Avenæ. q. s. 6ta quàque horà.

Oct. 2d. — Is free from complaint; tonsils slightly enlarged, but redness completely gone: medicine produced sickness, and a profuse perspiration: bowels were twice moved yesterday, and once to-day.

Intermit. Medicament.

CASE V. March 21th, 1840.—Wm. Taylor, æt. twenty-seven years, grocer, a stout active man, complains of severe pain of throat, much increased on deglutition; velum, pendulum palati, and uvula, much inflamed; left tonsil very red and enlarged; right tonsil red, but not swollen; headache; skin hot; pulse 96; breathes easy.

R Pulv. Guaiac. ʒiij.; Mucil. G. Arab. Syrup. Simpl. aa. ʒij.; Aq. Cinnamon. Aq. Puræ. aa. ʒij. M. et solve. Sumt. ʒij. 4ta. q.q. h.

12th. — Pain and enlargement of tonsil gone, as is nearly the inflammatory appearance of fauces; pulse 76; bowels freely moved.—Cont.

14th.—Complaints cured.

Intermit. Medicament.

CASE VI. Sept. 10th, 1840.—Miss E——y, æt. nineteen years, a healthy young lady, of fair complexion, and lively manner, complains of headache

and inability to swallow, from pain of throat, particularly left side ; left tonsil enlarged, and of a deep-red colour; right tonsil slightly red, and swollen ; tongue very much coated with a dirty brown fur; pulse 118, and skin hot ; bowels have been opened by some magnesia, which she took last night, when she was first attacked with chilliness, and pain of throat.

She was ordered the mixture pre- scribed in the last case, and, on the 13th, was free from all complaint.

CASE VII.   19th. — Mrs. C., æt. twenty-four years, a stout lady, com- plains of pain of throat, and severe headache; face flushed; both tonsils, particularly right one, enlarged and red ; velum, pendulum palati, and uvula, of a similar appearance ; tongue white and furred ; rigors; bowels con- fined ; catamenia regular.

Habt. ℞ Pulv. Guaiaci. ʒv.; Mucil. G.
    Arab. Syrup. Simpl. aa. ʒiij. ; Aq. Puræ.
    ʒxij.   M. et solve. Capt. ʒij. ; 6ta.
    q.q. hor.

21st.—Throat well.

Intermit. Medicament.

CASE VIII.   Nov. 21st, 1839. – A. M'Dougall, æt. twenty-eight years, of low stature, sallow complexion, black hair and eyes, complains of severe pain of throat, attended with inability to swallow ; headache; rigors.   On exa- mining throat, tonsils and uvula present a very inflammatory appearance; tonsils touch uvula on both sides; pulse 108; skin hot, and dry ; tongue covered with a thick yellow fur : was attacked two days since.

Habt. Pulv. Guaiaci. ʒss. ; ex decoct.
    Avenæ, q. s. 6ta quâque hora.

23d.—Cured.

CASE IX.   Nov. 28th, 1838.—David Wilson, æt. thirty-four years, complains of headache ; pain of throat and back ; has great difficulty in swallowing; tongued furred ; mucous membrane of fauces very red ; tonsils greatly enlarged, as is also uvula ; pulse 110 ; rigors; skin hot ; has had bowels freely moved by Ol. Ricini; has been ill for upwards of two days.   He was ordered the powder as in last case, and in two days was perfectly well.

I will not occupy much of your space by any lengthened observations, but conclude by merely remarking that my object in bringing the subject under

the notice of the profession was to show the beneficial results which I have experienced from the use of the drug in the disease in question—an affection in which I have every reason to believe it is but very little employed by practitioners.   I by no means claim any thing like infallibility for it.   I had two failures in my own practice, as I stated in my former communication ; and I have no hesitation in asserting that such will occasionally occur, par- ticularly in cases where suppuration has taken place previous to its admi- nistration : in instances where the patient cannot swallow it in sufficient quantities to produce a salutary effect ; and many other circumstances con- nected with particular cases may occur to prevent it producing any sanative influence.   But when timely exhibited, and in full doses, I am convinced it will prove signally successful in a vast majority of cases.—I am, sir,

Your obedient servant,
            JOSEPH BELL,
                    Surgeon.

PRODUCTION OF MESENTERIC HERNIA.

ADDENDUM TO DR. RUMSEY'S PAPER IN LAST NUMBER.

To the Editor of the Medical Gazette.

SIR,

THERE might seem to be some consi- derable difficulty in the way of a large intestinal tube insinuating itself through a small opening in the mesentery, where there was no known power to impel, and the mind, therefore, would be too incredulous of the occurrence.   But let it be recollected that the expansion of mesentery may be in a certain plane, the intestine in contact with it, and covering the morbid opening.   Such motions of the body might take place as had a tendency to raise the plane, and produce a vacuum below, thus re- ceiving, by a strong natural tendency, the first descent of the hernial mass. The same principle might, by similar repeated motions, propel it until it had reached its irremediable position.

By inserting the above you will oblige, sir,

Your obedient servant,
            NATHANIEL RUMSEY, M.D.

ANALYSES and NOTICES of BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Spinal diseases : with an improved plan of cure. Including what are commonly called nervous complaints, and numerous examples, from upwards of one hundred and fifty cases. By JOHN HEY ROBERTSON, M.D., Surgeon of the Faculty of Physicians and Surgeons, Glasgow ; Licentiate of Apothecaries' Hall, London ; Member of the Glasgow Philosophical, and Westminster Medical Societies, &c. &c. Glasgow, Edinburgh, and London, 1841. 8vo. pp. 160.

CONTRARY to our usual custom, we have given the title-page at length, as it is, in some measure, a critique on the book. When our readers peruse it they will say, " the book was written for the laity ;" and their guess will not be a bad one ; for in truth it is partly addressed to the profane. Yet there are some sensible observations in the essay, by which many members of the profession may profit, but of which the reception will be somewhat damped by the prodigious self-gratulation and unvarying success of the author.

The chief points insisted on by Dr. Robertson are two ; first, that phthisis and other diseases may be simulated by disorder of the spinal nerves ; and, secondly, that the symptoms are to be relieved by counter-irritation applied to the tender part of the spine.

Both these points have been illustrated of late years by other writers, particularly by Dr. Wm. Griffin and his brother, in their treatise on the functional affections of the spinal cord. Our author's favourite remedy is dry cupping, which he administers by means of large glasses, varying in capacity from six ounces to eighteen or twenty. Occasionally he uses acupuncture. He disapproves of the steel stays worn for curvature of the spine ; and prefers a corset made with a piece of ash-wood covered with leather, and with three straps of strong linen " put across it at certain distances, with buckles, and shoulder-straps, also with buckles ; the highest strap buckled quite loose above the breasts in the female, the other two at distances lower down." (p. 99.)

On the whole, we strongly approve of counter-irritation in its milder forms, in the treatment of spinal irritation, and a host of anomalous pains which have scarcely a place in the nomenclature of medicine ; but we should be glad to see the statistics of the practice, and are not much edified by the details of infallible success.

Remarks on the Surgical Practice of Paris, Illustrated by cases. Being a thesis, to which a gold medal was assigned by the Senatus Academicus of the Edinburgh University at the graduation of 1840. By W. O. MARKHAM, M.D. London, Edinburgh, and Dublin, 1840. 8vo. pp. 114.

THE little work before us is the fruit of some months' residence at Paris. It shows a spirit of observation, and much industry, and makes us augur favourably of Dr. Markham's future exertions in the domain of medicine. The picture which he draws of the surgical practice of the Parisian hospitals is, on the whole, extremely unfavourable. When we hear that in one winter Dupuytren lost twenty-one out of twenty-six amputations below the knee ; or, that " the same sponge which cleans a bubo or a chancre at one bed is carelessly rinsed, and then employed to dress a stump at the next, and in the same manner makes the circuit of the ward," we are tempted to ask whether the Hôtel Dieu is an institution for the preservation of life, and whether the poor would not have a better chance if attended at their own homes ?

We do not cite our author's critiques on the practice of individual surgeons, as he confesses that they are the opinions of one who is still young in the art ; and we feel sure that a longer stay at Paris would have cleared up many of his doubts and difficulties.

We do not think that a few months' residence in France entitles a man to say " grave accidents," when he means " serious symptoms." We might mention other phrases and sentences requiring correction ; but a word is sufficient to the wise.

Our author has omitted an index, or table of contents ; and instead of the unvaried running title, it would have been better to put one which changed with the subject.

MEDICAL GAZETTE.

MEDICAL REFORM.

WE last week gave insertion to a paper
on the subject of medical reform, which
has just been issued by the College of
Surgeons in Edinburgh, and rumour
says that there have been some delibera-
tions on the same subject not a hundred
miles from home. It would thus appear
that the stir which has been made during
the last year or two in various quarters is
likely to lead to some beneficial results :
not in the passing of Mr. Warburton's
absurd bill, or any thing the least
like it, but by leading to certain
changes in the existing corporations,
which, but for this " pressure from
without," would probably not have
been made. The great difference be-
tween our contemporaries and ourselves
upon this subject is, that while they
imperatively demand the utter annihi-
lation of the existing institutions, we
only require certain changes which,
if rigorously effected, would, in our
humble judgment, perfectly adapt them
to the necessities of the case.

There are two different points of view
in which the contemplated changes
are usually regarded. The first is,
as to the propriety of any diminu-
tion in the number of the licensing
bodies ; and the second refers to the
expediency of certain modifications in
the polity of the various corporations.

We have in Great Britain and Ireland
a great number of establishments pos-
sessing the right of licensing practi-
tioners, each requiring for this purpose
its own particular education, and each
conferring various degrees of power
and privilege. Now we are not, and

never have been, able to discover any
advantage which can accrue to the
public from this arrangement, and it
appears to us that it would be much
better were such power of examining
and granting licenses to practise con-
fined to the three capitals—London,
Edinburgh, and Dublin. The number
of Bodies in Scotland especially, exer-
cising the right of examining and
granting licenses to practise, is absurd,
and we may instance the local privi-
leges enjoyed by Glasgow—set forth
in a recent number of this journal, as
preposterous in the extreme.

But as we think it expedient that
the licensing bodies should be limited
to the capitals, so it further appears to
us no more than reasonable to require
that there should be such an amalga-
mation of views and arrangements in
regard to preliminary education, and
the standard of knowledge required, as
to enable the possessor of a diploma
in any of the establishments to pro-
cure his recognition as a licensed
practitioner in any part of the empire ;
or, to be a little more precise, a man
who had passed the College of Surgeons
in Edinburgh should be recognized as
a legal practitioner in his own depart-
ment in any part of the kingdom; and so
likewise of the members of the Colleges
of London and Dublin. We are aware
that some mutual arrangements ap-
proaching to this have been made, but it
ought to be based on an enactment of
the legislature, not the private under-
standing of the several Colleges. So,
also, with respect to the Physicians: not
that we would have the mere degree
(granted as it is in Scotland at much
too early an age) carry with it any
privilege beyond what it already has—
but we would have an equalization of
their educational schemes between the
Colleges of Physicians in Edinburgh
and London, and an admission of their
members to like privileges in all parts

of the kingdom. That there might be difficulties in accomplishing this we doubt not : neither, however, do we doubt that the strong arm of the legislature would be able to overcome them.

With respect to the corporate bodies themselves, the great and still unreformed evil in the London Colleges is the vicious principle of self-election ; while in the Society of Apothecaries the two greatest blemishes are the system of apprenticeship and the mode of remuneration.

The most obnoxious instance of self-election, because affecting the greatest number of individuals, is that afforded by the Council of the College of Surgeons. The sentiments which we expressed on this point ten years ago remain unchanged.

" It matters not what they do—were they of such noble natures, that, like Hotspur, their honour ·

————" stuck upon them as the sun
In the grey vaults of heaven;"—

yet would the Council of the Royal College of Surgeons of London have no honour rendered to them so long as those most forbidding and unconstitutional epithets, " self-elected," and " irresponsible," could justly be applied to them. We know not a more striking illustration of the different estimation in which men are held, according to the medium through which we view them, than is afforded in the present instance. What, then, is it in the atmosphere of Lincoln's - Inn - Fields which thus either changes or corrupts the nature of those who breathe it, or so perverts the moral optics of those who look upon them ? It is nothing more than this, that a governing body, self-elected and irresponsible, is repugnant to the spirit of the times : and were their acts those of perfect wisdom, and their purity immaculate, yet would they fail to please : so long as their members are brought together

by no exercise of any general privilege and so long as their proceedings are veiled from the public eye, so long will the Council of the College of Surgeons fail to acquire popularity, however irreproachable their conduct may be *."

Now we do not mean to deny that the selections made have generally been proper ; but in some instances they have not : and some recent proceedings in reference to the ulterior election into the Court of Examiners would lead us to suppose the majority of the Council do not in this respect differ from ourselves. But were it demonstrable that the best, and none but the best, were always chosen, still we protest against the principle ; and we feel assured that the members of the College generally will never be brought to look upon the governing body, as at present constituted, in the same light in which they would regard them if they owed their elevation to the results of a general election.

So also with respect to the College of Physicians ; though here the self-election excites less general dissatisfaction, because a much smaller portion of the medical community is implicated. In Pall Mall, indeed, we find two instances of the obnoxious principle. The Fellows elect those who are to be admitted into their own body, and the President is chosen—not by the College at large — not even by the Fellows—but by certain officers called the Elects, amounting to seven in number, and who are themselves nominated by the President. This last very unpopular and most objectionable arrangement is embodied in the charter, and out of the power of the College to alter; but not so the former. The mode of admission into the Fellowship has been altered at various times, and recently was most mate-

* MED. GAZETTE, April 9, 1831.

rially improved, by making it an elec-
tion from out the general body, and not
a mere matter of course to the holders
of an English degree. But here also
we have already recorded opinions
which remain unchanged.

" On a select committee of the Fel-
lows devolves the duty of choosing the
Censors, and what is still more, of select-
ing the *Licentiates*, who are to be
honoured by an admission to the Fel-
lowship.* This is one of the grounds
on which we apprehend that the con-
stitution of such a Council will be ob-
jected to: it will be said, and with
much show of justice, that it perpe-
tuates the system of self-election, the
grand point against which the most
violent opposition is every day and
constantly directed, in discussing the
organization of the corporate bodies.
When we find that the determination
of the *quot et quosnam* of the Licentiates,
who are annually to be co-opted among
the Fellows, is thus committed to a
body of the Fellows themselves, we
cannot but doubt whether such an
arrangement can or ought to give gene-
ral satisfaction." *

We have on former occasions given
the College of Physicians credit for
their liberality in progressively con-
forming to the spirit of the times,
and we now repeat, that there are
none of the Corporate Bodies in
which greater improvements have been
made; but we most earnestly en-
treat them to consider, that the time
has now come when they must
go a step farther. The Licentiates
must be acknowledged as members
of the College, and be the parties
to select from their own body those
whom they consider most fit to be
raised to the Fellowship. Let this be
done, and they will find the measure
more calculated to render the College

popular than all those put together
which they have previously adopted.
So likewise of the College of Surgeons—
they have done much—but they must
do more. The first step is to place the
election into the Council in the hands
of the general body. In this respect
the duty of the two Colleges of Physi-
cians and Surgeons is analogous. But
the Surgeons must not stop here: their
brethren in Pall Mall are poor almost
to bankruptcy ; *they* have immense
funds. Of those resources much has
been devoted to public objects — but
more than is becoming is still
reserved for purposes which, if not
strictly private, are at least unconnected
with objects in which the general body
of members take an interest.

Let the two Colleges adopt the sug-
gestions we have made, and they need
not fear the results of parliamentary
or any other interference ; for they
would carry with them the esteem and
co-operation of the numerous and re-
spectable body which constitutes their
members respectively in every part of
the kingdom.

With respect to the general practi-
tioner, the great points requiring reform
are as we have remarked above ; first,
the system of apprenticeship which
keeps him for several years most un-
profitably employed before he enters
upon his education, properly so
called ; and, secondly, the mode of
remuneration, namely, that of charg-
ing for his medicines. The former is
an evil which interferes greatly with
his education in early life ; the latter,
a blot which remains permanent, and
disfigures his whole career, tending,
in spite of any thing he can do, to
associate him with the tradesman.
Many gentlemen among the general
practitioners we are well aware know
and feel this blemish in the system
most keenly, and would do much to get
rid of it. No Act of Parliament can

---

* MED. GAZ. July, 1835.

avail them while this continues : the man who furnishes his employers with goods, and sends in his bill for them, never will hold the same place in society as is occupied by those members of the profession who furnish only their mental lore, and receive an honorarium in return. It is easy to declaim about it. It is easy to represent those who state the facts simply as they are, and who refuse to disguise the truth, as hostile to the general practitioner. It is easy, in short, to do precisely what the Editor of the Lancet does by us. But the facts still remain the same ; and it is because we earnestly wish to see them altered, because we would have the general practitioners occupy the place to which, as a body, their education and attainments entitle them, that we are, and always have been, so earnest in denouncing the unmerited evils to which, according to the present system, they are exposed.

The demand for amalgamating the several branches of the profession into one common class, of new creation, blending practitioners of every denomination in one general institution, does not appear to us to be either desirable or practicable. Were such a general fusion accomplished by legislative interference, the constituent parts forcibly brought together would speedily separate. The Baillies of the day would practise physic ; the Coopers surgery , and clubs or societies would be established differing only in name from the institutions of the present day. But to some Board of reference— some head, of which the existing branches of the profession should serve as members of a common body, we should not object ; and we do not conceive such a plan entirely hypothetical ;—but more of this hereafter.

ILL-TREATMENT IN THE HENDON UNION.

CASES of the following kind have become too common to need much commentary ; and, in the present instance, it is unnecessary to give the history of the case, as the jury have embodied it in their verdict. It may be useful to state that the inquest was concluded on the 17th inst., and that Hendon is a village seven miles from London.

" We find that the death of James Lisney was caused by an imprisonment in the gaol-room of the Hendon Union Workhouse, on the 4th and 5th days of the inclement month of November, 1840, under a sentence of the Board of Guardians of the Hendon Union ; and the jury beg to express their opinion that it was not humane to imprison him without fire and on low diet, the said James Lisney being at the time in an infirm state of health, in consequence of a disease called diabetes."—*Times*, Dec. 18, 1840.

ABERDEEN INFIRMARY REPORTS.

[Continued from page 458.)

Cases and Observations by —— LAING, Esq.

One of the Surgeons of the Hospital.

CASE OF DELIRIUM TRAUMATICUM FOLLOWED BY SECONDARY HÆMORRHAGE FOUR WEEKS AFTER AMPUTATION.

P. J. æt. 50, was brought to the hospital at 9 P. M. of the 22d of May, 1840, with compound fracture, and lacerated wound of the left leg, caused by a loaded cart passing over it. Both tibia and fibula were fractured in the lower third, and three or four inches of the tibia protruded. There was also another extensive wound above the malleolus externus : the tendo-achillis and great blood-vessels were divided, and the ankle-joint laid open. He had lost a great quantity of blood during a journey of five miles since he sustained the accident, and it continued to drain away from the very extensive wounded surfaces, in spite of the application of the tourniquet, and pressure over the femoral artery over the os pubis. It was therefore resolved to amputate immediately, as the only chance of saving his life. The operation was performed by forming a flap four or five inches below his knee. Very little additional blood was lost.

May 23d.— Had no sleep during the night, though he took a dose of morphia towards morning ; he complains of extreme pain in

the stump; pulse 120; tongue dry; skin hot. 9 P. M. has been extremely restless and incoherent during the day; tongue brown and dry; pulse 130; bowels not moved; stitches removed from the stump.

℞ Calomel, gr. v.; Opii. gr. i. formâ pilulæ horâ somni, et Ol. Ricini. ss. cras mane.

24th.—Is considerably better, and more collected to-day; pulse 110; tongue mois- ter; bowels freely opened, but much thirst; stump dressed with two or three adhesive straps, and water dressing.

Habeat Haust. Efferves. Subinde.

27th.—Continues still feverish and un- easy; pulse 106; tongue moister. No ad- hesions have taken place, but the flap hangs loose and sloughy; it is supported by two or three straps, and a poultice applied. The effervescing draughts and occasional doses of castor-oil continued.

29th.—Delirium again came on yesterday afternoon, and increased to such violence during the night, that it was necessary to put on the strait jacket to prevent him getting out of bed, and making for the window: pulse 110: tongue not dry; bowels not moved for two days. The head was ordered to be shaved, and cloths dipped in cold water constantly applied, and a blister put between the shoulders. In consultation it was agreed to give calomel in doses of two grain every four hours.

31st.—Delirium continues, but the pulse is rather stronger. Pergat. 8 P.M. Much the same; has had no sleep for 36 hours.

℞ Tinct. Opii. gtt. xxxv.; Aq. Menth. ʒss. M. Fiat haust.

June 1st.—Slept occasionally during the night, but is still very delirious; pulse 100; tongue foul; passes his urine unconsciously.

℞ Sol. Mur. Morph. gtts. xl., statim. Vin. Albi. Hispan. ʒiv.

9 P. M. Has slept a good deal, and is cer- tainly quieter; perspiration abated; pulse 96, and more regular.

℞ Sol. Mur. Morphiæ gtts. xlv.

3d.—Has improved gradually since last report, and is now quite sensible: pulse 96. He takes 45 drops of Sol. Mur. Morphiæ every night, and 30 every morning. Is ordered four ounces of white wine daily, nourishing diet, and effervescing draught at pleasure.

8th. — Improving steadily; has omitted the morning dose of the Mur. of the Morph. for two days. The wound is very large and open, but it is suppurating and granulating in a tolerably healthy manner. Pergat.

20th.—Considerable arterial hæmorrhage

took place this morning, which, however, ceased on the application of pressure to the femoral artery, and a piece of lint dipped in creosote over the bleeding point.

22d.—Hæmorrhage recurred this morning, but was soon arrested by the same means as before.

23d.—Arterial hæmorrhage came on to an alarming extent during the night, and again this morning: it was found to proceed from three distant points of the stump. From the state of the parts it was in vain to think of tying the vessels; it was, therefore, resolved to tie the femoral artery, and this accordingly I immediately proceeded to do, with the assistance of my colleague, Dr. Keith. A small cutaneous branch, which was divided in making the first incision, was immediately secured. A single ligature was then passed round the artery, and the wound dressed as usual. Next day the temperature of the stump, which had sunk two or three degrees soon after the operation, had risen to the natural standard; and the granula- tions, which had become somewhat livid, resumed their florid colour. The secretion of pus, which had been copious, gradually diminished from this time, and cicatrization went on steadily, The ligature came away from the artery on the 14th day, and the opening through which it passed soon closed. On the 20th of July the stump was nearly healed, and on the 10th of August he was dismissed cured.

CASE OF SEVERE EPILEPSY ARISING FROM ENLARGEMENT OF NERVES.

M. D., æt. 21, was brought to the hospital on the evening of the 17th of February, 1840, with the left hand lacerated by machinery. The first three fingers, and half of the little finger, were carried away; and the inner side of the thumb, the palm, and back of the hand, lacerated. The crushed bones were removed at the nearest joints, and as much as possible saved, to form flaps, which were brought over the wound by adhesive straps, and water dressing applied. For some time she went on well, but on the night of the 6th of March she was seized with irregular convulsions, for which an anodyne antimonial draught was ordered. On the 7th she was found unable to speak, and the jaw firmly locked, but she seemed sensible, and pointed to the region of the diaphragm: pulse regular, but weak. Six grains of calomel, followed by strong cathartic enemata, were ordered; the head shaved, and bathed with vinegar and water, and a blister applied to the scrobiculus cordis. At night a draught of Tinct. of Valerian, and Mur. of Morphiæ, was ordered. Next day the trismus continued, with occasional slight relaxations; the eyes were fixed and turned up, and the chest raised at times from the

bed by a degree of opisthotonos. These symptoms continued, with slight remissions, for three or four days, during which time leeches and a blister were applied to the head. Large doses of Tinct. Opii. administered; strong purgatives of calomel and jalap, followed by enemata, given; and the hand regularly poulticed. On the 10th the tetanic symptoms had almost entirely subsided, and the hand looked well, but she complained much of her head. It was again blistered, and pills of Aloes with Assafœtida given three times a day. From this time she improved regularly, and the hand continued to heal favourably till the 23d, when she was again attacked with trismus, and other tetanic symptoms. The head was again shaved, twelve leeches applied, followed by a blister, and a large dose of calomel with cathartic enemata. This treatment was successful: the hand healed gradually, without any further alarming symptoms, and on the 7th of April she was dismissed cured.

This patient returned to the hospital on 24th of June, on account of severe epileptic attacks. She had continued well for eight or ten weeks after she was dismissed, but about a fortnight ago suddenly fell down in a fit; and these attacks gradually became more and more frequent. They now recur five or six times a day, and last about five minutes, after which she lies a considerable time in a state of stupor. As she was of a full habit, she was immediately cupped from the nape of the neck to the extent of ten or twelve ounces.

℞ Calomel, gr. v.; Pulv. Jalapæ ∋i. M. Fiat pulvis, sint vi. tales; Capiat unum indies.

26th.—No change. The fits are so severe that it has been found necessary to put her in the strait-waistcoat, to prevent her from injuring her head and arms against the walls and the frame of the bed; and it requires two strong persons to keep her in bed. The head was shaved, and twelve leeches applied, and the purgatives continued. She also had occasionally a draught of Mur. of Morphiæ with Tinct of Valerian.

30th.—Fits continue unabated.—Adhibeatur vesicatorium amplum Capiti raso.

July 4th.—There has been a slight improvement for the last two days. She is now taking the Assafœtida pills thrice a day.

6th.—Epileptic fits have returned with severity.

℞ Nitrat. Argenti. gr. iv. Micæ panis. q. s. M. Fiant pilulæ xii. Capiat unam bis die.

16th.—The nitrate of silver has been continued regularly, the dose being increased to half a grain a day, without any marked improvement.

Repetatur Vesicat. Capiti. Continuentur pilulæ Nitrat. Argenti, et Pulv. Jalapæ c. Calomel pro re natá.

22d.—As she still complained much of her head, it was determined to carry depletion still farther. Accordingly she was placed upright, and twenty-two ounces of blood taken from the arm, which produced slight faintness. Continuentur cætera.

30th.—Little improvement. It has been observed for the last few days, that, when the fits are slight, they are confined chiefly to the arm that was injured. On touching the stumps of the fingers smartly, the arm is convulsively withdrawn; and, when this is done while she lies in a state of stupor, violent convulsions of the arm are produced. She also says, when questioned, that she often feels a sensation proceeding from the injured hand up the arm to her head, before the commencement of the fits.

August 10th.—Since last report the fits have been very severe, often confined to the arm, but always one or two general fits of great violence daily. As it seemed highly probable that the disease was occasioned by an affection of the extremities of the nerves in the injured hand, it was proposed in consultation either to amputate the hand, or cut down upon and remove a part of the nervous trunks leading to it. The first was preferred, first, because the hand was of little use, the remaining thumb being contracted and immoveable; and secondly, because, as the ends of all the metacarpal nerves seemed affected, it would be necessary to cut down upon the ulnar as well as the median nerve, which would have rendered the operation as severe and more tedious than amputation.

12th.—The amputation was performed to-day near the middle of the forearm, by the double flap formed by transfixion. This mode was preferred, as being the most rapid, and allowing less time for the occurrence of the convulsions.

On tracing the nerves of the injured hand by dissection, the digital branches of the median nerve, and the branch of the ulnar, which supplies the ring finger, were found enlarged to four or five times their usual size, for one-third of an inch from their termination, and their extremities bulbous, and firmly imbedded in the hard cicatrix. They were also of a slight rose colour near their extremities, and firmer than usual. The flaps adhered by the first intention, and the cicatrization was almost complete on the 30th of August. The patient never had the slightest appearance of epilepsy after the operation, and was dismissed cured on the 8th of September.

HYPERTROPHY OF THE ABDO-MINAL PARIETES.

MARGARET ADAM, æt. 33, of a lax and rather thin habit of body, was admitted on the 6th December, 1839, labouring under the following symptoms :—Belly is swollen, somewhat tense, tympanitic at its upper, and indistinctly fluctuating at its lower region. Complains of some weakness in back, but not of pain ; pulse 86 ; tongue white ; appetite very good ; bowels slow ; skin cool. Swelling commenced four months ago, shortly after childbirth, and has since continued ; uterus normal. She was at this time treated with purgatives, diuretics, and mercury to salivation, and left the house with the swelling greatly diminished on the 1st July, 1810. She returned on the 17th February, with similar symptoms. Belly much swollen, soft, and tympanitic, but no distinct fluctuation can be felt : complains of occasional dyspnœa ; appetite and general health good : bowels slow ; swelling began to increase about fourteen days ago ; urine rather scanty, and deposits some flocculi on being heated.

REMARKS.—This case is worthy of some observation, in as far as the diagnosis of abdominal diseases is concerned, for there was an apparent obscurity about the symptoms on the first examination, although it does not appear to be a disease attended with any particular, at least immediate danger. The abdomen, when percussed, has a peculiar doughy or fatty feel ; at the same time it is accompanied with a low or concealed tympanitic sound. It may be characterized as a tympanitic sound passing through a denser medium than the abdominal parietes of normal thickness ; such as occurs in very fat individuals. This patient, however, is of rather a thin habit of body, so that a natural accumulation of fat in that situation cannot enter into the calculation ; and she has no anasarca or fluctuation in the abdomen, while the integuments covering this latter cavity do not pit, in the slightest degree, by pressure ; dropsical effusion must, therefore, also be excluded. On examining the abdomen with the stethoscope, the intestinal murmur was heard pretty distinctly, but deep-seated, or not in such close proximity to the ear as in a normal state of the abdomen, and, on pinching up a fold of the integuments from the abdominal muscles, it was found to be thickened to the extent of about two inches and a half ; whereas, in most persons who are more than usually fat, the integument pinched up in this manner will not measure much more than half an inch, and frequently less, What, then, is the disease in this patient, since it is not ascites, anasarca, or a natural accumulation of fatty

matter ? It seems to depend upon two things, viz., first, the tympanitic swelling of the intestines, which does not exist to any great extent ; and, second, the thickening of the integuments and cellular texture covering the abdominal muscles. Since her last admission she has been treated, in some respects, as formerly, with purgatives of the P. Jalap C. every second night, diuretic powders, and a blister to the abdomen, the latter being employed for the purpose of exciting absorption. She was dismissed on the 10th of April, with the abdomen very much reduced in size, the tympanitic swelling being altogether gone ; but the integuments were still much thicker than natural.—*From a Clinical Lecture by Dr. Davidson, of Glasgow.*

ON THE

AUSCULTATORY PHENOMENA IN EXTERNALLY SITUATED ANEURISMS,

AND ON THE DIFFERENCE BETWEEN AN INDEPENDENT AND A COMMUNICATED PULSATION IN TUMORS.

By DR. SCHUK, of Vienna.

WHEN the stethoscope is placed over an aneurismal sac, or over a diffused aneurism, one perceives a very loud uninterrupted bellows-sound increasing with each pulsation. It is the more marked the more powerful the action of the heart is, the nearer the aneurism is to the heart, the rougher the wall of the artery turned towards the blood is, and the easier the blood contained in the aneurismal cavity can be put into eddying and vibratory motions by the wave of blood passing through it. The last circumstance explains why, in enormously large aneurisms with but few layers of coagulum, as well as in those of which the sac contains scarcely anything but layers of coagulated lymph, the bellows-sound is proportionally weak. In the first of these cases the quantity of fluid is too great for all its parts to be put into strong vibration by the current of blood; and, in the second, the quantity of fluid put in motion is small, and the layers of lymph, laid one over the other, hinder, in some measure, the conduction of the sound.

When the blowing is remarkably loud, it is observable that the note of the murmur is not equally high throughout ; but that at the beginning of the diastole of the artery it appears higher, and thence decreases remarkably till the next diastole.

This murmur extends for a considerable distance both towards the heart and even somewhat further towards the distal portion of the artery, and becomes weaker as it is examined at a greater distance from the aneurism.

The causes of the murmur are, first, the friction of the current of blood on the rough walls of the aneurism, or the fibrine, or on the edges of the orifice of communication between the artery and the aneurismal pouch; second, the vibration or eddying motion of the fluid blood contained in the aneurism, excited by the current of blood passing through it.

In a varicose aneurism the auscultatory signs are heard in the most striking manner. I had not long since two opportunities of observing this condition ; in both it resulted from unfortunate venesection at the bend of the elbow. In these cases the murmur, by its intensity, becomes a whizzing sound, and the equality of the strength, as well as of the note of the sound at the different movements of the motion of the blood, is very remarkable. These phenomena are already distinct at a period of the disease when, from its short duration, but little dilatation of the wounded vein has taken place, and they are, therefore, of essential use in facilitating and supporting the diagnosis. The loudest sound is heard at that part at which the purring can be most distinctly felt with the finger ; that is, where the arterial current excites the vibrations of the venous blood. With the distance from this part, the sound gradually decreases in loudness, and at last merges into a bellows-sound, which is audible only during the diastole of the artery, and which is recognized on whatever part of the limb the stethoscope is placed, as well at the shoulder-joint as at the dorsal and palmar surfaces of the hand.

The phenomena just mentioned are of themselves, and for their own sakes, interesting, and they increase the probability of the diagnosis of aneurisms of all kinds. But their practical value appears especially evident in reference to the fact, that by their means one may distinguish an independently pulsating tumor, *i. e.*, an aneurism, from one to which pulsation is only communicated. In all works on surgery we constantly meet with expressions of regret that it is in many cases so difficult to determine whether a tumor which has the symptoms of both a visible and a sensible pulsation is an aneurism, or whether the motion is only communicated to a morbid growth by the artery running under it. If the tumor can be pushed aside, and if, when its position is changed, the pulsation ceases because the artery now no longer runs under it, one may be quite sure there is no aneurism. But this cannot always be done, and, in such a case, doubt, as to the nature of the disease, must sometimes exist in the mind even of an experienced surgeon.

If by pressing it with the finger we lessen the calibre of an artery, for instance the external iliac, to a certain extent, and

sufficiently for the finger to perceive the sensation of purring, we may hear *a blowing sound at the moment of the pulsation*, along the whole course of the femoral artery down to the knee, but which, though evident and easily recognized, is yet far weaker than in an aneurism. It bears the greatest resemblance to what is called the placental murmur in pregnant women, only it is for the most part of short continuance, and limited to the moment of the arterial diastole. The phenomena that are thus artificially produced not unfrequently occur naturally in consequence of the pressure of tumors or morbid products on the arteries. If the pressure is too considerable, or too slight, no blowing is produced ; in the former circumstance, because the arterial walls are brought into contact, and the circulation is prevented at that part ; in the latter, because the slight pressure is not sufficient to give rise to such an obstruction of the blood as to produce a murmur of the increased friction between the blood and the arterial wall. Large thyroid glands, comprising, in some measure, the carotid, afford the most frequent opportunities of testing the truth of these observations. The blowing becomes in the same proportion weaker, and at last entirely ceases as the gland gradually diminishes in size under the use of remedies. This short consideration of the matter, therefore, warrants the following conclusion :—a tumor which pulsates synchronously with the adjacent artery may be considered to be an aneurism when the murmur heard with the stethoscope is loud, uninterrupted, loudest and often highest in its note at the commencement of the diastole of the artery, and gradually from that point of time decreasing in intensity ; but the pulsation is only one communicated from a subjacent artery when the murmur is either altogether absent, or, if present, is heard only at the moment of the pulsation.—*Med. Jahrb. des Orsterrei-chischen Staates, Bd.* xxi. *St.* 3.

DIVERSITY OF CLIMATES.

How comes it to pass, that in the same site, in one latitude, to such as are *periœci*, there should be such difference of soil, complexion, colour, metal, air, &c. The Spaniards are white, and so are Italians, whereas the inhabitants about *Caput bonæ Spei* are blackamoors, and yet both alike distant from the equator : nay, they that dwell in the same parallel line with these Negroes, as about the Straits of Magellan, are white-coloured, and yet some in Presbyter John's country, in Ethiopia, are dun ; they in Zeilan (Ceylon) and Malabar, parallel with them, again black : Manamotapa in Africk, and St. Thomas's Isle are extremely hot, both under the line, coal-black their inhabitants, whereas

Peruni they are quite opposite in colour, very temperate, or rather cold, and yet both alike elevated,   Moscow, in 53 [55] degrees of latitude, extremely cold, as those northern countries usually are, having one perpetual hard frost all winter long : and in 52 degrees of latitude, sometimes hard frost and snow all summer, as in Button's bay, &c. or by fits ; and yet England, near the same latitude, and Ireland, very moist, warm, and more temperate in winter than Spain, Italy, or France.   Is it the sea that causes this difference, and the air that comes from it ? Why then is the Ister so cold near the Euxine, Pontus, Bithynia, and all Thrace ? *frigidas regiones* Maginus calls them ; and yet their latitude is but 42, which should be hot.   Anevira, or Nova Albion in America, bordering on the sea, was so cold in July, that our Englishmen could hardly endure it. At Novemberga, in 45 degrees latitude, all the sea is frozen ice, and yet in a more southern latitude than ours.—*(Burton's Anatomy of Melancholy.*   Digression of Air.)

DR. GRIFFITH'S OPINIONS ON PHTHISIS.

THE use of chalybeates is strongly enforced in a small pamphlet of Dr. Moses Griffith, whose prescriptions have been very properly admitted into the London Pharmacopœia, notwithstanding the author's chemical error, in doubting the decomposition of the sulphate of iron by the subcarbonate of potass.   He adds to these salts nitre, in young subjects and recent cases, having begun with bleeding ; myrrh in a more advanced stage, and when there is more debility.   In all cases he recommends a diet of asses' milk, or skimmed milk, puddings, rice, and potatoes, with as little animal food as possible, of the lightest kind, once a day : snails also, either raw, or boiled in milk, he thinks materially beneficial, and prefers them to asses' milk : they may be bruised and hung up in a cool place, and the viscid fluid that issues from them may be made into lozenges.   The warm or tepid bath he has found very useful in inflammatory hectic, particularly for children ; and in one case he considers it as having cured a consumption in an advanced state.—*Dr. Young on Consumptive Diseases.*

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

A GOOD deal of blame has been cast on those gentlemen who have accepted the proposal of the Poor Law Commissioners with regard to vaccination : much, however, may be said in justification of those who are officially connected with Unions, in whom it would be unwise to give offence to guardians by opposing their wishes : but what is to be said of those who, not being medical officers of an Union, not only accept these terms, but actually underbid their brethren ?

The guardians of the Bridport Union issued notices of the division of the Union into several districts, stating that they were " ready to contract with vaccinators for any of the specified districts according to the appointment of the Poor Law Commissioners."   These notices were circulated amongst the practitioners in the town and immediate neighbourhood.   For every district but one offers were made to vaccinate for the sum recomended by the Commissioners.   One person, however, in no way connected with the Union, except as a resident, tendered for a district for ONE SHILLING for each successful case.

I am, sir,
Your obedient servant,
A CONSTANT READER.
Bridport, 25th Nov. 1840.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture XV.

Hæmorrhage : – most commonly by exhalation. Habitual hæmorrhages. Vicarious hæmorrhages. Idiopathic hæmorrhages, active and passive. Symptomatic hæmorrhages. Usual situations of hæmorrhage. Symptoms and diagnosis. Principles of Treatment.

In the course of that somewhat cursory account which I have been endeavouring to give you of the general facts and doctrines of pathology, as a preparation for the better understanding of special forms of disease, we reached, some lectures back, the subject of local plethora, or congestion. From that point our road branched off in three several directions. We have pursued the first and main branch to its termination ; that which led to the discussion of inflammation. We must now go back to the same point again ; and follow first the one and then the other of the two remaining branches, which conduct respectively to the consideration of *hæmorrhage* and of *dropsy.* These branches are shorter than that along which we were last travelling ; but they are not uninviting : they will open to us, if I mistake not, some interesting views of the country of which we propose, in the end, to make a more particular survey.

You are to observe that I treat of *hæmorrhage*, only so far as it falls to the care of the *physician.* The subject is exceedingly full of interest in its relations to surgery : and it will receive at the hands of my Colleague

all the attention which its great importance, as a surgical accident, demands.

But *we* also, as physicians, have much to do with hæmorrhage ; with what, for distinction's sake, I may call *medical* hæmorrhage ; which differs in kind, in cause, in its consequences, and in the treatment it requires, from that which surgery contemplates.

Hæmorrhage by exhalation.—In surgical or traumatic hæmorrhage the blood flows from some considerable vessel, which has been cut, or torn, or somehow ruptured. You would greatly mistake if you inferred from that circumstance, (as you naturally might) that it is *usually* so—the only difference being in the situation of the vessel—in medical hæmorrhage also.

Yet that is the popular notion. When blood rushes out from internal parts, through any of the natural apertures of the body, the person is said and supposed to have *broken a blood-vessel.* Yet this is rarely, though it is sometimes, the case. In nine instances out of ten, if there be any rupture at all, it is rupture of numerous capillaries only : but even of this there is often no evidence.

Whence then, and how, does the blood escape from its natural channels ? Why, it exudes from the unbroken surfaces of organs, without any appreciable lesion of arteries, veins, or capillaries ; just in the same manner as sweat oozes from the skin, mucus from the inner surface of the bowels, and serum or synovia from the membranes that respectively furnish those fluids ; and probably by the very same outlets.

This certainly is a very remarkable circumstance, if it be true : and you will naturally ask what proof we have of its truth.

The proof is simple and conclusive. We examine the surface from which the blood must have proceeded, and we find it entire : we wash and even macerate it ; we employ the microscope to assist our powers of vision ; yet we fail, after this careful inspection, to discover the slightest breach of substance, or any appearance of erosion.

When, for example, hæmorrhage has occurred so profusely from the stomach or bowels that the death which ensued could be sufficiently accounted for by the mere loss of blood, the whole tract of the alimentary canal has been diligently scrutinized, and has exhibited no ruptured blood-vessel, no abrasion even of its surface, nor any perceptible alteration of texture. Sometimes its mucous membrane appears, here and there, of a red colour, and, as it were, charged with blood. Sometimes it is pale and transparent, while the vascular net-work visible immediately beneath it is gorged and turgid. Sometimes the whole is colourless, the same net-work of vessels having been completely emptied by the previous hæmorrhage: and sometimes, again, (and this is very illustrative of the mode by which the blood has issued) vast numbers of small dark-coloured masses, like grains of fine sand, can be made to start from the surface of the membrane by slight pressure. There can be no doubt that these are minute portions of blood, which had remained and coagulated in the vessels or apertures forming the ultimate channels of the hæmorrhage.

We have absolute proof, therefore, that hæmorrhage may transude through an uninjured surface: nay, in some rare cases, the process has been actually witnessed. There are well-authenticated instances on record of *cutaneous* hæmorrhage; where a dew of blood has appeared upon some portion of the skin, has been wiped away, and has reappeared; and that again and again, without any perceptible alteration of the affected surface, beyond some occasional variation in its colour. So again the menstrual discharge has been seen to issue *guttatim* from the healthy surface of a living and inverted uterus. But I confess, that although this analogical fact helps our conception of the manner in which blood may be exhaled from an unbroken membrane, I should not lay much stress upon it for any other purpose. It is not exactly a case in point. The process of menstruation cannot be looked upon as a morbid process. During a certain portion of the life of an unpregnant female, it is not only consistent with perfect health, but even essential to it, and the fluid poured out is not strictly blood.

That the blood proceeds from the same vessels or apertures which, in health, pour out the fluids natural to the part, is rendered the more probable by this fact:—that certain hæmorrhages are ushered in and succeeded by an increased efflux of the fluids which belong to the surface concerned. In hæmorrhages from the mucous membranes the following succession of events is, in some persons, habitual. First, there is an augmented flow of mucus alone; then of mucus tinged with blood; then of pure blood: and

the hæmorrhage recedes by a similar, but inverse gradation, towards a mucous drain, which itself at length decreases or disappears.

When blood thus exudes, we say that the hæmorrhage takes place by *exhalation*. It is a convenient word, and will spare circumlocution. What the vessels or outlets to which we give the name of exhalants really are; whether they be branches from the capillaries not large enough in the natural state to admit the red particles, or whether they be mere pores in the sides of the capillaries; these are points concerning which we have no positive knowledge. We know, indeed, that such channels must exist, though we cannot demonstrate or see them; and we know that while every part of the body is in a state of health and integrity, they do not allow the blood, as such, to pass through them.

Now, although internal hæmorrhage may happen in other ways; as from the bursting of an aneurism, or from an opening made in a large vessel by progressive ulceration; yet in by far the greater number of cases it takes place by exhalation. Exhalation is the rule—other modes of hæmorrhage furnish the occasional exception.

I must exclude, however, from this general statement one very important hæmorrhage. In the brain, the former exception becomes the rule. In almost all cases cerebral hæmorrhage results from the rupture of a blood-vessel.

There are various kinds of hæmorrhage by exhalation. I will bring them before you, in succession, as clearly and concisely as I can.

Habitual hæmorrhages. — In the first place there are hæmorrhages which, although they do not belong to the state of health, if we take mankind in general, yet when they do occur, cannot properly be called diseases. There are some persons—I believe I may say there are many persons—who are subject, during the greater part of their lives, to discharges of blood; which happen again and again, commonly at regular intervals, without any perceptible detriment to the general health, independently of any obvious exciting cause, and (as it would seem) from some inherent property or necessity of the system.

Hæmorrhages thus occurring, I will call *habitual hæmorrhages.* They proceed more commonly from the rectum, or from the nares, than from any other part; although instances are recorded of their taking place from the bladder, and from the bronchi. Appertaining to the original constitution of the body, this disposition to periodic hæmorrhage has been sometimes observed to be hereditary.

You will at once be struck with the analogy

which obtains between these habitual hæmorrhages occurring in either sex, and the monthly discharge which is peculiar to the female. The analogy is even closer than it may at first sight appear : but it is more distinctly marked in some individuals, liable to habitual hæmorrhage, than in others. It was one of the singular notions of the celebrated phrenologist M. Gall, founded upon this analogy, that there is such a thing as male menstruation. The points of resemblance between the two phœnomena will be manifest in the following summary of the characters belonging to habitual hæmorrhage.

Like the catamenia, these hæmorrhages do not ordinarily prevail throughout the whole course of life. In most cases they do not commence before the period of adolescence ; and they cease altogether, or recur at distant intervals only, in declining age. Their first eruption is sometimes preceded by a state of general indisposition, more rarely by slight febrile disturbance, and even (according to some observers) by a sort of chlorosis similar to that which affects young girls in whom the menstrual evacuation is delayed or suspended. The hæmorrhage sometimes recurs at precisely regular intervals, and by *monthly* periods more commonly than any other : being announced, on each occasion, by the same preludes, proceeding from the same part, continuing for the same space of time, and furnishing always about the same quantity of blood. Its accidental interruption is almost uniformly the cause or the consequence of some derangement of the health : and when it becomes excessive, it becomes, like too profuse menstruation, a disease.

Vicarious hæmorrhages.—It forms a very curious part of the general history of hæmorrhages that they are not unfrequently *vicarious*, or supplemental, sometimes of each other, but more often of the monthly discharge from the uterus. Females are liable to perverted menstruation, (so to call it) through other channels than the natural one : and here again the analogy between the catamenia and habitual hæmorrhage comes into view. The hæmorrhages which belong to the constitution are apt to wander in their seat. As bleedings from the lungs, stomach, rectum, or skin, sometimes follow upon the suspension of the menses, so bleedings from the bladder, from the mouth, and from other parts, has been occasionally observed to succeed the suppression of habitual hæmorrhois.

These hæmorrhagic deviations take place commonly by the same organ on each occasion ; more seldom by different organs in succession. It is almost always in this supplementary manner that the rarer forms of hæmorrhage occur, and those of the skin in particular.

This singular migration, this interchange of place between certain hæmorrhages seems calculated to throw some light upon the obscure doctrine of *revulsion ;* a doctrine to which I have already more than once referred, and which, though it is very imperfectly understood, is of frequent avail in the practice of physic.

Vicarious hæmorrhage always denotes a disordered state of the general health : and must be considered, in itself, as a malady.

Idiopathic hæmorrhages.— Again, there are certain forms of hæmorrhage, not habitual, which may be denominated *idiopathic ;* inasmuch as they are apt to arise without any perceptible connexion with antecedent local disease.

In other respects, however, they differ considerably, and require to be farther distinguished : and the terms *active* and *passive*, which are in common use, will sufficiently express the two forms of idiopathic hæmorrhage that I wish to bring under your notice.

Active hæmorrhage is preceded by active congestion, and therefore is akin to inflammation ; and it often requires the treatment of inflammation.

Passive hæmorrhage often occurs without any apparent previous congestion of any kind. Hæmorrhage of this passive character has been ascribed to some change—different from that which we conceive to be produced by the distension of plethora—in the vessels or apertures through which the healthy exhalations are transmitted. The change is considered as being of the nature of morbid debility or relaxation. That such a state may sometimes exist is not impossible, nor even unlikely : but as we are altogether ignorant of the natural condition of these outlets, it is difficult to reason about the alterations to which they may be subject in disease. This hypothesis derives its chief support from the occasional efficacy of *astringent* substances (either applied locally, or taken into the system) in checking the effusion of blood ; when other remedies have failed.

A more probable hypothesis perhaps is that which supposes some alteration in the consistence or composition of the blood itself ; which thus becomes attenuated, and capable of passing through channels or orifices that healthy blood, under ordinary circumstances, cannot penetrate. In support of this supposition are adduced the facts that hæmorrhages are known to occur where the blood is more thin, pale, and serous than common : and still more remarkably where that fluid has undergone a demonstrable change in its chemical nature, or is even

visibly altered in its sensible qualities; as, for example, in certain cases of purpura and sea-scurvy. And hæmorrhages of this kind are often cured by measures calculated to repair the blood; to restore it to its natural condition by improvements in diet; or by food of a peculiar kind, as the juice of lemons.

Whatever may be the true explanation of the differences in question, there can be no doubt that they exist, and are often strongly pronounced, in cases of hæmorrhage, which, inasmuch as they cannot be traced to any pre-existent local disease, we class together as *idiopathic*. And it will be worth while to run over the distinctive characters of active and passive hæmorrhage, as they are broadly and decidedly visible, in well-marked cases.

Active Hæmorrhages.— Active hæmorrhage (which is preceded, I repeat, by active congestion) occurs principally in persons who are young and robust, who live fully, and lead indolent lives, and are subject to the influence of those causes which tend to generate plethora. Occasionally the hæmorrhage can be traced to some exciting cause, such as exposure to heat, strong mental emotion, violent exercise, or bodily efforts. More frequently, perhaps, no exciting cause is apparent. It is sometimes ushered in by a set of symptoms expressive of what has been called the *molimen hæmorrhagicum.* The patient experiences a general feeling of indisposition, with wandering and obscure pains that gradually settle in the part from which the blood is about to be discharged. A series of local symptoms, such as a sensation of weight, or of tension, or of heat and tingling, sometimes a slight degree of turgescence and redness, and a visible fulness of the larger veins, indicate the afflux of blood towards the labouring organ, and the parts in its vicinity: while chilliness, paleness, and shrinking of distant parts, and especially of the feet and hands, denote an opposite state of the circulation in *them*. And to this state of things there often succeeds a general increase of heat, with a frequent, full, and bounding *pulse*,—a pulse which is so characteristic sometimes, as to have acquired a name: you may often hear or read of, a *hæmorrhagic* pulse. The blood, when at length it breaks forth, commonly escapes with rapidity; is of a florid colour; proceeds from a single organ; and readily coagulates, though it seldom separates distinctly into serum and crassamentum. While it is flowing, the signs of local congestion diminish and disappear; warmth returns to the extremities, and the pulse regains its natural strength and frequency. The patient becomes conscious of a sensible relief; and feels stronger and more lively than before. This kind of hæmorrhage is, in some sort, its own remedy; it ceases in virtue of the discharge of a certain quantity of blood, and it is followed by

morbid consequences only when that quantity has been excessive; or when it inflicts some mechanical injury upon the parts along which the blood passes.

I said that active hæmorrhage is preceded by active congestion, and is consequently akin to inflammation. Perhaps it may be more true that in some of these cases we actually have the initial stage of inflammation, of which the hæmorrhage proves the natural cure: strangling it in its birth; applying, in the very moment when it is most effective, that remedy which, in the last lecture, I told you was the most potent of all the remedies of inflammation; namely, *loss of blood*.

Passive Hæmorrhages.—Passive hæmorrhage on the other hand is characterized by circumstances of an exactly contrary nature. It occurs in those who are naturally feeble, or who have been debilitated by disease, fatigue, insufficient nourishment, great evacuations, or the depressing passions. It is not, in general, announced by any precursory symptoms, nor attended by any re-action. The effused blood is of a dark colour, serous, and but little disposed to coagulate: and it often is poured forth from several parts of the body at the same time. If the quantity lost be at all considerable, the natural debility of the patient is rapidly augmented: his face becomes pale, and his body loses its heat. The hæmorrhage leaves him in a worse condition than that in which it found him. The flow of a certain quantity of blood is not, as in the cases of *active* hæmorrhage, suspensive of its farther effusion; frequently, indeed, passive hæmorrhage resists the means opposed to it the more, in proportion as it has continued longer, or been more profuse.

Symptomatic Hæmorrhages. — Hæmorrhages of the kind I have now been describing—that is to say, depending upon no palpable disease of any organ, and, therefore, idiopathic—are of no uncommon occurrence, whether we regard the active or the passive form in which they appear: but by far the greater number of hæmorrhages by exhalation are *symptomatic ;* that is, they result from some previous disease, either in the organ from which the blood proceeds, or some other organ connected therewith by some community or dependence of function.

These secondary or symptomatic hæmorrhages are preceded by congestion, but for the most part the congestion is not of the active, but of the mechanical kind; and has more to do with the veins of the part than with the arteries.

Thus we have hæmorrhage from the bronchial membrane, in consequence of crude tubercular matter in the lungs, filling up a portion of the pulmonary tissue, and obstructing the circulation of the blood through it. This is an example of symptomatic

hæmorrhage by exhalation, depending upon previous disease in the organ itself from which the blood proceeds.

In some of these cases the presence of pyrexia renders it probable that the hæmorrhage is the consequence and the relief of active congestion, provoked by the irritation of tubercles ; rather than the result of a mechanical obstruction of the circulation.

Again, we have hæmorrhage into and from the lungs, as a consequence of such disease of the heart as mechanically impedes the return of the blood from the lungs to that organ : a narrowing of the mitral orifice, for instance. Here the blood is barred up, as it were, in the lungs, till at length the capillaries, incapable of farther distension, either give way ; or become so dilated as to allow of the exit of the blood through their exhalant openings, or through inorganic pores in their sides. In precisely the same way blood is poured out by the mucous membrane of the stomach and bowels, in consequence of disease in the liver, obstructing the portal circulation. These are examples of symptomatic hæmorrhage by exhalation, depending upon previous disease, not of the organ itself from which the blood proceeds, but of another organ intimately connected with the former.

When I say that hæmorrhage into and from the lungs may result from such a disease of the heart as implies an impediment to the circulation, you must not suppose that the lungs are the only channel through which the mechanical congestion can be relieved. Disease of the central moving organ of the circulation leads often, at length, to *universal* venous congestion : and the hæmorrhage, which is apt to be the consequence of such congestion, may burst forth from any part where the veins are so overloaded. Hæmorrhage from various portions of the mucous membranes are in truth very common effects of cardiac disease.

The influence of mechanical congestion as a direct cause of hæmorrhage is sometimes very distinctly seen in the bodies of persons who have been hanged. You know that when suffocation has been produced by suddenly cutting off the access of air to the lungs ; the right side of the heart, the great veins, and indeed the venous system generally, become loaded and distended with dark blood. Dr. Yelloly examined the stomachs of five men who had been executed by hanging : he found them all exceedingly vascular; and in two of the five cases, blood was actually extravasated, and adhering to the surface of the membrane : there had been, in short, unequivocal hæmorrhage.

There are several things, worthy of notice, in respect to hæmorrhage by exhalation, of whatever kind.

In the first place it occurs much more frequently and readily from some tissues of

the body than from others ; and most especially of all, from *mucous* surfaces. Thus we have hæmorrhage from the mucous membrane lining the nasal cavities ; from the pulmonary mucous membrane ; from the stomach and bowels ; from the urinary organs ; and from the uterus ; constituting distinct forms of disease, which we are by and by to investigate more particularly. *Epistaxis, hæmoptysis, hæmatemesis, melæna, hæmorrhois, hæmaturia, menorrhagia,* are names descriptive of hæmorrhage as it is apt to occur from different parts of one or other of the three tracts of mucous membrane met with in the body : and you will find that these comprise very nearly all the complaints enumerated by nosological writers under the head of hæmorrhagy.

Now, this is a very remarkable fact : and very interesting questions arise out of it. Has it any relation to the manner in which these membranes, and the tissues subjacent to them, are supplied with a capillary circulation ? Or may the fact be explained by the laxity of their attachment, which facilitates and favours the accumulation of blood in the vessels of the submucous tissue ? Or has the density or consistence of their natural exhalations any thing to do with this disposition to hæmorrhage in the mucous membranes ? May we suppose that the vessels or orifices appointed to exhale *mucus*, afford a more easy passage to the blood than those which give egress to thinner fluids ; serum, for example, or the cutaneous perspiration ? Whatever answers may be given to these questions, you will do well to recollect the fact which has suggested them.

Hæmorrhages by exhalation are not, however, exclusively confined to mucous surfaces. They are liable to occur, but much more rarely, from serous membranes. In the majority of cases, however, in which blood is found effused into any of the serous sacs, it has either been an event of inflammation, or the blood has been poured out from an accidental opening in some considerable vessel. Cutaneous hæmorrhage is also very rare ; probably because the cuticle opposes a barrier to the exit of the blood : for the little red spots which characterize purpura are in fact hæmorrhages, although the blood has not penetrated the epidermis. There are cases, however, as I mentioned before, in which blood has transpired, in a sort of dew, from the external surface of the body.

Another important general fact in respect to hæmorrhages by exhalation is that they proceed more frequently from certain parts of the mucous membranes than others, according to differences of *age*. Thus in children they are most common from the membrane that lines the nasal cavities : in youth from the mucous membrane of the lungs and bronchi ; in the middle years of life, and

towards its decline, from the rectum, uterus, and urinary organs. I should add here, from the blood-vessels of the brain, in old age; except that this, as I have already intimated, is not (speaking generally) hæmorrhage by *exhalation*.

Of course when I say that, in the instances specified, the blood is commonly poured out by exhalation, you will understand that the hæmorrhage sometimes occurs from the laying open of a single vessel of some magnitude. Thus hæmorrhage from the fauces may be the result of ulceration there, which has penetrated the coats of a vein or artery: hæmoptysis is occasionally produced by the laceration of a blood-vessel during the softening and expulsion of tubercles. Hematemesis sometimes is the consequence of the lesion of a considerable blood-vessel in the progress of cancer of the stomach, or by the extension of small corroding ulcers; hæmorrhage from the bowels is no uncommon effect of ulceration, such as happens in fever, of the mucous follicles of the small intestine; calculous matter in the kidneys will often lead to the rupture of some of the blood-vessels there, and to the discharge of blood by the urethra. Aneurisms also may burst into almost any part of the body. But events of this kind are infrequent when compared with hæmorrhage from the same parts in the way of exhalation.

In the head, however, the ratio is reversed. Blood does sometimes, I believe, exude from the *membranes* of the *brain*, but much more commonly cerebral hæmorrhage is caused by the giving way of a diseased *artery* in the brain.

How, in all these cases, to distinguish whether the blood has oozed out by many orifices from a surface, or has escaped from a hole in the sides of a vein or artery, will form matter for future inquiry. Sometimes we *can* make the distinction; and sometimes, it must be confessed, we cannot.

You will readily understand that hæmorrhage must vary greatly, in respect to its importance, and to the danger which it implies, according to the part from which it proceeds, and the circumstances under which the blood is poured out. It sometimes happens that death ensues from the mere loss of blood; either at once, by one profuse bleeding, or more slowly, by repeated bleedings which we are unable to restrain: but this is comparatively rare, and when it does happen, the blood is generally found to have proceeded from one considerable vessel, which has been ruptured or eroded. The ease approximates to traumatic hæmorrhage, except that we cannot cut down upon and tie the injured vessel. Much more commonly danger arises from the presence and pressure of the extravasated blood in and upon internal parts: upon the brain, for example,

in cerebral hæmorrhage; in the lungs in pulmonary.

The symptoms also are liable to much variation in different cases. Even the diagnosis of hæmorrhage is not always equally easy, or certain. When the part into which the blood is directly poured communicates with the exterior of the body, the expulsion of some of that fluid will, generally, sooner or later, demonstrate the case to be one of hæmorrhage. I say *generally*, because cases have been known to occur, in which patients, previously in a state of great weakness, have died outright, by syncope, from the mere extravasation of the blood, and before any of it made its way out of the body. The stomach and bowels have been found full of blood, when none had passed either by vomiting or by stool. And when the blood does make its appearance outwardly, it is sometimes not easy to determine whether it has come from a certain organ, or from the parts that lie between the same organ and the natural outlet by which it ultimately escapes. For instance, it is sometimes a matter of uncertainty whether the blood, in hæmaturia, proceeds from the kidneys, or the bladder, or the urethra.

The blood itself, when it reaches the exterior, will generally be more fluid, and brighter, in proportion as it is effused in greater quantity, and nearer the surface: more in clots, and darker in colour, in proportion to the length of time that it has remained within the body after its escape from its proper vessels; and this length of time may depend upon the smallness of the quantity of blood effused, and the consequent tolerance of the organs through which it may have passed; or, upon the actual space traversed. Respecting the *colour*, however, of the effused blood, I shall have some curious explanations to offer you when I come to speak of hæmatemesis as a disease. It would be superfluous to enter upon them now.

If the site of the hæmorrhage does not communicate with the external air, we are without that certainty which results from the actual spectacle of the blood. But in such cases we are much assisted by local disturbances of function, springing from the pressure upon, or the laceration or distention of the suffering organ, or of the parts contiguous to it. And we may derive good information from observing the indirect symptoms which declare themselves through the system at large; many of which indirect symptoms are the same whether the blood reach the exterior or not. They principally vary according to the quantity of blood poured out, and to the *rapidity* of its effusion: and some difference will occur according to the age and strength of the patient.

Some of these indirect symptoms have not

always been imputed to their true cause. Paleness of the face, feebleness of the pulse, coldness of the extremities, and a tendency to syncope—symptoms which are apt to be connected with hæmorrhage—have sometimes been ascribed to the alarm and sense of danger which the sight of the blood is calculated to produce in the mind of the patient. This may, to a certain extent, be sometimes true; but the explanation cannot apply to those cases in which the hæmorrhage is strictly confined to the interior of the body, yet in which the symptoms just alluded to are often strongly marked. They *then* depend—and probably in all cases they *chiefly* depend—upon the actual abstraction of the blood from the circulation.

The management of individual cases of hæmorrhage must be mainly regulated by the particular circumstances under which they occur. The few observations that I have at present to make respecting their treatment cannot be otherwise than very general.

But a preliminary question, of some importance, presents itself. Is it in all cases of hæmorrhage proper, or safe, to attempt to stop the bleeding?

Without going into detail, it may, I think, be laid down as a rule, that what I have called habitual hæmorrhages ought not to be interfered with, so long as they have no perceptible injurious influence upon the health, and so long as they proceed (as they mostly do) from parts, of which the *structure* is not likely to be spoiled, nor the *function* impaired, by the repeated passage of the blood. The most common seat of these habitual hæmorrhages I have stated to be the rectum; —to which the two conditions just mentioned are, fortunately, both of them applicable. Epistaxis supplies a less frequent example of the same kind. When they deviate from their usual channel, and are transferred (as it were) to some more important organ, it will generally be right, among other remedial measures, to endeavour to *recal* the original hæmorrhage. It is very seldom that the metastasis takes place *for the better*,—i. e. from a part where the bleeding is attended with danger, to one where it is comparatively harmless.

However, when these habitual hæmorrhages happen, as they often do, in plethoric persons; and when they are urged and kept up, as they frequently are, by intemperate and luxurious habits; we ought not to content ourselves with merely looking on. Hæmorrhois often performs the office of a safety-valve in such persons; and there are many who have what are called bleeding piles, and who would rather continue to have them, than submit to any change in their mode of life, or to the employment of other means of evacuation. Certainly these are cases in which nothing should be done to stop the

bleeding; yet such patients ought to be told that the hæmorrhoidal discharge is but a precarious, and often an inadequate relief of the plethora: that while the plethora is suffered to exist there is danger of a cessation of the piles, and of the supervention of serious or fatal affections of other parts, and especially of the head. Apoplexy, or cerebral hæmorrhage, has frequently been known to follow hard upon the suspension of constitutional hemorrhois. The patients should be admonished also that the discharge of blood from the vessels of the rectum may become excessive; that if it be aggravated by exercise, or in any other way, it may lead to inflammation about the anus, and to great inconvenience; and that there are safe and tolerably sure methods of getting rid of the plethora (which is what chiefly constitutes the danger of such cases), if they will submit to the observance of them. It is in the intervals between the hæmorrhages that the danger of which they are in some sort the token, may best be met.

Again, it will seldom be proper to employ *direct* expedients for stanching the flow of blood, in the small class of active idiopathic hæmorrhages; unless the quantity lost is so great as to endanger the safety of the patient. Such hæmorrhages have commonly a tendency to cure themselves, by relieving the general plethora, or the local congestion, on which they depend. For these hæmorrhages, which bear so strong an analogy to inflammation, the *treatment* of inflammation may often be requisite, as an indirect mode in which their amount may be moderated, and their recurrence obviated.

With these exceptions, both direct and indirect measures are to be used, for arresting the effusion of blood as speedily as may be.

To this end the patient is to be surrounded as much as possible with cool fresh air, and kept in a state of absolute quiet. All motion of the body, and emotion of the mind, all kinds of stimulating food and drink, every thing, in short, which has a tendency to hurry the circulation, should be diligently avoided: and that position of the body should be chosen which is the least favourable to the afflux of blood towards the part affected. The horizontal posture will be proper in hæmorrhage from the bowels, the uterus, or the urinary organs. In epistaxis, and in cerebral hæmorrhage, the head should be raised.

In two words, the *antiphlogistic regimen* should be strictly enjoined in all cases of hæmorrhage sufficiently severe to require medical assistance.

Of the actual remedies used for checking the farther escape of the blood, one of the most important has already been alluded to— I mean venæsection. We are guilty of homœopathy in this matter: to prevent bleeding, we draw blood. After what was

stated respecting the use of blood-letting in inflammation, I need not dwell upon the objects aimed at by this measure : they are briefly, to abate the vigour and force of the heart's contraction, to lessen general plethora when it exists, to remove local congestion, and to divert the current of the blood from the suffering organ. The method, and the amount, and the repetition of the blood-letting, must of course be regulated by the circumstances of each particular case. And the same objects may sometimes be effected by other modes of general depletion, especially by the use of purgative medicines.

Next to blood-letting, *astringents* constitute the great resource against actually existing hæmorrhage : and among these, *cold* is one of the chief. It may be placed in direct contact with the bleeding surface :—as when ice is *swallowed* to restrain hæmatemesis : or cold water injected into the rectum in excessive and exhausting hæmorhois ; or into the vagina, in flooding from the uterus. Or it may be applied to the surface of the body, as near as possible to the seat of the hæmorrhage; as to the nose and forehead in epistaxis; to the chest in hæmoptysis; to the epigastrium in hæmorrhage from the stomach ; to the lower part of the abdomen or to the perinæum in hæmorrhage from the intestines, uterus, or urinary organs. But the influence of cold in constringing the smaller vessels is not confined to the part with which it is in contact ; it will stop hæmorrhage by the sympathetic shrinking which it produces in distant parts. Epistaxis, for example, has often been arrested by the sudden apposition of cold water to the neck, back, or genital organs. The nursery remedy consists in slipping a cold key down the back between the clothes and the skin.

Of even the mischievous power of cold in this way we have continual illustration in the suppression of the catamenia by cold and wet accidentally applied to the feet.

There is a long catalogue of medicinal substances which are esteemed to possess more or less of a specific virtue, when taken internally, in checking the flow of blood. Most of these are of an astringent nature, and some of them are eminently useful. The acetate of lead enjoys, in this country, a higher character, perhaps, than any other of these substances.

Many vegetable matters, and some artificial compounds, frequently employed in internal hæmorrhages, seem to owe their astringent and styptic properties to the gallic acid which enters into their composition. Such are the rhatany root, uva ursi, bistort, tormentil, the pomegranate, kino, catechu, the several preparations of gall-nuts, and the nostrum called *Ruspini's styptic*.

The power of arresting internal hæmorrhage has also been confidently ascribed, by

different persons, to nitre given in large doses, to the mineral acids, to the muriated tincture of iron, to alum, to the oil of turpentine, to the secale cornutum or spurred rye, and to various other substances ; a more particular account of the rules and indications for administering which, I may return to, when I have to speak of individual hæmorrhages.

LECTURES
ON
MORTIFICATION,

Delivered in the Medical Theatre at St. George's Hospital,

By Sir Benjamin C. Brodie, Bart. F.R.S. &c.

Lecture II.—Dec. 2d, 1840.

Mortification from Strangulation or Ligature.

I now call your attention to some other varieties of mortification.

A ligature drawn round any part of the body, so as to intercept the communication with the great vessels and the heart, may cause that part to perish. But the effect of the ligature is not the same in all cases ; and it does not always produce mortification in the same way. You apply a bandage round the arm before you bleed a patient, to make the veins of the forearm become distended, the object being merely to stop the circulation in the superficial veins. If you take it off at the end of a few minutes, the hand is at once just as it was before the ligature was applied. If you were to leave it on for twelve hours, the whole hand and forearm would become swollen, and would remain swollen for some time after the bandage was removed. The swelling in such a case arises from the congested state of the veins, and from the consequent effusion of some of the serum of the blood into the cellular membrane. If the ligature round the arm be still tighter, so as to obstruct the circulation to a greater extent, but without arresting it altogether, the same effect is produced, namely, serous effusion, which may continue for some time after the cause which produced it is taken away. The first effect, then, of a ligature which obstructs the circulation without arresting it completely, is to produce serous infiltration of the cellular membrane, and an œdematous swelling. The different kinds of dropsy depend on the same principle. Disease in the heart, impeding the circulation through it, gives rise to anasarca of the legs, and dropsy of the pericardium and pleura. Disease of the liver produces dropsy of the peritonæum.

But let us suppose that a ligature is applied in this manner round the arm, and allowed to remain, so that the impediment to the circulation continues. A low sort of inflammation is set up, the œdematous swelling and the tension are aggravated, and this may terminate in mortification.

This is one kind of mortification from ligature. But let us suppose that the ligature is drawn tighter still: that it completely intercepts not only the venous, but the arterial circulation. It is evident that the part below the ligature, being altogether deprived of that supply of scarlet blood which is necessary to the maintenance of vitality, must lose its vitality: and this, then, is another way in which a ligature produces mortification.

In the course of your practice you will meet with numerous cases illustrative of the different effects of ligatures according to the degree of constriction which they occasion. Thus, a woman has a femoral hernia. A large portion of intestine is protruded through the narrow crural ring in the act of coughing. The ligature is as tight as possible. The strangulation is complete. The arterial circulation as well as the venous is completely obstructed. If you perform the operation for strangulated hernia on such a patient, even in half an hour, you may find the intestine dead. But if (as generally happens) the degree of constriction is less, in consequence of the opening being larger, or the protruded intestine being smaller in quantity, then the venous circulation is obstructed more than the arterial; there is no mortification immediately: there is venous congestion, followed by inflammation, which may end in mortification in the course of two or three days, or, perhaps, not until after the lapse of a longer period. A man has a phimosis. He pulls back the præpuce, and the orifice becomes a stricture behind the *corona glandis*. There is venous congestion. The glans is swollen, assumes a purple colour, then becomes exceedingly inflamed, and that inflammation is followed by mortification. Again, a patient has internal piles. They protrude at the anus; the sphincter muscle acts spasmodically upon them. They cannot be pushed back through the sphincter: the return of venous blood is prevented; they swell, inflame, and, in the course of a few days, they mortify. By and by the slough drops off, and the disease is cured.

You will now understand the principle which ought to be kept in view when we use ligatures in surgical operations. You cure internal piles by a ligature. If you draw the ligature only moderately tight, you do not kill them at once: they swell: they inflame: they may die at last, but not till after a painful and tedious process. But if the ligature be drawn as tight as possible,

it stops the flow of the arterial as well as of the venous blood, and the piles die directly. This is the way in which a ligature should be applied in almost all cases of surgical operation: it should be drawn as tight as possible. In dealing with piles, or nævi, or tumors of the tongue, the tighter you draw the ligature the sooner the sufferings of the patient are over. If you do not draw it tight, he suffers for a very long time, and very greatly; nay, perhaps severe constitutional symptoms may ensue.

I have said that when you apply a ligature in a surgical operation, your object should be to stop the flow of arterial blood at once; and you might suppose that if the ligature were kept on for half an hour, or an hour, that that would be sufficient; that the part being deprived of the flow of arterial blood for such a time it would certainly lose its vitality. But this is not exactly the case. You apply a ligature round an artery, draw it as tight as you can; it divides the middle and inner coats, but only compresses the outer coat. It makes a slough of a little piece of the latter; and when the ligature comes away at the end of ten days, or a fortnight, you find the slough in it. But if you cut off the ligature in half an hour, or an hour—an experiment which has frequently been made—there is no slough. The artery may be obliterated, or it may not, by the effusion of lymph; but the piece of the outer coat that was included in the ligature recovers itself; at least it does not come away as a slough. I once had occasion to observe the same thing illustrated on a larger scale. I had a patient with a malignant tumor of the tongue, which, according to the method suggested by Sir Everard Home, I determined to remove by ligature. I drew the double ligature as tight as I could; and when I saw the patient half an hour afterwards, the piece of the tongue included in the ligatures was quite livid, and apparently dead. I saw him again in three or four hours, and found him suffering a great deal of pain and inconvenience. It occurred to me that the piece of the tongue had been dead for some time, and that I should, perhaps, give relief by cutting off the ligature. With some little trouble I succeeded, but, to my great annoyance, the next day I found the whole piece, which appeared to be dead, alive again. The ligature, therefore, in surgical operations, must be drawn as tight as possible, and then left on until it is separated by a natural process.

Mortification from pressure.

Parts may be killed by pressure. The mode of death here is nearly the same as when parts are killed by ligature. The difference being simply this: the pressure is like a ligature applied to a broad surface, operating not on the arterial and venous

trunks, but on all the small vessels and capillaries. Mortification from pressure is chiefly observable when the pressure is made on parts which lie over a bone ; where there is no cushion of flesh between the skin and the bone. If the pressure be very tight, it may produce mortification immediately. I remember that when I was a student, a man came into the hospital with a fracture of the leg. The surgeon applied splints, and drew a bandage over them round the foot as tight as possible. The next day the man was in a great deal of pain and suffering. The bandage was removed, but it had already occasioned a broad slough of the skin over the instep. I have in other instances seen sloughs produced in the same manner, as it were instantaneously, in consequence of bandages being applied too tight.

But in the great number of cases where mortification is the result of pressure, it does not occur immediately, but after the lapse of some time ; and it is not a direct, but a secondary consequence of the pressure. A man, for instance, is bed-ridden ; he lies on a hard mattrass ; he becomes very thin ; the skin over the os sacrum becomes tender to the touch, it inflames, assuming a dark red colour ; vesications form upon it ; the inflammation goes on, and ends in mortification. Hence, though pressure may produce immediate mortification in some instances, yet in ordinary cases it does so by causing inflammation first, which inflammation, the pressure being continued, ends in the same manner.

This kind of mortification from pressure takes place under certain circumstances more readily than under others. A man is weakened by continued fever, and, from the state of debility in which he then is, pressure on the skin over the os sacrum and other projecting parts of bone will produce mortification, while it would not produce it if he were in vigour and health. After injuries of the spinal cord, mortification from pressure is very readily induced. A man has the spinal cord torn through in the middle of the back ; and you find, almost before you suspect that there is any thing wrong, a great slough over the sacrum. Nay, the pressure of the mattrass against the ankles will, in such cases, produce mortification. I have known mortification begin in the ankle within twenty-four hours after an injury of the spine ; and a remarkable circumstance it seems to be, that injuries of the spinal cord should thus lessen the vital powers, so as to make the patient liable to mortification, when we consider how many circumstances there are that would lead us to doubt whether the nerves have any influence over the capillary circulation. The circulation, viewed by a microscope, in a frog's foot, goes on just the same whether the nerves are divided or not. In an experiment which I

was making on poisons, I divided all the nerves in a dog's axilla ; I then divided all the skin which was attached to the anterior extremity, and then the muscles and cellular membrane, so that there was an absolute want of union between the extremity and the trunk, except by means of the axillary artery and vein, which I left untouched. The animal, at the expiration of twenty-four hours, was killed ; but the limb maintained its vitality perfectly all the time. In spite, however, of this and of other circumstances which I might mention of the same kind, a concussion of the spinal marrow makes the patient liable—and sometimes almost immediately—to mortification of the parts below.

Patients are more or less liable to mortification from pressure, accordingly as they are more or less emaciated. A man with a good cushion of fat between the skin and the os sacrum, or the skin and the great trochanter, is not so liable to the formation of sloughs in those parts as a thin one ; and that for obvious reasons.

When you suspect that pressure on any part is so great as to be likely to occasion mortification, you can do nothing but remove the pressure. When a bandage is placed in a case of fracture, you must remove it as soon as you suspect that the swelling of the parts has made it very tight, lest mortification should follow. When a patient has been so long confined to his bed, that you expect mortification will take place, you must endeavour to guard against it. It is more easy to prevent it than to stop it when it has once begun. How, then, is this to be accomplished ? If a patient lies on his back, the skin sloughs over the os sacrum ; if on one side, then it sloughs over the great trochanter. Endeavour, when he can manage it, to make a patient vary his posture. If he can be shifted, let him lie at one time on his back ; at another, on his side : nay. let him turn round, and lie occasionally on his face. If you have what they call a prone couch, properly constructed for the purpose, he may, in many instances, use it to great advantage. In one of the worst cases of this kind, when mortification had begun, I used to turn the patient on his face many hours in the day, and with perfect success. But sometimes the patient cannot be shifted. There may be fracture of the thigh, and he must lie always on his back. You must then endeavour to take off the pressure by other means—by an air cushion with a hole in the centre, the tender part over the os sacrum being in the hole of the cushion. But in all cases where you use an expedient of this kind you should first apply a piece of common soap plaister, spread on calico, over the part, to support it. If you merely place the hole of the cushion under the os sacrum, the skin will bulge into the hole, and the patient will

lie as bad as if there were no hole at all, or even worse. The same rule applies to all cases where you use contrivances to take off pressure, as in those of corns and bunnions. In cases where you can have recourse to it, the water-bed is very useful in preventing mortification from pressure. Dr. Arnott's hydrostatic or water-bed diffuses the pressure every where. When you lie on a mattress, the pressure is thrown on all the prominent parts of the body, and little elsewhere; but in using the water-bed the water rises to fill up the hollow places, and the pressure is not greater on the sacrum than on other parts. No doubt this bed is the best method which has yet been contrived for preventing mortification from pressure—the only objection to it is, that it is not applicable to all cases. In cases of compound fracture of the thigh or leg, for example, it would not give sufficient steadiness to the injured limb.

But another plan may be adopted to prevent mortification from pressure—that is, to prevent the inflammation which precedes it. The thicker the cuticle the more it will protect the parts beneath it. You may, if you attend to it in time, add to the thickness of the cuticle by stimulating the surface of the skin. Nurses know this very well, for when patients are bed-ridden they wash the parts subjected to pressure with brandy. What is better, is a lotion composed of two grains of the oxymuriate of mercury to an ounce of proof spirits. When you think that a patient is likely to be confined so long in bed that there may be mortification from pressure, wash the parts two or three times a day with this lotion. I have found it useful in other cases where a patient suffers from pressure. A man has a rupture which requires to be supported by a very powerful truss. It galls and frets the skin, and may at last cause inflammation and sloughing; but under the use of the lotion, a thicker cuticle is generated, and this mischief is avoided.

The sores which remain after the separation of a slough produced by pressure, are to be treated like common sores; this being kept in view, that the skin will slough again if the pressure be continued. You must, if possible, contrive to take the pressure off these sores; but, unfortunately, it is not always possible for you to do so, and in spite of all your care and trouble slough will form after slough, exposing the sacrum or trochanter, or other bony structures, whatever they may be.

Mortification from contusions and traumatic gangrene.

I now come to speak of mortification from a blow or other mechanical severe injury. It may be said that pressure is mechanical injury, but I now speak of a sudden injury operating for a short space of time, such as a contusion or a wound.

The effect of mechanical injury may be to produce mortification, which is confined to the parts actually injured. For instance, a man gets a kick on the shin, and the next day there is a slough, and the skin is dead, just where he was kicked. Why? Because the kick bruised the skin against the bone, ruptured the capillary vessels, and destroyed the organization in the part, so that life could not go on. But here the mortification is confined to the part actually injured. A remarkable circumstance happens in some of these cases. The cellular membrane has not so much vitality as the skin, and therefore perishes more easily. A blow will disorganize the cellular membrane which will not disorganize the skin. A man came into the hospital who had had a severe blow on the instep; there was a purple appearance, but no very extensive ecchymosis, and I thought nothing of it. The next day I found the part inflamed, the following day there was a good deal of swelling, and on the third day the skin was beginning to slough. I divided the skin with a lancet, and found a large slough of the cellular membrane. The blow had pressed the skin and the cellular membrane against the bones of the instep, and had killed the latter but not the former. The slough of the cellular membrane would have been followed by an extensive sloughing of the skin if, acting on the principle explained in my last lecture, I had not divided the latter freely. In cases in which you suspect that the cellular membrane may be destroyed while the skin is not, you must watch the patient, and if there be swelling and inflammation you should divide the skin, and save it from perishing as far as you can, though you cannot save it entirely.

But in other cases the mortification is not confined to the part actually injured, but may extend to the greater part of the limb. These are the cases to which the name of traumatic gangrene is applied. A man sustains a severe injury in the leg, and a great part of it mortifies. It would appear that the mode in which traumatic gangrene is produced varies in different cases. Mr. Guthrie, for example, describes a case in which mortification of the leg took place as high up as the knee, in consequence of a blow on the back of the leg. The limb was amputated, and when he came to dissect the parts it was found that the blow had lacerated the lining membrane of the popliteal artery, in consequence of which there had been effusion of lymph into the cavity of that vessel, stopping it up. That alone might not have produced mortification, but the anterior and posterior tibial arteries were torn through also, and the result of this double injury was that the limb, not getting a proper supply

of blood, perished.   In this case the pressure of extravasated blood might have contributed, in some degree, to produce the mortification.   But local extravasation of blood, if it exist to a great extent, is, of itself, sufficient to produce this effect. When I was house-surgeon a man was brought into this hospital with some kind of tumor about the groin, but no pulsation was felt in it, and no one suspected that it was an aneurism. There was severe pain felt in the thigh, evidently arising from pressure on the anterior crural nerve, and the event proved that there was an aneurism, though it had not been indicated by the usual signs. It burst one day into the cellular membrane; the man screamed out as if he was being murdered, so horrible was the pain.   The next day there was gangrene as high up as the groin, and the man died in about a fortnight.   On dissection we discovered an aneurism of the internal iliac artery, which had burst under Poupart's ligament. The extravasation of blood had prevented the circulation from being carried on in the limb, and hence it mortified.   There was a man in the hospital, long ago, who had popliteal aneurism. I had fixed the day for tying the femoral artery; but on the day previous to this, the aneurism burst into the calf of the leg, and the next day the limb was in a state of mortification ; so that instead of tying the artery I amputated the leg. The vessels below were all quite pervious, and the circulation would have gone on very well but for the pressure produced upon them by the immense extravasation of blood. No doubt, in many cases of traumatic gangrene, this is one principal cause of the mortification.

But traumatic gangrene takes place in another way, and, to illustrate what I mean, I will mention the circumstances of a case which occurred in the hospital some few years since. A poor boy was jumping over a ditch, and came with considerable force upon his feet. There was a compound fracture of the leg above the ankle. The external wound was trifling, but it was evident that a great shock had been given to the foot and the leg. Four days afterwards the limb was in a state of mortification as high as the knee, and the mortification seemed to be extending to the thigh. I amputated the thigh as high up as I could, near to the great trochanter.   We dissected the limb very carefully. The large arteries, and also the large veins, were quite pervious. There was, in fact, no injury whatever to the arterial trunks : but the cellular membrane, the muscles, and, in short, all the structures, seemed to be more or less disorganised. There were spots of ecchymosis in the large nerves ; the periosteum was universally detached from the fibula, and very nearly so from the tibia.

How does the periosteum adhere to the bones ? By the small vessels. It is evident, then, that the shock of the accident must have occasioned a great injury to the small vessels connecting the periosteum to the tibia and fibula, and the probability is, that the same kind of injury inflicted on all the capillary vessels of the limb laid the foundation for the mortification. I do not see how the occurrence of mortification in cases ike this can otherwise be explained.

It has been a sort of *dictum* of the schools of surgery, that you should not amputate while mortification is going on; and certainly, when there is mortification from ossified arteries (as I shall hereafter explain), or where there is mortification from inflammation, you ought to wait for the mortification being stopped, and for the formation of a distinct line of separation, before you proceed to an operation.   But it must have been palpable to everybody who took the pains to consider the subject, that this rule would not apply to all cases of mortification. For example, a man has a strangulated hernia ; when you open the sac you find the omentum strangulated, a part of it dead, and the mortification still extending.   You would not hesitate in a case like this to cut off the dead and dying omentum. If piles were undergoing the process of mortification from being strangulated by the sphincter muscle, you would not hesitate to cut them off. You may conceive many other cases, in which the cause of mortification is local, and to which the general rule which I have just mentioned does not apply. Baron Larrey has the credit of having pointed out more distinctly than had been done before, that where there is mortification from local injury you may venture to amputate, though the mortification is still spreading. But I apprehend that the operation must be had recourse to at once, and that the case admits of no delay.   If in consequence of local injury to a limb mortification has begun, but has not yet produced any severe shock on the system, there you may amputate. But where the mortification has been going on for some days, so that the system has begun to be influenced by it, the pulse getting weak, perhaps intermitting, and with great prostration of strength, in such a case you must not venture to amputate. Under such circumstances it is probable that the system is not in a state to bear the additional shock of the operation. However, I believe that cases enough may be adduced to prove that Baron Larrey's rule of not waiting to amputate till the mortification has stopped, is applicable in a great number of instances where the disease arises from local injury. It is good in theory, and there is now sufficient experience to enable us to say that it is good in practice also.

A FURTHER ENQUIRY
INTO THE
ACTIONS OF THE OBLIQUE MUS-CLES OF THE EYE.

BY C. RADCLIFFE HALL, MANCHESTER,

[*For the London Medical Gazette.*]

THE existence in most mammalia of the suspensory muscle of the eye, must more or less complicate any results that may ensue from the division of other orbital muscles. The only experimental mode of obtaining decisive conclusions applicable to human physiology, appears to consist in stimulating the individual muscles themselves, or the nerves from which they derive their motor energy. In a previous paper,* I have stated the results obtained by the latter mode of experimenting on the dog and cat, and as the anatomical distribution of the third and fourth nerves, as far as the muscles are concerned, is the same in these animals as in man, it seems fair to conclude that similar effects would be produced by like experiments in the human being. In the dog and cat, whenever the eye-ball is retracted by the suspensorius, the rudimentary membrana nictitans (the haw) is protruded. The sixth nerve supplies the suspensorius and rectus externus exclusively; hence, when galvanism was applied to this nerve, the eye-ball was retracted, the haw projected, and the cornea directed outwards; in man, the last— eversion of the cornea—would have been the only effect. The principal conclusions arrived at by Mr. Duffin, from division of the tendons of the various orbital muscles in dogs, as stated in a late number of your GAZETTE, appear to be the following :—

1. When all the orbital muscles are in a sound and healthy condition, division of the adductor or abductor causes the antagonist muscle to contract in the fullest degree of which it is capable, producing strabismus, and "the movements of the eye-ball, in the direction of the cut muscle will be wholly destroyed."

2. "The oblique muscles take very little part in the lateral movements of the eyes."

3. When the internal rectus is divided, the obliques have no power of

inversion; and when the rectus externus is cut through, the pupil becomes less inverted than it is everted on the division of the adductor,—a difference in degree attributed to the combined action of the two obliques, which are supposed by Mr. Duffin to assist the rectus externus. The power of inversion possessed after the common operation for convergent strabismus is ascribed more to the "acquired influence of the inner fibres of the superior and inferior recti, than to the action of the oblique muscles."

4. When the inferior rectus was divided, three days elapsed before the cornea was displaced upwards by the action of the superior rectus.

5. Division of the superior rectus caused no alteration in the position of the cornea.

6. On division of all the straight muscles, "the pupil remained fixed in the visual axis of the orbit : *** it was quite impossible to decide what influence the oblique muscles exerted, or whether they produced any special movement at all. It was clear, however, that they neither drew the eye towards the outer nor the inner angle of the orbit."

7. On division of the superior oblique and internal rectus muscles, the eye-ball protruded considerably, and the pupil—" dilated in a most extraordinary manner "—was drawn diagonally outwards and upwards. This diagonal direction of the pupil is attributed to the contraction of the inferior oblique when unopposed by the trochlear.

8. Division of the inferior oblique and internal rectus caused protrusion of the eye-ball, and the pupil was directed outwards but not upwards; and in this situation it remained immoveably fixed.

The experiments, from which I have abbreviated the above conclusions, appear to have been performed skilfully, and with every due precaution, and were doubtless observed with the utmost accuracy, but the results prove, I conceive, how difficult is the application of inferences so obtained to account for the action of the orbital muscles in man. Sir C. Bell divided the superior rectus in the rabbit ; the eye remained stationary. In a short time, however, the pupil was depressed, and the animal had no power of raising it. Sir Charles accounts for this, by considering that during the experi-

---

* Medical Gazette for October 16, 1840.

ment, the eye was spasmodically fixed
by the general action of the muscles,
and particularly by the powerful re-
tractor.* Neither this result, nor those
marked above, 4 and 5, would have oc-
curred on the human subject. Instead
of the marked protrusion of the globe
and dilatation of the pupil which Mr.
Duffin found to attend the division of
either of the oblique muscles in the
dog, Mr. Bransby Cooper states that
the result of dividing the oblique in
the rabbit was "the permanent re-
traction of the globe within the orbit,
its depression on the floor of that cavity,
the contraction of the pupil, without
however any lateral direction."†

A careful examination of the ana-
tomy of the oblique muscles would
seem to leave little doubt as to their
principal actions, but from the inac-
curacy of many plates of the orbital
muscles in man, they might have been
sketched from dissections of other ani-
mals. The exact situation of the inser-
tions of the two obliques differs according
to the obliquity with which the eyes are
placed in the head. In the sheep, for in-
stance, the tendon of the superior oblique
is inserted between the cornea and the
greatest transverse diameter of the
globe; in birds, also, it is anterior to
its point of attachment in man; whilst
in fishes, in which the eyes look almost
directly outwards, the arrangement is
peculiar. In the cod-fish and haddock
the obliqui pass from behind forwards
and outwards, and are both inserted on
the outer part of the eye-ball a few
lines distant from the cornea. The su-
perior oblique has no pulley, but the
circuit which it makes over the globe
probably gives it to some extent the
power of rotating the eye outwards,
whilst its insertion posterior to the
transverse central line—as in man—
is unnecessary, on account of the dif-
ferent direction in which the muscle
acts. The inferior oblique, by drawing
the outer and front part of the eye-ball
downwards, backwards, and inwards,
the other muscles being passive, would
produce the direction of pupil by which
the fish seems to endeavour to exclude
too strong a light. I concentrated the
rays of the sun on the eye of a gold
fish, both in and out of water, without
producing the least change of size in
the pupil, and the fish betrayed no other

evidence of the light being unusually
strong, than by drawing the lower part
of the globe inwards and rather back-
wards so as slightly to conceal the inner
and lower portion of the pupil, and, at
the same time, to project the upper part
of the globe. This, I conceive, was
due to the action of the obliquus in-
ferior, which, in this case, would sub-
serve the same purpose which it does
in man by the opposite means of di-
recting the pupil upwards and inwards.
Such a motion in the fish, having no
eye-lids, would defeat the intention,
and as strong light invariably enters
the water from above, the means though
slight seem well adapted to fulfil the
end in view. If the globe of the hu-
man eye be distended to its natural
size by mercury, or wax, and the in-
sertion of the oblique muscles accu-
rately dissected, no one can question
that they both pass from within out-
wards and backwards, and are con-
nected to the sclerotica posterior to its
greatest transverse diameter. Assum-
ing other muscles to be passive, and
the eye-ball to be capable of partial
revolution on the optic nerve as its
axis, the shortening of the tendon of
the superior muscle draws the outer and
back part of the globe forwards and
inwards, and throws the cornea into
just the reverse direction. If the infe-
rior oblique possessed just the same
direction as the last, its action should
be that of directing the cornea up-
wards and outwards; but its origin is
considerable, and extends within the
orbitar ridge beneath the eye-ball, as
far back as the roof of the infra-orbi-
tar canal, so that most of its fibres pass
much more directly backwards and
upwards, than does the tendon of the
obliquus superior backwards and down-
wards. Its insertion, also, is more ex-
panded, and commencing more ante-
riorly, extends closer to the optic nerve
than that of the superior oblique.
Hence, the effect of shortening the
fibres of the inferior oblique is that of
depressing the outer and posterior part
of the globe, and drawing it slightly
forwards, thus producing a slight rota-
tion of the eye-ball on the optic nerve,
and directing the cornea upwards and
inwards. Acting alternately, the two
muscles produce the rotatory move-
ments, but contracting together they
tend to draw the globe slightly for-
wards and inwards.

In the ape, the eyes are directed forwards, and their muscles resemble in number and arrangement those of the human eye. Having obtained a full-grown monkey, I made the following experiments in the presence of Mr. Turner (lecturer on Anatomy and Physiology), Mr. Hunt (lecturer on the Eye). Messrs. Furnival, Redfern, and other professional friends.

Dec. 4th. The left eye operated on.

Obs. 1. The inferior rectus was divided—the cornea became directed slightly more upwards than that of the opposite eye.

Obs. 2. The internal rectus was cut through—the eye was drawn outwards for an instant, but resumed its previous situation immediately.

Obs. 3. The superior rectus being divided, the cornea assumed a directly central axis.

Obs. 4. The eye could still be inverted, but not nearly to the full extent, and could be directed diagonally upwards and inwards, but not at all directly upwards. There was complete power of eversion, and the pupil could be directed diagonally downwards and outwards, but not directly downwards.

Obs. 5. The rectus externus was then divided, by which all power of direct eversion was destroyed, but the cornea could still be directed downwards and outwards, though not to the extent that existed before the commencement of the experiment. The cornea, when the attention of the animal was not excited in an opposite direction, was fixed upwards and inwards, though not to the extent that could be induced in the other eye.

Obs. 5. The upper eye-lid was then cut through close to the edge of the orbit, and the tendon of the superior oblique brought forward by a curved probe and divided. The cornea was now directed upwards and inwards, but when the other eye was moved from side to side, slight vacillation was perceptible; but the cornea never passed more outwards than the central line.

Obs. 7. The pupils of both eyes simultaneously underwent changes, as the eyes were more or less exposed to the light, but no effect was produced on the iris by the section of any of the recti muscles, or of the superior oblique. It was thought that the pupils were more contracted after than before the infliction of the injury attending the experiment.

Obs. 8. The eye slightly protruded from the orbit, and the swollen condition of the eye-lids added to the appearance of protrusion.

Obs. 9. The direction of the cornea before closing the eye (the inferior oblique being the only muscle undivided) was upwards and inwards.

To afford a more satisfactory view of the eye, no incision towards the temple through the outer commissure of the lids, was made at the commencement of the experiment. On being set free, the monkey immediately picked off the adhesive straps which had been applied to the eye-lids, and thus left the upper part of the cornea exposed through the wound made in the upper lid for the section of the obliquus superior.

Dec. 10th. I was favoured by the presence of Messrs. Holland, Furnival, and Dorrington, surgeons.

The left eye-ball appeared rather sunk, and its cornea opaque through the wound in the upper lid which had not healed.

Right eye. The external commissure was divided, so as to give a better view of the eye-ball.

Obs. 10. The tendon of the rectus externus was cut through :—the cornea immediately became turned inwards, producing convergent squint. It could still be turned downwards and outwards to a certain extent, but all power of direct inversion was lost.

Obs. 11. The tendon of the rectus internus being divided, the cornea immediately returned to the centre: but, by attracting the attention of the animal, the cornea could still be directed inwards, but not to the same extent as it could before the section of the tendon.

Obs. 12. The tendon of the rectus inferior was divided :—the cornea was immediately directed upwards in the central line, so as to be half hidden when the upper eye-lid was not held up. It was difficult to excite the attention of the monkey so as to cause downward and outward motion, but this was, nevertheless, several times distinctly effected. The animal was readily made to move the cornea upwards and inwards, and to a slight extent, directly inwards, but generally the upward direction much predominated.

Obs. 13. The obliquus inferior was then cut through. No alteration from the upward direction and central situa-

tion of the cornea was perceived. The eye was several times caused to look downwards and outwards, and when the upper lid was much elevated, the cornea was occasionally raised upwards, and then more slowly lowered again to the horizontal median line, below which it was never depressed. No inversion, or any modification of inward motion, could be excited.

Obs. 14. No especial alteration in the size of the pupil attended the division of any particular muscle ; except that, on the division of the obliquus inferior, the pupil appeared for the instant largely dilated. This was probably owing to the greater pressure made by the probe on the eye-ball, which was twined half round to bring the inferior oblique into view. During the whole time the iris was in almost constant action, the pupil being alternately contracted and dilated : but its size before and after the experiment appeared the same.

The animal evinced no sign of suffering acute pain, except at the commencement during the cut through the outer commissure.

The altered direction of the cornea from the action of any muscle after the division of its antagonist, was never so marked in degree as in cases of similar obliquity, from severe strabismus. When the outer rectus, for example, was divided, no portion of the cornea was so much inverted as not to be distinctly visible, whereas in many cases of strabismus the internal commissure obscures a small portion of the cornea.

Eighteen hours from the performance of the last experiment, and seven days from that on the left eye, the monkey was destroyed by hydrocyanic acid. On making a careful dissection of both orbits, the following were the appearances noticed. Left eye :—the cornea had sloughed, its place being occupied by large pulpy shreds ; but the eye-ball had not completely collapsed. The wound in the upper eye-lid was not at all united. The swollen condition of the lids had in a great measure subsided. All the muscles but one were adherent to the remains of the globe, but the obliquus inferior was the only one inserted by its natural tendinous expansion. The tendon of the obliquus superior was lying loosely amongst some gelatinous coagulum posterior to the trochlea. The anterior extremity of

each of the other muscles presented a swollen linear eminence, in which the muscular fibres terminated abruptly, without any vestige of tendon. The adhesion to the sclerotica was less firm than it appeared, the slightest traction being sufficient to separate the end of the cut muscle from its new point of attachment ; when separated, the sclerotica presented no rough torn appearance at this point, but a smooth, slightly elevated surface.

Right eye. No swelling of the eyelids ; cornea quite clear: pupil dilated ; slight ecchymosis around the incisions. All the muscles except the superior rectus and superior oblique were perfectly detached from the eye-ball ; their anterior extremities being free, lying loosely on the sclerotica, a thin layer of coagulated blood intervening, but connected laterally to each other by rather firm cellular tissue. The insertions of the obliquus superior and rectus superior were in every respect natural.

From the above, I believe it may be justly inferred that the oblique muscles are subject to the will, and not purely involuntary. They are probably of the mixed class, since the revolving motions of the eye which accompany winking are certainly performed unconsciously. Sir C. Bell writes, " It would appear that the inferior oblique muscle has a power of elevating the cornea under the eye-lid, and causing the eyeball to revolve many degrees further than the rectus superior does."* From obs. 5, I am inclined to doubt the power of the inferior oblique to raise the cornea to a greater extent than the superior rectus, or even to the same extent. I believe that the action of the upper and inner rectus combined will produce a direct diagonal movement of the cornea upwards and inwards in a greater degree than the inferior oblique can ; and that the contraction of the external and inferior rectus conjoined will produce a direct diagonal movement of the cornea downwards and outwards to a greater extent than that of the superior oblique. I think it probable that the inferior oblique is the only muscle of the eye - ball in action during sleep, when the degree in which the cornea is turned upwards and inwards is less than the maximum of which the individual is capable. The difference between the action of the

---

* On the Nervous System, 3d edition, p. 159.

oblique and that of two recti combined, is, that by the former muscles, the globe is rotated on the optic nerve until the cornea attains its diagonal position, whilst the recti, though producing the same position, can only do so by acting in a straight line, since they cannot in any case cause the eyeball to revolve."[*]

In reference to strabismus,—in one case, after complete detachment of all the fibres of the rectus internus, the cornea remains still slightly inverted, but by a voluntary effort this inversion can be increased. In another case, after the operation, the cornea is in the exact visual axis, but can be voluntarily inverted to a certain extent. I refer the voluntary inversion in both cases to conjoint action of the oblique; the degree of inversion which remains in the first case, is probably owing—as Mr. Liston and Mr. Duffin suppose—to an acquired action of the innermost fibres of the superior and inferior recti.

To recapitulate in brief, may we not conclude, that the obliques are both muscles of the mixed class ; that the uncombined action of the superior obliquus is to rotate the eye to a downward and outward direction, which is less in degree than can be attained by the external and inferior rectus acting together ; that the superior oblique alone never abducts the eye ; that the inferior oblique, acting by itself, rotates the eye-ball so as to direct the cornea upwards and inwards, but not to the same extent as that which results from the full contraction of the superior and internal rectus combined ; that when both obliques act consentaneously, the recti being passive, the eye is slightly drawn forwards and inwards, and the cornea directed inwards ?

ŒDEMA of the FACE AND TONGUE, ULCERATION, &c.

To the Editor of the Medical Gazette.

SIR,

THE insertion of the following case in your widely circulated medical periodical, will greatly oblige, sir,

Your obedient servant,

JAS. SYME, L. R. C. S. Edin.

Alloa, Dec. 23, 1840.

Miss H——, a girl eight years of age,

moderately stout and generally healthy, having had scarlet fever in a form so mild that medical aid was deemed unnecessary, was allowed to go out soon after, as she seemed to be quite recovered : after being out her face was discovered to be slightly swollen, the quantity of urine passed was also observed to be very deficient. On account of these symptoms I was requested to visit the child, on the 2d inst. She had little or no fever, and the following powders were prescribed :—

℞ Submur. Hydrarg. ; Pulv. Scillæ, aa. gr. i. ; Digitalis, gr. ss. M. One to be taken at night, and one in the morning.

She had only taken four of the powders when the urine was observed to be quite natural in appearance and abundant in quantity, and the two remaining powders were not used ; so that she had four doses of calomel, containing one grain each, given at intervals of twelve hours. In about two days after she complained of her mouth being sore, which soreness rapidly increased, and, about the third day after taking the medicine, her face and tongue were greatly swollen, and the inside of the right cheek and lips severely ulcerated, at the same time saliva mixed with blood flowed in considerable quantity from the mouth. By the use of astringent gargles, decoct. sarsæ. &c., &c., she recovered in the course of eight or ten days.

In a case of this kind the medical attendant is exceedingly liable to be severely censured ; as it is generally presumed that these unusual symptoms have been occasioned by the injudicious or unskilful use of medicine. In this case it could not depend upon idiosyncrasy, for the child has had, on former occasions, larger doses of calomel, when no other than the ordinary effect was produced. But there are many instances on record, in which salivation has occurred, without any medicine having been previously taken. A case is mentioned by Dr. Huxham, in the Philosophical Transactions (which has been quoted, along with others, by Mason Good), of a man forty years of age, whose life was endangered by a spontaneous salivation. Might not the exposure of the child to cold so soon after scarlet fever affect the salivary glands ? It is certain the face was swollen before the child took any me-

---

* Vide Mr. Hunt's paper, in Trans. Prov. Med. Assoc. for 1836.

683.—XXVII.

2 N

dicine; it is equally certain that calo-
mel is prescribed by medical men of
all grades every day in *much larger* doses
to younger children; it is also very
often prescribed by midwives and
nurses in larger doses, and often without
any restriction as to confinement. But,
admitting that the medicine has really
been the cause of such an unpleasant
occurrence, it can only be regarded as
an extraordinary circumstance which it
is impossible to guard against, and for
which no man can be held responsible.
Another medical practitioner was called
to see the patient after the face and
tongue were swollen, who mentioned to
me that he had seen six times the
quantity of calomel in each dose given
to a child, and repeated several times
the same day with complete success, in
a case considered hopeless.

ON THE
POSITION OF THE PLACENTA.

To the Editor of the Medical Gazette.
Sir,

I beg to send you the following case
for publication, if you deem it of suffi-
cient interest to obtain a place in your
columns. It has special reference to a
very important point in the controversy
that has recently occurred between Mr.
H. Carmichael and Dr. Doherty, of
Dublin, respecting the position of the
placenta.— I am, sir,
Your obedient servant,
JOSEPH BELL,
Banhead, Dec. 15th, 1840.   Surgeon.

Dec. 9th, 1840. 9 o'clock, A.M.—
Mrs. L——, æt. twenty-three years,
stout active female, of fair complexion,
second pregnancy, has been troubled
all night with trifling pains, but they
have been more intense since 6 A.M.;
water escaped about fifteen minutes
ago; head is resting in perineum; no
puffiness, but slight wrinkling of inte-
guments of scalp; pulse 86. At half
an hour past nine o'clock, that is, half
an hour after I saw her, a female child
of ordinary size was expelled. After
the infant was separated, I supported
the uterus with both hands. At ten
minutes past ten o'clock, there being
no appearance of placenta coming away,
a half drachm of powdered ergot was
given in a little gruel; gentle friction

was made over uterus with the hand,
and a slight pull was given occasionally
to cord. The discharge of blood was
not much greater than usual, and the
uterus felt firm, but large: its fundus
reached the umbilicus. At fifteen
minutes to eleven, no change had taken
place, except the occurrence of a slight
pain, which expelled a few dark-coloured
clots from vagina. The hand was now
gently introduced into vagina, which
was partly filled with clots. Os uteri
was far up; its edges felt thick and
firm; it was contracted considerably;
the circumference of its outlet, I think,
would measure about four inches and a
half: at its posterior border there was
about an inch of the placenta hanging
into vagina. The fingers were gently
introduced into uterus, and carried up
along its anterior wall, to which the
placenta was found firmly and exten-
sively adhering. It was separated with
considerable difficulty, after which it
was immediately expelled along with a
few clots on its surface. The uterus
contracted firmly, and descended to hy-
pogastrium. No hæmorrhage followed;
a bandage and compress was applied;
the patient felt well; pulse 80.

The placenta was small, and pre-
sented on its uterine surface a number
of small, round, hard, whitish coloured
spots or granulations. In this case,
although, from the partially contracted
state of the uterus when the hand was
introduced, we cannot state with preci-
sion the distance that the placenta was
placed from the os uteri, yet we are
certain that it had its position on the
anterior wall of the uterine cavity.
The patient had no hæmorrhage from
uterus during pregnancy, and that
which occurred after birth of child was
not excessive; by no means so profuse
as it generally is in cases of partial
placental separation. All the blood
lost would not amount to more than
thirty ounces. Both mother and child
have as yet done well.

I may mention that I attended this
woman in her former confinement, on
the 20th of January last. She had then
a tedious labour. The child was still-
born; and from the abraded state of
the cuticle it seemed to have been dead
in utero for some time. The placenta
came away in a few minutes afterwards.

ON CHYLE AND LYMPH.

To the Editor of the Medical Gazette.

Sir,

If the following analysis and observations be of sufficient interest, you will oblige me by inserting them in the Medical Gazette.—I am, sir,

Your obedient servant,

G. O. Rees, M.D., &c.

Guilford Street, Russell Square,
Dec. 18, 1840.

The chyle and lymph have at different times been objects of inquiry to many physiologists and chemists, and considerable discrepancy is to be observed in the results obtained from their researches. Even the cause of the colour of the chyle remains still a matter of doubt, and is a subject on which we find Müller differing with Tiedeman and Gmelin. The great interest which attaches to this subject prompted me gladly to accept an offer which I lately received from my talented friend Mr. Samuel Lane, to make a full analysis of the chyle and lymph taken from the same animal immediately after death, and thus to have an opportunity of instituting a comparison more complete than any which I believe has as yet been made, and which appears to be of considerable importance.

At 5 o'clock a.m. a young ass was fed with beans and oats, of which it partook largely, and at 12 o'clock was killed by a blow on the head. The chyle and lymph were immediately and most dexterously procured by Mr. Lane; the former from the lacteal vessels, passing from the lacteal glands to the thoracic duct : and the latter from the lymphatics of the lower extremity.

I immediately commenced a careful analysis of the fluids, using precisely the same method, in order that the comparison I wished to make might be as complete as possible.

Before noticing these analyses I will describe a few observations which I made on a portion of chyle, with a view of ascertaining those qualities which are not so well detected during the steps of an analytic process. The following tests reacted on this fluid as follows :—

1. Acetic acid rendered the fluid more pellucid.

2. Test papers indicated a neutral condition.

3. Nitric acid caused a strong coagulation.

4. The specific gravity of the fluid was 1012*.

5. Boiling caused a firm coagulation.

6. Strong acetic acid rendered the curd produced by boiling quite transparent ; and on water being added partial solution occurred.

The analysis of the specimens of chyle and lymph obtained as above described gave the following results :—

	Chyle.	Lymph.
Water	90·237	96.536
Albuminous matter . .	3·516	1.200
Fibrinous matter . . .	0·370	0·120
Animal extractive matter		
soluble in water & alcohol	0·332	0·240
Animal extractive matter		
soluble in water only .	1·233	1·319
Fatty matter	3·601	a trace
Salts. {Alkaline chloride, sulphate, and carbonate, with traces of alkaline phosphate, ox. of iron}	0·711	0·585

100·000   100·000

The albuminous matter of the chyle, as estimated in this analysis, was of a dead white colour, which was probably owing to admixture with a substance of a peculiar character to be hereafter described. The albumen from the lymph showed no peculiarity ; both specimens yielded an earthy phosphate by incineration ; that from the chyle was in admixture with a considerable proportion of oxide of iron.

The fibrinous matter from both the chyle and the lymph reacted chemically as albumen.

No very marked difference was detected in the aqueous or alcoholic extractives obtained from these fluids.

The fatty matters were elain and stearin, and yielded no perceptible quantity of ash on incineration.

The whole of the alkaline carbonate mentioned in these analyses was obtained from the alcoholic extractives, indicating a large proportion of lactate of soda. The existence of iron in the extractive soluble in water is interesting, and makes it a matter for consideration whether this variety in the locus of iron observed in these analyses may not in some way relate to the absence of the red colouring matter of the blood.

I have stated that the albuminous matter of the chyle contained a sub-

---

* This was a specimen from the thoracic duct ; the other observations are from the lacteal chyle.

stance in admixture, which rendered it of a dead white colour. This in the foregoing analysis has been estimated with the albumen. It may be obtained separate as follows :—

If chyle be agitated with ether, the mixture speedily separates into three distinct portions — the lower a clear serous fluid, the upper a solution of fatty matter, and the middle portion a layer of a pearly white glairy substance insoluble in ether, and apparently owing its separation from the chyle to the abstraction of the fats by the ether, as it does not separate from pure chyle by simply allowing the fluid to remain at rest : at least not until decomposition occurs, when it falls to the bottom, and may be collected by decantation of the supernatant serum.

Having collected some of this matter for examination, I found it to react as follows :—

It was insoluble in alcohol both hot and cold, insoluble in ether, miscible with water, and soluble in liquor potassæ. When it had been dried on platinum foil, the addition of water made it pulpy, and it was found still to be miscible with that fluid, from which, however, it separated in flakes on the addition of diacetate of lead. These properties, together with its physical characters, at once showed it to be allied to mucus, and from some comparative experiments which I have instituted, it appears to resemble the mucoid matter obtained from the saliva. I may state that this substance as obtained from the chyle gives out while drying precisely the same odour as saliva does when subjected to the same process. It is probable that the white milky colour of the chyle is in great measure owing to the abundance of this substance which it contains, and not to the fat alone, as stated by Tiedeman and Gmelin. Certainly the results of this chemical inquiry strongly corroborate the observations of Müller.

As there has been considerable difference in the descriptions given by different authors of salivary mucus and salivary matter, I think it best to state that I compare this substance obtained from the chyle by agitation with ether to an animal substance which may be obtained from the saliva by a similar operation. Thus, when the saliva or chyle is agitated with ether, the fluid is separated into three strata—the upper

in the case of saliva being nearly pure ether, in the case of chyle containing fatty matter; the lower consisting in either case of the principal constituents of each fluid ; the intermediate stratum in both cases consisting of an animal matter insoluble in ether, and floating upon the surface of the lower stratum of fluid, and which I consider as one and the same animal principle, and as a constituent both of the chyle and the saliva. If these analyses of chyle and lymph be compared, we shall have an opportunity of discovering what those parts of the blood are which require most frequently to be renewed, or, to express it differently, which are most largely consumed in the capillaries for the purposes of secretion or growth ; the chyle being the freshly supplied nourishment to the organismus, and the lymph that part of the blood which requires admixture with other matters before it can again assist in nutrition.

We observe that the water of the chyle is exceeded in proportion by that of the lymph, and the deficiency of solid matter thus indicated in the latter is principally accounted for by a deficiency of albumen, fibrin, and fatty matter ; the loss in the last instance being by far the greatest. The alcoholic extractive has been largely called upon in the nutrition of the body, while the aqueous extractive would seem to take little or no part in the process.

The salts are considerably diminished in the lymph. The vast quantity of fatty matter, the formation of which appears necessary to carry on the process of nutrition, cannot but excite surprise, and obliges us to conclude that in some way an alteration by a transposition of ultimate elements must occur in the far greater portion of it before it can be used as a nutritive matter ; for fat is not the principle most largely deposited by the secretory vessels, and indeed exists but in small quantities in the blood, when compared with the fibrin and albumen of the fluid.

The change of a fatty or hydrocarbonous body into one resembling albumen, can only be effected by the addition of oxygen and nitrogen ; and if such a transformation really occurs, which seems more than probable, it becomes a matter of great interest to inquire how far respiration is concerned in the operation. It is exceedingly improbable that chemical analysis will ever detect

a difference between the blood of the right ventricle, which is only very gradually receiving the chyle, and that of the veins, before admixture with the contents of the thoracic duct — our means of analysis are not sufficiently delicate—notwithstanding that it seems impossible but what some difference must really exist. The question now arises, do we observe during respiration any action which may be serviceable in freeing of an hydrocarbonous ingredient, that blood which is sent to the lungs from the right ventricle? The contradictory statements of different writers on respiration, and the curious diversity of results, not only as regards the quantity of carbonic acid expired, but also as to the existence or non-existence of that acid in venous blood, render the solution of this question a matter of no ordinary difficulty. From what is at present known, however, it is almost certain that a considerably larger proportion of oxygen is absorbed by the blood than re-appears in the form of carbonic acid. The power of this absorbing quality of the blood is well proved by an experiment made by Sir Humphry Davy.[*] Now all that would be required for the transformation of the fatty ingredients of the blood is not afforded by this supply of oxygen, for nitrogen must be superadded in order to form those animal matters of which the great mass of the organismus is composed. If we examine the results obtained by different experimenters as to the absorption of nitrogen, we observe some declaring none to be absorbed or exhaled by the process of respiration : others stating that nitrogen is exhaled, and a third class of experimenters (among whom we find Sir H. Davy) concluding that nitrogen is absorbed to the amount of one-seventeenth of the volume of oxygen which disappears from the atmosphere. It is greatly to be regretted that no experiments concerning the part taken by nitrogen in respiration are recorded, in which the time of taking food is noted, inasmuch as the contrary results which I have above mentioned are evidence that some varying cause (which may perhaps be chylification) is in action.

If it could be shown that nitrogen was absorbed during the time when the chyle might be supposed to be entering

the blood, it would be a strong proof that it was useful, together with the oxygen, in decomposing and combining with the hydrocarbonous matters from which it seems necessary that the blood should be purified.

Though many facts and co-relative conditions require to be observed before a theory of this kind can in any way deserve a general reception, still I cannot refrain from suggesting this view of the subject, inasmuch as I think there is good ground for believing that it may be fully confirmed, when further experiments have been made bearing on this interesting branch of physiology.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à alonger ce que le lecteur se tue à abriger."—D'ALEMBERT.

Aphorisms on the Treatment and Management of the Insane, &c. By J. G. MILLINGEN, M.D., &c. London, 1840.

DR. MILLINGEN, who was lately medical superintendent of the Asylum at Hanwell, thought that an epitome of the prolix volumes written on insanity would be useful to young practitioners, and has accordingly produced the little work before us. The aphorisms, which are five hundred and three in number, are partly the result of our author's reading, and partly of his own experience. They are generally instructive and judicious, but occasionally border on the splenetic. This alloy arises, no doubt, from his discomfort at Hanwell. The resident physician at a public lunatic asylum is almost necessarily in a false position; for he is subject to the advice, remonstrance, and command of those, who, if he is worthy of his place, are more fit to be his pupils than his masters. Yet, on the other hand, a dictatorship of the resident physician would have its inconveniences. Would it be well to adopt the plan suggested by Dr. Conolly, and approved of by Dr. Millingen, of placing all madhouses under the immediate conduct of the State ? We doubt it.

An Inquiry into the Efficacy of Digitalis in the Treatment of Idiopathic Epilepsy. By EDMOND SHARKEY, A.B., M.D., &c. London, 1841.

THE method of administering digitalis in epilepsy, recommended by Dr.

Sharkey, is to give one large dose, by which the danger is avoided which may follow an accumulation of small ones. Yet when the single dose is very large, the effects are staggering, and sufficient to make us pause before we imitate the prescription. Thus in the case of a young lady, treated by our author's father, where the patient took a quarter of an infusion made with three ounces and a half of fresh foxglove leaves, and some polypodium of the oak, the report is as follows :—

" 5th. Took the draught yesterday, and in ten minutes had a fit less severe and shorter than usual ; vomited frequently and violently till 12 of this day, her pulse sinking from 120 to 54, intermittent and irregular; complains much of pain of head, and soreness of epigastrium on pressure, &c."

The next day the report is,

" 6th. Has had no fit ; vomiting continued violently till 10 o'clock this morning : pulse 40, irregular and intermittent : great prostration of strength. Took a cup of coffee yesterday, and continues decoct. avenæ. Cramps of legs returned last night. Pupils have been dilated from the beginning of treatment." (p. 21.)

The vomiting and the dilatation of the pupils continued two days longer ; but the case terminated in a complete cure. This was an instance where, as Darwin once said, the patient was poisoned into existence; but a practitioner must be a bold fellow to repeat such an experiment. Yet repeated it was ; for in the next case, Dr. Sharkey's father treated a gentleman in the same way, and with the same success. " The prostration of strength and diminution of pulse in this case was absolutely frightful."

Other cases are narrated, which were treated with digitalis in various doses, and with various events. Dr. Sharkey has, we believe, omitted to mention in what dose he would recommend it to be administered. He compares it with turpentine and nitrate of silver, the two other remedies which have acquired the greatest reputation in the treatment of epilepsy, and gives it the preference. He believes it more efficacious than either, and objects to the nitrate of silver the dreadful discoloration which it is liable to produce. We agree with our author when he rejects so deforming a medicine, but we prefer the oil of

turpentine, which has its cures to boast, to so ticklish a remedy as digitalis in an emetic dose. We are inclined to apply to it, what the College says of Veratria, " non temerè adhibenda est."

We must observe that our author recommends the foxglove only in those cases which are uncomplicated, as well as idiopathic, and attributes the failure of the treatment in some instances to this distinction having been neglected.

The cases are candidly narrated, and this little work does Dr. Sharkey credit.

A Manual of Pharmacy, for the Students of Veterinary Medicine ; containing the Substances employed at the Royal Veterinary College, &c. By W. J. T. MORTON, Lecturer on Veterinary Materia Medica, &c. Second Edition.[*]

THIS is a useful work for the veterinary surgeon, and does credit to the talents and industry of Mr. Morton. It is by no means confined to the horse : thus in speaking of nitrate of potash, our author says, " To CATTLE the nitrate of potassa may be given in the same quantities as to the horse. The dose for the SHEEP should not exceed one drachm ; for the DOG, from five to ten grains. As a local remedy it is equally applicable for all animals." (p. 240.)

Of tartar emetic he observes, " Calves are readily purged by it in quantities of from two to three drachms.

On the dog it acts as an emetic ; the dose being from one to three grains. A very large and strong dog might require four grains. Applied externally it quickly induces nausea, followed by vomiting—the stomach of the dog being easily acted upon ; and hence the many agents that are extolled as emetics for him. Some are highly objectionable, from the violence with which they operate, as Turbith mineral—*subsulphas hydrargyri flavus ;* crude antimony—*antimonii sesquisulphuretum,* and common salt ; although they are favourites with sportsmen. Vomition appears to be almost a natural act of the dog, or, at any rate, it is generally attended with salutary effects. The agent partaken of by him in order to produce it is the dog-grass — *cynosurus echinatus.*" (p. 101.)

MEDICAL GAZETTE.

Friday, January 1, 1841.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

MEDICAL REFORM.

IT is scarcely possible to take up a number of any medical journal, without observing the interest excited by the subject of professional reform. Now, we read of a meeting of some Medical Reform Association; now, a letter or petition from a simple individual; at another time, it is a pamphlet showing how easily the author could make the profession happy, if certain wicked monopolists would only let him. These multiplied efforts prove the deep uneasiness which pervades our serried ranks, and indicate, at any rate, that their condition is far from prosperous. For, though the hypochondriac often mistakes the nature both of his disease and of the remedies which it requires, he is more rarely a *malade imaginaire* than the superficial suppose. Many of our brethren persuade themselves that their discontent is the offspring of charters, or arbitrary regulations, when, in fact, it arises from the want of profitable employment. Certain of these malcontents envy not only men of other professions, but those of different branches in their own. The physician, during his long probationary period of gratuitous practice, envies the quick success of his neighbour, the apothecary; while the general practitioner speaks of the easily earned guinea of the doctor, as if it were a common occurrence. Perhaps when roused by some trifling case at six in the morning—

Sub galli cantum consultor ubi ostia pulsat—

he envies the man whose gratuitous patients come at more civilized hours;

and hopes that a cheap M.D. manufactory will convert general practice into something new, retaining all its profits, and none of its disadvantages.

The topic of medical reform so long mooted among ourselves, will now be more and more discussed in unprofessional circles. Besides the never-to-be-forgotten Bill of Mr. Warburton, besides the occasional appearance of the subject in newspaper columns, it has found its way into the last number of the Quarterly Review[*], in a very clear-headed and sensible article. On this we shall offer some comments regarding a few topics on which we do not quite agree with the writer, and we shall then subjoin extracts on some important points.

According to the reviewer, the problem to be solved by the Committee of the House of Commons was, "The best mode of conducting medical education, so as to ensure a supply of well-informed and honourable practitioners, who, while they fulfil their duties to society in the best possible manner, maintain for themselves a respectable station in it." The Committee never made a report, and, consequently, never even attempted to solve the problem. The reviewer is not surprised at this; partly because a large portion of the evidence did not bear on this question at all; and partly, because the evidence consists of discordant materials, the analysis and arrangement of which would be an almost endless undertaking.

To us it seems that the analysis of 800 folio pages may be accomplished within a finite time; and if the Committee had passed over the large portion (three or four hundred pages, says the reviewer), devoted to the disputes between the Fellows and Licentiates of the College of Physicians, any literary man would have analyzed the rest for

[*] No. CXXXIII., December 1840.

them in a month. But to reconcile discordant opinions, so as to form a rational and satisfactory report, would not have been quite so easy.

One of the best things in the article of the Quarterly, is the answer to the one-faculty eccentrics. The divisions of the Profession, far from having been fixed by any headstrong despot, or mistaken lawgiver, have been the creations of social progress—the result of constant struggles for good advice and physic on the part of the community.

Here and there, we suppose, a one-faculty man may be found, who, having taken leave of his senses, and without any friends to care for him, really wishes to abolish the grades of physician and surgeon ; that is, who intends to put a stop to improvements in physic and surgery ; but, on the whole, we think better of these angry talkers, and suppose that they merely intend that physicians should know much of surgery, and surgeons much of physic— which few will be found to gainsay. As to the quantum of professional qualifications, no precise rule can be laid down ; the standard has been constantly raised for many years, and may, no doubt, be still raised with advantage. " Roderick Random," says the Quarterly Reviewer, " became a surgeon's mate in the navy, with no other stock of knowledge than that which he had obtained from the surgeon-apothecary to whom he had been apprenticed ; and we conclude that many private practitioners must have been in the same situation at the time when Smollett wrote ; as schools of anatomy and medicine were then only just established in Edinburgh and London, and these, in London especially, were of a very imperfect kind. At present, however, the case is widely different."

Perhaps the reviewer goes too far when he says, " Let honour be given where honour is due. The first im-

provements were made by the Society of Apothecaries ; and it was not until they had set the example that the Colleges of Physicians and Surgeons awoke from their long slumber, and discovered that the time was come for requiring a more extended medical education in every department of the profession." We are by no means inclined to depreciate the honour due to the Worshipful Society for their successful endeavours to raise the standard of medical education ; but it must be recollected that, in 1815, they began with zero, and that several advances were requisite before the Colleges could be alarmed at their emulous progress, or think it necessary to awake.

The Reviewer thinks that no alteration is advisable in the length of the medical education now required by the College of Surgeons and the Society of Apothecaries ; but he is of opinion that much alteration is wanted otherwise. He justly objects to the long period of apprenticeship spent in pharmacy, and he does not see why every candidate for the Apothecaries' license should necessarily have been apprenticed to an apothecary. Suppose a man has graduated at Oxford or Cambridge, and afterwards, from a want of adequate fortune, cannot live as a physician, why should he be prevented from practising as an apothecary ? Can any reasonable person say that it would be for such a man's advantage, or for the advantage of the public, that he should be bound apprentice for five years, at the age of three or four-and-twenty, to learn the mystery of making effervescing draughts or pill acocia?

The Reviewer also disapproves of the early age at which the Society allows candidates to go up for examination ; and thinks that the best encouragement to pupils to obtain a good general education would be to remove every inducement to their beginning their pro-

fessional studies before eighteen or
nineteen. General or preliminary edu-
cation, however, is not altogether
unnoticed in the Society's Regulations;
for they recommend the study of French,
German, the Classics, and the Elements
of Mathematics and Natural Philoso-
phy, before the commencement of the
apprenticeship. They also express
their regret that the greater part of the
five years of pupilage, and sometimes
the whole of them, should be devoted
to pharmacy; and wish the pupil to
attend lectures during his apprentice-
ship. If apprenticeships are to be
continued, we would certainly have this
interpretation rendered compulsory; for
it is too bad that five precious years
should be spent in mixing and grind-
ing. But this we have discussed suffi-
ciently on former occasions.

OPINIONS OF THE QUARTERLY REVIEW,

On various Points of Medical Reform.

SUPPRESSION OF QUACKERY.

And here another question arises. Should
those who have passed their examination,
and received their license, have a monopoly
of practice? Should there be penal laws to
prevent their being interfered with by the
competition of the ignorant, the uneducated,
and unlicensed? or is it sufficient that the
public are supplied with a list of those who
are supposed to be qualified practitioners, it
being then left to individuals to procure
medical assistance where they please? To
us it seems not in the least doubtful that the
latter is the proper course to be pursued. It
is right that no individual should be allowed
to be inoculated for the small-pox, because
he may communicate the disease to others;
but in what concerns himself alone, we see
no justice in the interference of the state.
It may be foolish to be rubbed with St.
John Long's balsam, or to trust to the
prayers of Prince Hohenlohe, but mankind
do many things more foolish than these, and
nothing can prevent them. There can be no
greater mistake than to suppose that, if
there be no penal laws to prevent the
existence of unlicensed practitioners, there
will not be sufficient inducement to those
who enter the medical profession to go
through a long course of study, and then to
subject themselves to an examination. The

empire of opinion here, as in most other in-
stances, will do more than legislative enact-
ments: and this is no speculative doctrine,
but the result of actual experience.

The College of Physicians possess, under
their charter, confirmed by acts of parlia-
ment, a monopoly of medical practice in the
metropolis, and within the distance of seven
miles from it; and they in many instances
instituted legal proceedings against the un-
licensed physicians by whom those privileges
had been invaded; but, finding that no good
arose from these prosecutions, either to
themselves or others, and that they were in
fact altogether ineffectual, they have for
many years abandoned them. The London
Society of Apothecaries possess a similar
monopoly, under the act of parliament of
1815, but on a still larger scale, as it extends
to the whole of England. They also have
frequently resorted to courts of justice in
defence of their privileges, but with so little
success that it is notorious that many apo-
thecaries are practising without their license,
either in open defiance of the law, or (which
is no difficult matter) contriving to evade it.
On the other hand, the London College of
Surgeons have no monopoly, no privileges,
no power to prosecute. Any one may
establish himself as a surgeon, even next
door to the College, and no one can molest
him. But the College is of royal foundation,
and the diploma which it grants has affixed
to it the signatures of many of the leading
surgeons of London; and so necessary has
it become to any one who makes the least
pretension to practise surgery, that there are
few, either in England or in the colonies
(with the exception of those who have a
similar diploma from the colleges of Dublin
or Edinburgh), who venture to call them-
selves surgeons without it.

We are aware that the foregoing observa-
tions will not be very acceptable to many of
the medical profession. It is natural that
the managing bodies of the several corpora-
tions should be anxious to maintain and
extend their powers and privileges; and it
is also natural that licensed practitioners,
who have expended considerable sums of
money, and no small portion of their lives,
in their education, should be jealous of the
competition of others. Accordingly we find,
among the resolutions and petitions of the
lately formed medical associations, no sub-
ject connected with schemes of medical
reform put so prominently forward as the
suppression of quackery. Let them, how-
ever, be assured that this is what no legisla-
tion can accomplish. It is no more pos-
sible to put down quackery in medicine than
it is to put down quackery in politics or
religion. The medical profession, while
human nature continues to be such as it is

now, and always has been, can never meet the demands which are made upon it. That men are born to die ; that the power of giving relief is limited ; that many diseases must prove fatal in defiance of all remedies ; that other diseases, though not of a fatal tendency, may be incurable—no one will doubt the truth of these as general propositions : but the individual who labours under the inflictions of disease will always indulge himself in the hope that he is at any rate safe on the present occasion, and that the time is not yet come when he can derive no benefit from art. " It is very extraordinary," said a gentleman who had known little of the infirmities of age until he approached his eighty-eighth birth-day, " that no one can discover a cure for my complaints." Where the resources of skill and science fail, the instinct of self-preservation will lead many sufferers to look for other aid ; and the honest and well-educated practitioner will always have to contend not only with the St. John Longs of the day, but with those among his own brethren who do not partake of his anxiety to avoid making promises which cannot be fulfilled. There are in fact no more offensive impostors than those who march under the banners of the true faith, and we suppose that even the most sanguine of the petitioners against quackery will not expect that such as these can be extinguished by an act of parliament. Let us not, however, be misunderstood, as recommending that no distinction should be made between those who are properly educated and licensed, and others. Each individual in society has, with respect to his own complaints, a right to consult whom he pleases ; but it is quite different where he is to provide medical attendance for his fellow-creatures. The governors of a parish union, or a bench of county magistrates, should be bound to make their selection from those who are properly authorized to practise. They have no right to confide the care of the parochial poor, or the inmates of gaols and lunatic asylums, to any other persons. The same rule applies to merchant-ships, to schools, to the army and navy, and every other department of the public service.

AGE AT WHICH LICENSES ARE GRANTED.

But although no alteration in the system of education may be wanted in this respect, it appears to us that much alteration is wanted otherwise. By the Act of 1815, it is made necessary that every candidate for a license to practise as an apothecary should have been apprenticed to an apothecary, who also had been licensed, during a period of at least five years ; and the regulations of the Society of Apothecaries have from the beginning admitted the candidates for exa-

mination at the age of twenty one-years. The College of Surgeons formerly did not allow candidates to appear before them until they had completed their twenty-second year, but of late (for what reason it is difficult to understand) they have taken off one year, and they now admit them at the same age as the Apothecaries.

Now we hold that the minds of very few young men can be sufficiently matured at the age of twenty-one years to fit them for such serious and responsible duties as those of a medical practitioner : and we further see another great evil as the result of this regulation, that it induces parents, in their anxiety to get their children off their hands as soon as possible, to send them to begin their professional studies while they are yet boys, and often without the advantage of even a moderate degree of education previously. We have conversed with many persons who have been engaged in the education of young men, not only for the medical profession, but for others also, and have always been informed that those whose minds have been prepared by a good preliminary education have on the whole been found to be much more diligent, and to have gained knowledge much more easily, than others. Our own experience, which has been sufficiently extensive, would lead us to the same conclusion ; and we suppose that no one will venture to deny that there are moral as well as intellectual advantages belonging to a well-trained mind which are nowhere more likely to be conspicuous than in the various departments of the medical profession.

As matters now stand we find the subject of general or preliminary education altogether unnoticed in the regulations both of the College of Surgeons and of the Society of Apothecaries, except indeed that the latter require that the candidates should construe some scraps of Latin. If education be a thing of so much importance, ought such an omission to exist ? and ought not proofs of a good general education to form a part of the documents which the candidates are expected to produce as entitling them to examination ?

With all our prepossessions on the subject we doubt the policy of any regulation of this kind ; and we would willingly avoid the fault of recommending that over-legislation which so frequently defeats itself. What is to be considered as a test of a good preliminary education ? and in what does it consist ? On these points there may be great differences of opinion ; for while the mental faculties may be improved by the cultivation of various branches of knowledge, each individual is apt to regard that as most important which has most contributed to the improvement of his own. To require

degrees at colleges and universities for the whole of those who enter the medical profession would be manifestly absurd ; and, after all, the common degree of B.A. at Oxford and Cambridge is not incompatible with very little study and a very low degree of knowledge. Are the candidates to be especially examined as to their general as well as professional attainments ? There being not fewer probably than five or six hundred candidates in the year, who would undertake the task ? and, if such examinations were instituted, would they not soon degenerate into a mere empty form ? Are the licensing bodies to be satisfied with certificates from schoolmasters and tutors ? Those must have very little knowledge of the world, or of the nature of testimonials generally, who think that these would be of the smallest value. Let us look at the question as we will, we perceive insurmountable difficulties in the way of any other system than that of offering a negative encouragement to young men to obtain a good general education, by the removal of every inducement to begin their professional studies before they are eighteen or nineteen years of age. But further, we believe that this would be found to be generally sufficient. A father will not incur the expense of entering his son at a medical school sooner than is really necessary ; and, for his own sake, if not for his son's, he will be disposed to keep him employed in some kind of study, rather than that he should dissipate his time in idleness. Besides, satisfied as we are of the vast advantages which the many are likely to derive from a good preliminary education, we are aware that intellects of a higher order may overleap the barrier which the want of it places in their way, and we should be sorry to witness the adoption of any measures the effect of which would be to prevent these master-spirits from entering the medical profession. The Inns of Courts have acted wisely in this respect. The tendency of their regulations is to encourage those who propose to be called to the bar to be liberally educated. They do not insist on it, and, if they had done so, the legal profession would have been deprived of some of its brightest ornaments.

But it may be urged that, if young men are not able to obtain a license to practise until they are twenty-three years of age, so many to whom it is important to obtain a livelihood in early life will be deterred from enterring the profession, that there will be an inadequate supply of licensed practitioners, and that the result will be to call into existence a number of other practitioners, who are unlicensed and unqualified. It is true that such was the effect of the too stringent regulations of the College of Physicians in former times, and such would be the effect

of too stringent regulations at any period. But there must be much greater changes than those which we venture to suggest to make us liable to any such danger at the present moment. The supply of medical practitioners is in fact not only very much beyond the demand, but very much beyond what is necessary to ensure a just and useful degree of competition. For the truth of this assertion we venture to appeal to the experience of all those who will be at the trouble of making their observations on the subject ; and to this cause may mainly be attributed the present restless and uneasy state of the profession. In this, as in all other pursuits, a certain degree of competition is required for the security of the public ; but in the medical profession it is easy to conceive that the competition may be not only beyond what is really wanted, but so great as to be actually mischievous. We have heard it suggested that a tax in money should be levied on those who are brought up as medical practitioners, in the same manner as on attorneys and solicitors ; but such a tax would be of little service to the Chancellor of the Exchequer, and surely one in the shape of a better education would be much preferable.

APPRENTICESHIPS.

The addition of one or two years to the age at which a candidate may be admitted for examination would, however, be of little avail, unless another change were made at the same time. We have pointed out that by the Act of 1815 it is made necessary that an apothecary should have served an apprenticeship. We understand, from the evidence given before the Medical Committee *(page 21 of the Report on the Apothecaries)*, that Mr. Rose, who introduced the bill into the House of Commons, objected to this clause ; that it was in consequence struck out ; but that it was afterwards inserted in the House of Lords (we believe on the suggestion of one of the bench of bishops). Dr. Burrows, who gives this piece of secret history, says that " the Association of General Practitioners were anxious for the apprenticeship clause, on account of the great difficulty of getting apprentices ;" but what could have passed in the mind of the Right Reverend Prelate which led him to this notable piece of legislation, about a year after Parliament had passed an Act abolishing the necessity of apprenticeships in other cases, it is difficult to comprehend : nor is it less remarkable that twenty-five years should have been allowed to elapse without any attempt having been made to repeal a clause so unjust and mischievous.

We use these expressions not unadvisedly. The tendency of the apprenticeship system is always to throw a great impediment in the

way of obtaining a good general education;
and in a great number of instances to pre-
vent it altogether. The law requires five
years' apprenticeship, and the corporate
bodies require three years of study in a me-
dical school, making eight years in all.   If
a young man is to obtain his license (as he
may now obtain it) at the age of twenty-one,
and serves the full term of his apprenticeship
in a village or town, in which there are no
lectures and no hospitals, he must be taken
from school and apprenticed at thirteen years
of age. If the law be evaded, as it sometimes
is, by the master giving up two years of the
term of apprenticeship, still there are six
years left, and the boy is taken from school
at fifteen.   If the master reside in a large
town, in which the apprentice has the oppor-
tunity of pursuing his studies in the hospital
and lecture-room from the beginning of his
apprenticeship, still, even under these more
favourable circumstances, under which it can
fall to the lot of very few to be placed, he is
launched in his profession at the age of six-
teen, just as he is entering on that important
period in which, in the course of two years,
a well-disposed young man will make greater
progress with respect to his general educa-
tion than in all the former years of his life
put together.

But these are not the only objections.   Is
this a just monopoly?   Is there no way of
learning pharmacy, but by means of an ap-
prenticeship?   A member of the Committee
asks with great reason, " If young men, in
addition to the customary four years of study
in the University of Edinburgh, were to pass
ten or twelve months exclusively in learning
pharmacy, why should they not be permitted
to act as general practitioners?"—*(Report
on the Apothecaries,* p. 22). And again,
" Were a young man to graduate as a bache-
lor of medicine at Oxford or Cambridge, and
afterwards to apply himself to the study of
medicine, and from the want of an adequate
fortune be at length prevented from prac-
tising as a physician, why should he be pre-
vented acting as a general practitioner?"
Yet both these descriptions of persons are
prevented practising in that capacity under
the existing law.

We have not the smallest doubt that a
residence for a limited period in the house
of an apothecary is likely to be very useful
to the student who proposes to enter on the
same line of practice; but we cannot con-
ceive that an apprenticeship for five years,
or even for three years, is necessary; nor
indeed any apprenticeship at all.   At all
events there are good reasons why the legis-
lature should not interfere with a matter of
this kind.   It may very well be left to the
discretion of the parents and guardians, and
of the young men themselves; especially if

the Society of Apothecaries require, as they
have a right, and indeed as they are bound
to do, that the candidates for their license,
before they had begun to learn anatomy, or
at any rate in in addition to their other
studies, should have devoted a certain time   ·
to the study of pharmacy.

BOARD OF VISITORS.

Let us suppose that an act of parliament
were passed making some such alterations as
we have already suggested in the charters of
the colleges, and in the apothecaries' act of
1815, and any others which on further con-
sideration of the subject might be found to
be desirable; and that the government were
authorised to appoint certain persons who
should form a Board of Control, or, if they
please to give them a gentler appellation, a
Board of Visitors, whose office it should be
to superintend the concerns of the different
medical institutions; and we believe that
under such an arrangement all that is re-
quired might be accomplished.

The regulations as to the education of
medical students, and the licensing of prac-
titioners, should either originate with the
Board of Visitors, or should not be valid
until they had received their sanction.   In
like manner they should superintend the ap-
pointment of the examiners.   Reports should
be made to them at stated periods of the
individuals to whom licenses have been
granted; of the monies received in payment
of them; at the same time explaining in
what manner these funds have been expended.

At present, when a vacancy has occurred
in the Council of the College of Surgeons,
the remaining members select the individual
who is to succeed to the vacant seat; and
this has always, and not without reason,
been made a subject of complaint against
the constitution of the College.   Yet, as
matters now stand, we do not see what other
arrangement can be made.   To throw the
election open to the ten or twelve thousand
members of whom the College consists would
be absurd; and there is no other consti-
tuency.   If, as we have proposed, another
degree were established for those who would
be candidates for the situation of surgeons
to hospitals or teachers of anatomy, there
would, in the course of time, be a body of
persons to whom the election might, without
inconvenience, be intrusted; and in the
meanwhile the objections to the present
system might be in a great measure obviated
by making the appointments of the Council
subject to the approbation of the Board of
Visitors; or the visitors might select one
from a list of persons submitted to them as
properly qualified by the council.

What are called the Elects in the College
of Physicians are, with respect to the mode

of their appointment, in the same situation as the Council of the College of Surgeons; and the same rule might be applied to them, or otherwise the election of them might be conducted in the same manner as that of the Censors.

But a question will arise as to the exact mode of appointing the Visitors themselves. We would suggest that they should be nominated by the Queen in Council rather than by the Secretary of State, believing that the effect of this would be to remove the appointment, in some degree, from the influence of party politics; and we would further suggest that the Board should consist of two classes of persons, of some who do, and of some who do not, belong to the medical profession.

Being assured that some of the highest interests of society are involved in the state of the medical profession, and knowing that the reflecting members of the profession are not well satisfied with the existing order of things, we confidently hope that those who concern themselves in the management of public affairs will perceive the necessity of giving the subject their early and serious attention; and in that case it will be by no means difficult for any one, who takes the pains to do so, to fill up the faint outline of the scheme which we have offered to their consideration. We cannot doubt that, if the task of mending the medical institutions be honestly undertaken and pursued, a real and lasting service will be rendered to the public. We are sanguine enough to believe that what is required may be easily accomplished; that the question, if fairly discussed, with a desire to do only what is right and useful, will be found to lie in a narrow compass, and to be surrounded by no difficulties which may not be readily surmounted.

CAUTION TO THE PROFESSION.

MEDICAL IMPOSTORS.

To the Editor of the Medical Gazette.

Sir,

There are two men now in London practising every variety of imposition on the profession. They are so similar in their appearance, that I have little doubt of their relationship, and they are making their visits to the houses of medical men at times when they expect to find them from home. Having been entrapped the other day by one of them, (and he I have no doubt the brother of the one who sent me a few nights since on a fruitless errand to Pentonville,) I deem it right to put the profession on their guard.

Just as I was leaving my house a few days

since, a gentlemanly-looking man, short, stout, about 35 years of age, with blue spectacles and in a pilot coat, drove up to my door in a brown private cabriolet, with a dark bay horse. He gave me his card "Dr. Rogers," and stated that he resided in Welbeck Street, Cavendish Square, that he had formerly attended my lectures at St. Bartholomew's Hospital, and also those of Mr. Abernethy, and wishing to examine a book at the British Museum, requested a line or two from me to Sir Henry Ellis to secure that privilege. Recognising in his features an old Bartholomew student, and being pressed for time, I unsuspectingly put my name to a declaration that I believed him to be a medical man deserving of admission to the reading room of the British Museum.

On his leaving my house he dropped a silk handkerchief having the initials J. C., and these not corresponding with the name on his card (Dr. Rogers) awakened my suspicion, now confirmed by finding no such person in Welbeck Street. Believing, therefore, that he has obtained my signature for some sinister purpose, most probably to lead the unwary to suppose that he is known and recognised by me, I hereby caution the profession and public, and give it as my opinion that the man is an impostor.—I am, sir,

Your very obedient servant,

J. T. Conquest.

13, Finsbury Square, Dec. 24, 1840.

CASE IN WHICH
SIX PREGNANCIES OCCURRED
DURING AMERNORRHŒA.

By Dr. Flechner, of Vienna.

A woman, now 35 years old, menstruated for the first time in her fourteenth year, being then but imperfectly developed. Menstruation continued regular for some time, but then ceased for nine months, during which time many symptoms of chlorosis appeared. She then fell into a feverish condition, which continued for several weeks, but left her in a better state of health than she had previously enjoyed. During her convalescence the catamenia reappeared, and they now observed a regularly periodical type for several years, though still usually accompanied by congestion of blood about the head and chest. In her twenty-second year she married, and during the next year gave birth to a healthy child, which she suckled for only a few months, for her supply of milk then decreased, though no traces of return of the process appeared. Instead of the latter there came on periodically pains in the head, varying in severity and length of continuance,

with a sensation of pressure and heat in the frontal and parietal region, and frequently great distress of breathing and palpitation of the heart, or even more or less distinct parox- ysms of asthma. Notwithstanding the phy- siological energy of the uterus seemed com- pletely paralysed, yet after two years she again became pregnant. Gestation and par- turition were gone through in the same manner as at the first time; and then, in the place of the catamenia, which were still suppressed, the same train of periodical symptoms again came on. In this way the woman became a mother six times in the course of thirteen years, without a trace of menstrual fluid ever once appearing; and she declared that during this time she had observed neither a blennorrhœa nor any morbid secretion of the uterine or other sys- tem, that could be deemed vicarious of the catamenia.

Cases of conception during lactation, before the return of the catamenia, are by no means rarities, and the secretion of milk continued for a year sometimes hinders the secretion of menstrual blood without at all excluding the possibility of conception. But in this case the peculiar condition induced by lacta- tation could have had nothing to do with the suppression of the menses.—*Medicinische Jahrbücher Osters Staates*. Bd. xxx. St. iv.

DAILY REVOLUTIONS OF THE PULSE.

THE doctrine of Cullen and other physiolo- gists, that the healthy circulation is subject to a double diurnal excitement, and that the chief period of excitement occurs in the evening, was first disproved by Dr. Knox, in 1816. He found that there was only one diurnal revolution, independently of in- cidental excitements; that the pulse is more frequent and excitable in the morning on awaking, gradually becomes less so towards evening, and acquires its greatest state of depression about midnight or before going to sleep. The writer having, in ignorance of these investigations, made some experiments of the same nature, a few years afterwards, he can confirm the results at which Dr. Knox arrived, except that instead of observing actual excitement of the pulse in the morn- ing, he found only very marked excitability. Under a careful avoidance of all accidental stimuli, such as food, exercise, mental exci- tation, and the like, he found no difference whatever either in the pulse or animal heat, in the course of the whole day and night; but on awaking in the morning, there was so great excitability, that trifling stimuli raised considerably the pulse and temperature;

after mid-day this excitability gradually de- creased; and towards midnight it was lower than at any previous period. It is remark- able, therefore, that the ordinary period of greatest excitement in hectic fever, con- tinued fever, and many other febrile diseases, occurs exactly at the time when there is the least excitement or excitability in the healthy state of the functions.—*Dr. Christison, in the Library of Practical Medicine*, vol. i. p. 287.

WHITE SLAVE-DRIVING.

THE following occurs in the evidence of William Rastrick, before Mr. Sadler's Com- mittee in 1832.

Was it not found necessary to beat chil- dren to keep them up to their employment? Certainly.

Did the beating increase towards evening? Their strength relaxes more towards the evening; they get tired, and they twist themselves about on their legs, and stand on the sides of their feet.

When you were employed as an over- looker, and had to superintend those chil- dren, was not the employer aware that you had to stimulate them up to labour by severity? Certainly he was, and it is always considered indispensable.

Would he himself rather urge you to that course than to the contrary? His object was, in every case, to get a certain quantity of work done; it must be done by some means or other; but when it was necessary for the overlooker to use severity, he had to bear the stigma of it, and not the master.

Did you not find it very irksome to your feelings, to have to take those means of urging the children to the work? Extremely so; I have been compelled to urge them on to work when I knew they could not bear it; but I was obliged to make them strain every nerve to do the work, and I can say I have been disgusted with myself and with my situation; I felt myself degrade I and reduced to the level of a slave-driver in such cases.

Is not tying the broken ends, or piercing, an employment that requires great activity? Yes.

Does not the material often cut the hands of those poor children? Frequently; but some more than others. I have seen them stand at their work, with their hands cut, till the blood has been running down to the ends of their fingers.—*Evils of the Factory System demonstrated by Parliamentary Evidence*. By Charles Wing, Esq. (A useful work).

CASES FROM THE DANISH MEDICAL REPORTS.

THE following cases occurred in the practice of Dr. Mürer, of Lyngby :—

1. *Contraction and thickening of the intestines.*—An old woman, who had suffered for a short time from constipation, discharged small and hard fæces with difficulty, but without considerable pain, and frequently not until a suppository had been employed. Several laxatives, croton oil internally and externally, oily clysters, and even the use of an elastic tube were without advantage. The elastic tube caused much pain, and could not be introduced more than three or four inches. The abdomen became tympanitic, and the patient, who was 84 years old, died after a short struggle. On examination the great intestines were found much distended with air, the sigmoid flexure of the colon filled with small hard fæces, and above it there was so narrow a stricture of the gut, that not even a sound could be passed. There was no volvulus, but an almost cartilaginous thickening, about half an inch thick, and two inches long.

2. *Two remarkable monstrous births.*— One of these monsters had no cranium ; the brain hung in its membranes like a bag, the ossa bregmatis were entirely wanting, and, of the other bones of the head, the lowest only were present, with many unusual inequalities and thickenings of the edges ; the ears were very misshapen, but the child was otherwise well formed, and at its full time. In the other case a considerable part of the ossa bregmatis was wanting ; the child was born dead, and had a misshapen jaw, *(wolfs-rachen)* ; nearly the whole of the os palati was wanting, and the nose and lip were unusually cloven. So far, therefore, its development had been arrested ; but, on the other hand, there were six fingers on each hand, and six toes on each foot. The mother said that in the third month of her pregnancy, she suddenly saw a stone-cutter, who had a very deformed face, or what is called, a half-face, which frightened her so much that she fell into a swoon.

Transposition of the viscera.—Dr. Ewertzen, of Hilleröd, reports a medico-legal dissection of a boy nine years old, in whom several viscera of the abdomen (namely, the spleen, the transverse portion of the colon, and parts of the small intestines), were found in the thorax. He supposes they had been there from birth.

Tetanus cured by morphia.—Dr. Schiötz, of Rotschild, mentions a patient with tetanus, which had probably arisen from cold, and which was cured by the endermic application of the acetate of morphir. Half a grain was applied three times a day to a spot on the back, from which the cuticle had been removed.

Dr. Möller, of Helsingör, reports two cases. The first was a peculiar inflammation of the thick skin covering the heel, occurring in a woman of 45. Menstruation had ceased, but the woman had suffered from violent leucorrhœa, which had been cured by suitable remedies, after which she was quite well for some time.

A copious and very fetid suppuration was produced by emollient poultices, to which solution of chlorine was afterwards added ; and a cure was at last effected by the internal use of carburet of iron (black lead) after the whole of the thick skin had separated. Something similar appeared on the hands likewise. The patient has been well ever since.

2. *Ioduret of potash in syphilis.*—In a case of inveterate syphilis with tophi, violent pains at night, and sleeplessness, Dr. Möller used ioduret of potash with evident mitigation of the symptoms. Two drachms were dissolved in 8 ounces of water, and the dose was a tablespoonful four times a day. Dr. Möller convinced himself of the effect of the remedy on the system by a chemical examination of the urine ; and when the patient had taken an ounce of the salt, he was freed from his complaints, got an appetite, slept well, and was better, as he said, than he had been for many years. He had been previously treated with mercurials and other remedies, by different physicians, and is now perfectly well.

Dr. Klem, of Helsingör, reports as follows —

1. *Indigo in epilepsy.*—Among the remedies which have been most recommended against epilepsy, I have seen the root of the Artemisia vulgaris very beneficial. On the other hand, in the case of a man aged twenty-five, who had been treated in vain with this and other medicines, indigo, in the dose of ten and fifteen grains four times a day, was so advantageous that the fits, which had previously occurred almost daily, did not take place for a whole month.

2. *Aqua laurocerasi in Gastralgia.*—When nervous pain of the stomach has not yielded to the magistery of bismuth, (the trisnitrate) which is commonly an excellent remedy, I found cherry-laurel water very useful, sometimes given alone, in the dose of twelve drops four times a day, and sometimes with a fourth part of acid elixir [dilute sulphuric acid ?] In a couple of cases, where the pain was sometimes violent, and even the mildest food was vomited, and where there was pain on pressure, so that I suspected rheumatic inflammation of the stomach, the cherry-laurel water was not borne, but prussic acid effected a perfect cure. The dose was from four to six drops of the preparation of the

Holstein Pharmacopœia, every three hours, together with infusion of salep, leeches, and narcotic fomentations.

3. *Two remarkable mercurial salivations.* —The first case was that of a woman aged 45, and the origin of the salivation was quite a riddle to me, as she had not used any remedy to cause it either internally or externally. At last her husband confessed that, to drive away vermin, he had rubbed quicksilver and fat on several parts of his body; and I am compelled to suppose that the evaporation of the mercury in bed produced salivation in the woman, who is of a leucophlegmatic habit.

The second case occurred in a weakly girl of twelve, and it was not possible to learn from the parents what was the cause of it. It disappeared under the use of suitable remedies, though it had reached such a point that blood flowed out of the sores in the mouth, and great attenuation took place. I then prescribed the tincture of iodine, (5ss. in ʒiv. of water, with mucilage; ʒij. to be taken every two hours), alternating with decoction of bark, and decoction of elm, to rinse the mouth with; and in a few days the disorder had disappeared. The girl soon recovered her strength*.

Dr. Raon, of Helsingör, reports the following case :—

Violent convulsions in a puerperal woman, which continued after delivery.—The woman, who had been in excellent health up to the day when she expected to be confined, was suddenly attacked with vomiting and spasms, which soon attained a frightful height; her face was swollen and pale; her eyes fixed and red; foam issued from the mouth; her respiration was stertorous, and the pulse quick and tense. The bowels were open. The paroxysms returned every quarter of an hour. Meantime, she was delivered by the forceps; the child was dead, and unusually small, but at its full time. Antispasmodic remedies could not be swallowed. Bleedings, clysters of assafœtida and laudanum, and rubbing the abdomen with camphorated oil, did no good; the spasms continued after delivery. Ten leeches were applied to the temples, venesection was repeated, and morphia was administered endermically, at the pit of the stomach. Yet, though the lochia were regular, and the body open, the convulsions returned every quarter or half hour for two days. They then ceased, but were followed by wild phantasmata, which did not cease till the ninth day after delivery. For four days the woman was perfectly speechless.

* It does not clearly appear whether the tincture of iodine was to be swallowed, or used to rinse the mouth; if the former, the doses seem too large.—TRANSLATOR'S NOTE.

THE LATE DR. RYAN.

(From a Correspondent.)

WE sincerely regret to hear that the late Dr. Ryan has left a widow and four infant children in a most destitute situation. The following letter has been addressed to the widow on the part of the Metropolitan Free Hospital, of which Dr. Ryan had been a physician.

[The letter is highly complimentary to the deceased, and we regret that we cannot make room for it.]

Dr. Ryan was well known as a medical journalist and teacher. The case of his family is one which we think will excite the sympathy of his medical brethren and the public. We understand the friends of the family are already exerting themselves in endeavouring to raise a fund for the purpose of placing his widow in a situation to support herself and her children.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Tuesday, December 22, 1840.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XVI.

*Dropsy: its general pathology. Passive
dropsy; cardiac, and renal. Active, acute,
or febrile dropsy. General principles
of treatment in dropsies.*

THERE remains now only one subject, of the
pathology of which it will be convenient and,
I hope, instructive, to take a short general
view, before we enter upon the consideration
of special diseases. I proceed to speak of
Dropsies: i. e. of serous effusions into one
or more of the shut cavities of the body, or
into the cellular tissue, or into both ; inde-
pendent of inflammation.

We have already considered serous effusion
occurring as an effect or event of inflam-
mation. We are commonly able to say of
this, that it *has* originated in inflammation ;
either from its being mixed with some of the
less equivocal *products* of that disease, such
as coagulable lymph ; or from its having taken
place while *symptoms* of inflammation existed.
But there are numerous examples of serous
accumulation, which cannot with any shew
of reason be regarded as events of inflamma-
tion. It is to these that I would apply the
simple term dropsy.

It has been said—and said with much
truth—that dropsy is rather a symptom of
disease, than a disease in itself. And it has
been affirmed that it would be more philo-
sophical and scientific to treat of the original
malady upon which the effusion or accumu-
lation depends ; to erase dropsy from the
list of substantive diseases, and to place it
in the catalogue of mere symptoms.

But this, in my mind, is a very mistaken
view of the matter. For, first, it is often-
times uncertain, while the patient is yet alive,
what or where the primary disease may be ;
and even after death we sometimes can dis-
cover no organic change that would satis-
factorily account for the effusion. Practically
speaking, in such cases the dropsy *is* the
disease, and the sole object of our treatment.

And, secondly, dropsy is, in fact, to a
medical eye, in *all* cases, something more
than an effect or symptom of disease. The
imprisoned liquid is often a *cause* of various
other symptoms ; embarrassing, by its pres-
sure, important functions, and even extin-
guishing life. The removal of the dropsy
(although its original cause, of which it
was a symptom, may remain behind, un-
touched, to be again productive of effusion
under circumstances favourable to its opera-
tion)—the removal of the dropsy will often
restore a person to comparative comfort ; or
even to what, so far as his sensations, and
powers, and belief are concerned, *is*, to him,
for the time, a state of health.

You see then, already, that in a dropsical
person, whose dropsy depends upon organic
disease, there are two sets of symptoms to be
distinguished : viz. those which depend on
the primary disease ; and those which depend
on the collected fluid. The latter, often the
most grievous, are often to be got rid of :
the former, frequently permanent, are fre-
quently also but little complained of or felt
by the patient, except when effusion is the
result.

Some persons, I fancy, have regarded
dropsy as a less attractive subject of investi-
gation than it might be if it were less fre-
quently, in its nature, incurable. But as far
as the dropsy itself is concerned, the com-
plaint often *is* curable ; and there are some
forms of dropsy that are curable in a more
absolute sense : that is, both the effusion, and
that condition which was the physical cause
of the effusion, are sometimes remediable.

Besides, it is our business to cure when we can ; but whether we can cure or not, to relieve and palliate human suffering ; and this, under Providence, we are able to do, in many or most cases of dropsy, to a very considerable extent.

Wherever there is a shut sac, or wherever there is loose and permeable cellular tissue, there we may have dropsy.

Thus there may be dropsy of the ventricles of the brain, or of the meshes of the pia mater, leading to death by *coma* : of the pleuræ, of the cellular texture of the lungs, or of the submucous cellular tissue of the glottis, any of which may cause death by *apnœa* ; of the pericardium, producing death by *syncope*. I mention these instances in particular, to shew that almost every mode of dying may result from dropsical effusion ; and to win your attention to a disorder so full of peril.

When the cerebral ventricles are distended with water, we express the diseased condition by the term *hydrocephalus*. When serous liquid collects in the pleuræ, or in the pericardium, we say that the patient has *hydrothorax*, or *hydropericardium*. If the cavity of the peritoneum be the seat of the effusion, we call the complaint *ascites*. When the cellular tissue of a part becomes infiltered with serous fluid, the part is said to be *œdematous ;* and *anasarca* is the name given to the more or less general accumulation of serum into the cellular tissue throughout the body, and especially to visible subcutaneous œdema of considerable extent. Finally, the term *general dropsy* signifies the combination of anasarca with dropsy of one or more of the large serous cavities.

Other local dropsies indeed there are, but, as they belong entirely to surgery, I need not enumerate them.

General pathology of dropsies. — Now what reasonable account can be given of these remarkable conditions ? How is it that the hollows and interstices of the living body, or of parts of the body, became thus water-logged ?

To solve this question, we must carry in our minds some physiological recollections.

The closed cavities or cells within which the fluid of dropsy is confined, are kept moist, during life and health, by a continual serous secretion from their surfaces ; and they are kept *merely* moist, for the fluid thus constantly secreted is as constantly reabsorbed into the circulation.

When these cells or cavities, without having undergone inflammation, become filled and distended with the serous fluid which they habitually secrete, one of three things must have happened. Either the quantity of fluid exhaled has been augmented, the absorption remaining the same ; or, the absorption has been diminished, the exhalation continuing the same ; or else the exhalation has been increased while the absorption was either lessened or not proportionally increased at the same time.

The last is a mixed case ; and we need only consider the two first.

Now the balance between exhalation and absorption is often deranged, and dropsies do actually arise, in each and all of these ways.

It will best suit my purpose to speak first of those dropsies which are occasioned by defective absorption, and which are usually called chronic or passive dropsies.

The direct agency of the blood-vessels in the production, as well as in the removal, of dropsy, although indicated by many common and obvious facts, has not been generally recognized till a comparatively recent period. Perhaps I should rather say that more importance used to be assigned, in these respects, to the agency of the lymphatic absorbents, than they are really entitled to. You will find that pathologists, even in modern times, speak of a want of tone, of deficient energy, in the absorbents, as a cause of dropsical accumulations ; the superfluous fluid of the part is not adequately taken up (they say) by the enfeebled absorbents, meaning the absorbents strictly and anatomically so called. And this view of the matter, connecting dropsy always with debility as its cause, has led to a corresponding plan of treatment : the object aimed at being the stimulation of the absorbents to more energetic action.

But to the doctrine that dropsy is a consequence of the deficient action of the absorbents, this obvious difficulty presents itself,—that absorption really goes on, and goes on very actively, in dropsical patients : their adipous matter disappears, they become wretchedly thin. There is no complaint in which wasting and emaciation go to a greater extent than in dropsy. You will find also that persons labouring under anasarca are readily enough affected by mercury ; which must of course be absorbed before it can produce any of its specific effects.

It must be confessed that our knowledge respecting the mechanism of absorption is neither complete nor certain ; but there is good reason for supposing that the process is shared among the lacteals, the lymphatics, and the *veins* ; and it is probably distributed between these sets of vessels somewhat in this manner ;—that the lacteals absorb the chyle from the surface of the alimentary canal, and convey into the blood the materials of its renovation ; that the office of the lymphatics is to take up and carry into the blood those old and effete portions of the solid constituents of the body, which require to be removed to make way for a fresh deposit ; while the veins imbibe the serous fluid exhaled from the surfaces of serous membranes, and into the meshes of the cel-

lular tissue, as well as poisons and other substances that are soluble and dissolved in that fluid.

If this be so, the difficulty just now mentioned vanishes. Of the two sets of absorbing vessels, the lymphatics and the veins, one set may continue to perform its functions, while the other fails to do so. This theory is quite consistent with the actual phenomena of dropsical disease ; and whether it be altogether true or not, a part of it is certainly true ; that, namely, which assigns to the veins a *large* share in the whole process of absorption. The experiments of Magendie and of others are quite conclusive upon that point.

It has also been fully established, that fluids may and do pass into or out of the veins, in the living body, not by any vital process, but by mere physical imbibition and transudation, through the coats of those vessels ; that when the veins are distended to a certain degree with watery fluid, the entrance of more of the same fluid, through their sides, is impeded or prevented ; that, when the distension is still greater, the aqueous part of the blood may even pass in the other direction out of the vessel ; and that, on the other hand, when the veins are comparatively empty, the surrounding serous fluid passes readily into them, or, in common language, is absorbed. The venous absorption is explicable therefore upon the principles of *endosmose* and *exosmose*, as laid down by Dutrochet ; or I would rather say, according to the more general and more simple laws of *heterogeneous attraction*, as explained by Professor Daniell.

Imbibition, being a form of that attraction, belongs in various degrees to all the tissues of the body. Its rapidity—and even its direction in respect to the elastic coats of a vessel surrounded by fluid, and also carrying fluid of a certain consistence—will vary with the varying distension of the vessel. When the vessel is moderately full, the exterior fluid passes uninterruptedly inwards, and is conveyed away by the internal current. When, on the other hand, the vessel is kept much distended by its contents, the contained fluid, or its thinner part, passes continually outwards ; and there is an intermediate degree of distension, at which the pressure is just sufficient to prevent the transit of fluid in either direction. Magendie found, accordingly, in a well-conducted and conclusive series of experiments, that by regulating the conditions of comparative emptiness or fulness of the circulating system, he could accelerate, retard, or suspend altogether, the operation of a poison dissolved in the humours of the body. In other words, he could thus accelerate, retard, or prevent, the process of absorption or imbibition through the blood-vessels.

Bearing these physiological truths in remembrance, we shall have no difficulty in shewing that the chronic forms of dropsy are attributable partly, and chiefly, and in many instances entirely, to undue plenitude of the veins ; and that this venous repletion is produced, almost always, by some impediment to the free return of the blood towards the heart.

Passive dropsy from venous obstruction. —When the cellular tissue of a limited part of the body becomes filled and distended by serous liquid, we call the swelling *œdema :* but this is exactly the same, in its nature, as anasarca. Now œdema is often the consequence of some mechanical obstruction to the venous circulation. We can produce it whenever we will. Our countryman Dr. Lower, 170 years ago, tied the jugular vein of a living dog. When a few hours had elapsed, he observed that all the parts beyond the ligature, reckoning from the heart, were much swollen : and upon dissecting the animal after death he found that the cellular tissue of the head and face was filled, not with red blood, as he had expected it might be, but with clear and limpid serum. On another occasion he placed a ligature upon the vena cava, just above the diaphragm : death soon ensued, and a large quantity of water was discovered in the cavity of the peritoneum.

Precisely similar phænomena succeed the compression or obliteration of a large vein in various parts of the body. In operating for popliteal aneurism, Mr. Travers was obliged to tie the femoral vein : the cellular tissue of the limb was speedily infiltered with serous fluid. Long-abiding œdema of one foot and ankle has been cured at once by the reduction of a crural hernia, which had been pressing for the same length of time upon the femoral vessels. You have heard, most probably, of the disease called *phlegmasia dolens ;* a disease that is very common in women soon after childbirth, although it is not peculiar to them, nor to the female sex. The foot, leg, and thigh, become enormously œdematous. The essence of this disorder is inflammation of the femoral vein, which blocks up that vessel near the groin, and retards or precludes the return of the venous blood from the limb. One arm often swells in the same way, and from a similar cause, in women who are afflicted with cancer of the breast. In pregnancy, the gravid uterus sometimes presses upon the iliac veins, and obstructs the current of blood within them : the consequence is, anasarca of the lower extremities, which disappears as soon as the pressure is removed by the delivery of the woman. The flow of blood through the vena portæ is frequently hindered, by disease in the liver, or by other causes ; and serous liquid accumulates in the peritoneum, con-

stituting ascites. A French physician, M.
Tonnelle, narrates several cases in which se-
rosity was found in the cavity of the arach-
noid, in conjunction with obliteration of
the venous sinuses of the dura mater. In
all these instances we have retardation of the
venous current, undue plenitude of the veins,
and dropsy of the part from which they pro-
ceed. The natural exhalation goes on, and
the exhaled fluid collects and stagnates, be-
cause the channel through which it ought to
be drained away is choaked up. The larger
the vein, and the nearer we approach the
heart, the more extensive is the dropsical
accumulation : and if we could plant an ob-
stacle at the very termination of the venous
stream, we should dam up the blood in the
whole system of veins, and produce a general
dropsy.

Such an obstacle is frequently placed there
by disease. The returning blood is checked
at its entrance into the heart : at the con-
fluence of all the veins of the body, where
they unite to empty themselves into the right
chambers of that organ : and then anasarca of
the universal cellular tissue comes on, and
water collects in all or most of the great serous
cavities.

It is no part of my present purpose to
inquire how such disease of the heart as is
productive of dropsy, arises. Commonly
we find the right auricle and ventricle en-
larged in capacity, the opening between
them unnaturally wide, and the tricuspid
valve unequal to its office of closing that
aperture. Such a morbid state of the right
heart may be occasioned by any cause which
impedes the flow of blood *out of* its cavities.
The diseased condition of those cavities may
be primary ; but it is oftener perhaps conse-
cutive to other disease. It may be produced
by disease of the lungs, preventing the right
ventricle from freely delivering its contents
into the pulmonary blood-vessels. Or the
retarding cause may be still more distant, in
the left side of the heart, keeping the pulmo-
nary blood-vessels unduly full, and thereby
hindering indirectly the escape of the blood
from the right ventricle. The dropsy may
ultimately depend, therefore, upon some bar to
the circulation placed even at the mouth of the
aorta. Obstacles situated any where in the
circuit formed by the right heart, the lungs,
and the left heart, have the effect of produc-
ing secondary changes in the parts behind
them. But disease, thus propagated in a
direction retrograde to the course of the blood,
is propagated gradually, and sometimes very
slowly. These are points of much interest,
which we shall investigate together by and
by. I allude to them now, that you may not
be perplexed by a knowledge of the fact,
that diseases of the heart often exist for a
long while without inducing dropsy. It is
with disease of the right side of the heart,

whether primary or secondary, that passive
dropsy is especially associated.

As if to furnish the *experimentum crucis*
in respect to this doctrine, disease does some-
times, with a curious precision, dam up one
only of the two great venous trunks, at the
junction of which the left auricle is placed :
and then the dropsy is as curiously limited
to that half of the body in which the tri-
butary veins of the obstructed trunk ori-
ginate. The first example of this which I
ever saw was a most remarkable one. The
patient was dropsical in his upper half only.
His arms were so hugely anasarcous that he
could not bring his elbows near his sides ; his
neck and face were hideously bloated and
exaggerated, and his eyes prominent and
staring ; while his lower limbs were of their
natural size, and appeared preposterously
small and out of proportion. The poor man
looked as if the upper part of his body had
been stuffed, for acting some ridiculous part
upon the stage. The cause of this strange
and distressful state was found to be the
obliteration of the vena cava superior, close
to the auricle. Its sides had been pressed
together by a large aneurism of the aorta ;
and a portion of the vein was fairly sealed
up. I have seen two similar cases since.

Objections have, however, been taken to
the accuracy of the conclusions drawn from
such cases as I have related ; and it is fit that
you should be aware of them. Thus it is
stated that veins have been found obliterated,
and yet there was no dropsy. Now to this
objection it may be answered, in the first
place, that it is not every vein, the oblitera-
tion of which would cause manifest œdema.
It must be the principal venous trunk of the
part concerned. When some of the secon-
dary and smaller veins alone become imper-
vious, the blood may reach, and return by, the
primary branches with sufficient readiness to
relieve the turgid capillaries, and prevent
any serous accumulation.

But (it may be said) the principal vein
itself has been found converted into a solid
cord, and still there was no dropsy. Granted :
but it does not follow that there never *had
been* dropsy. You know that when a large
artery is tied, the circulation is carried on in
the corresponding limb, by means of colla-
teral arterial branches : imperfectly indeed at
first ; but at length, as the supplemental
channels become more numerous and free,
the supply of blood to the limb is as co-
pious as ever. It is precisely the same, *mu-
tatis mutandis*, with the veins ; only that
the anastomosing venous tubes are not
(perhaps) so readily developed as the arterial.
Now I am not aware of any instance in
which it has been shewn that the principal
vein was obliterated, and yet there neither
was, nor had been, any œdema of the limb.
The recorded cases have been met with in

dissecting rooms, and the previous history of the subject has been unknown or unregistered. Mr. Kiernan has told me that he once examined the body of a woman who had excited much curiosity among the medical men by whom she had been seen during life, on account of a remarkable and enormous dilatation of the superficial veins of the abdomen. She was not dropsical, and the cause of the huge varix was sought for with great interest after her death. The inferior cava was obliterated. Here the compensating result was obvious to the sight; the new channels had answered their purpose, and performed the functions of the original channel. The history of this case was incomplete : it was not ascertained whether the woman had always been free from dropsy.

I hold this objection therefore to be invalid, until some authentic instance shall be brought forward of the obliteration of a large venous trunk, without a corresponding accumulation of serous fluid, either at the time when the observation is made, or at some previous time in the life of that individual. It is, besides, possible enough, that the obstruction of a large vein may be effected gradually, by the slow encroachment, for instance, of a growing tumour; and the collateral circulation may begin to be enlarged with the first impediment in the vein, and may keep pace with and counterbalance that increasing impediment, till the closure of the vessel is complete ; so that, from first to last, there may be no noticeable dropsy.

Again, it is affirmed, and truly affirmed, that anasarca often occurs, without any obliteration of veins, and independent of any discoverable organic disease in the heart, or anywhere else. We see this every day, in weak chlorotic girls, with bloodless cheeks, and pale lips. Some of you saw a case of this kind which was lately under my care in the hospital ; besides the anasarca, the systolic sound of the heart was accompanied by a loud, unmistakeable bellows sound. This girl got quite well, and left the hospital without bellows sound, or any other trace of disease. There could not then have been an organic change : in fact there was not. Yet was there, virtually, a retardation of the venous circulation : not by any mechanical obstacle opposed to its course, but in consequence of the debility of that hollow muscle, the office of which is to propel onwards, with a certain degree of force, the blood that reaches it. Girls of this description have weak and flabby voluntary muscles ; and it is reasonable to presume that the involuntary muscle, the heart, partakes of the general debility of the muscular system, and becomes incapable of sending the blood forwards with the requisite energy. Nay, I believe that a heart thus feeble may yield a little and dilate under the resisting pressure of the blood that enters its chambers ; and that so an occasional but temporary bellows sound may arise, from the altered relation between the cavities of the heart and their outlets. Certainly this view of the matter is strengthened by the *juvantia* and *lædentia*. If you are tempted, by the pain complained of by your patient, or by the violence with which her heart is throbbing, to take away blood, you find that she is ultimately made worse by the depletion ; on the other hand, if you give her steel, feed her well, keep her bowels free, and place her every morning under a cold shower bath, you find that she recovers her lost strength, that colour returns to her lips and cheeks, that her palpitations cease, and her dropsy vanishes. In proportion as the muscular system in general receives fresh tone and vigour, does that particular muscle the heart also regain the degree of power necessary for the effectual discharge of its proper function, which is very much that of a forcing pump. Such is the way in which I should explain both the cause of the dropsy, and the cause of its cessation. In such cases our patients do not simply *recover* ; they are *cured*. I should apply a similar explanation to some other forms of dropsy. Andral describes a certain *cachectic* disposition of the body to be a cause of dropsy ; persons may be bled into a dropsy, and starved or weakened into a dropsy. These are genuine instances of dropsy from debility, such as the ancients conceived all dropsies to proceed from. It may be that the thin and watery quality of the blood induced by frequent bleedings, by insufficient nourishment, by certain poisons, or by other causes, may facilitate its passage through the coats of the veins. But admitting this as a concurrent cause, I am disposed to the belief that all passive dropsies occurring under the circumstances just adverted to, and without any apparent organic disease or change, are mainly to be ascribed to debility of the heart ; and viewed in this way, they are all brought under the same general principle ; viz., the retardation of the blood in the veins.

General Dropsy, cardiac or renal. — A large class, then, of passive dropsies, depending upon mechanical congestion, and defective absorption by the veins, are traceable, in their origin, to the heart ; and we call them, accordingly, *cardiac* dropsies. But another class, perhaps as numerous, are connected in a remarkable manner with certain diseased conditions of the kidneys ; and these, for the sake of distinction, we style *renal* dropsies. I shall say a few words respecting them, after I have briefly considered the other source of dropsical swellings, adverted to in the commencement of this lecture ; namely, excessive *exhalation* of serous liquid. Dropsy so caused comes on suddenly and tumultuously, and is spoken of as being

acute or *active*. It borders closely upon inflammation, and sometimes can scarcely be discriminated from inflammation with serous effusion. The condition of the capillary circulation is supposed to be intermediate between that in which the ordinary amount of secretion is maintained, and that in which inflammatory effusion takes place. The excessive increase of secretion is analogous to what we observe in other parts and predicaments of the body ; to the abundant perspirations, for example, that are occasioned by violent exercise : to the plentiful flow of tears caused by any irritation of the eye, or by the passion of grief ; to the augmented watery discharges from the mucous membrane of the bowels, produced by purgative medicines ; all of which may be independent of inflammation, but all of which are attended with congestion that might readily be pushed into inflammation. In point of fact, if the secretions to which I have now referred were poured into closed cavities, instead of proceeding from surfaces that are situated on the exterior of the body, or communicate readily with the exterior, they would *constitute* dropsies.

Active dropsy.—The phænomena of active dropsy are of this kind : a labourer is engaged in some employment, which, while it requires considerable bodily exertion, and causes copious perspiration, necessarily exposes him also to the influence of external cold and moisture : he has been digging (perhaps) in a wet ditch, in winter time, and he pauses to take his meal; or he has been unloading a waggon, and rides home, some miles, in a heavy rain that wets him to the skin ; or he has been mowing, in the heat of summer, and lies down to sleep upon the damp grass. All these suppositions are derived from actual occurrences. The perspiration is suddenly checked ; and in the course of a few hours he becomes universally anasarcous. Again, a patient recovering from scarlet fever ventures out into a cold atmosphere, while the process of desquamation is yet going on ; and he is attacked with dropsy of the cellular tissue, and, it may be, of some of the larger cavities also. The urine at the same time is observed to be scanty, troubled, mixed with blood.

To comprehend this rapid change from a state of health to a state of dangerous disease, we must again have recourse to the findings of physiology.

Besides the constant exhalation that takes place from the inner faces of the shut serous cavities, a large amount of watery fluid is continually thrown out of the system, by all those surfaces that communicate with the air ; by the skin, the lungs, the bowels, the kidneys. Now it is well ascertained that when the excretion of aqueous fluid from one such surface is checked, the exhalation from some other surface becomes more copious. It is probable that the aggregate quantity of water thus expelled from the system in a given time, cannot vary *much*, in either direction, without deranging the whole economy. But we are sure that the amount furnished by any excreting surface may vary and oscillate within certain limits consistent with health, provided that the defect or excess be compensated by an increase or diminution of the ordinary expenditure of watery liquid through some other channel. Sound health admits and requires this shifting and counterpoise of work between the organs destined to remove aqueous fluid from the body. This supplemental or compensating relation is more conspicuous in regard to some parts than others. The reciprocal but inverse accommodation of function that subsists between the skin and the kidneys affords the strongest and the most familiar example. In the warm weather of summer, when the perspiration is abundant, the urine is proportionally concentrated and scanty. On the other hand, during winter, when the cutaneous transpiration is checked by the operation of external cold, the flow of dilute water from the kidneys is strikingly augmented. All this is well known to be compatible with the maintenance of the most perfect health. But supposing the exhalation from one of these surfaces to be much diminished, or to cease, without a corresponding increase of function in the related organ, or in any excreting organ communicating with the exterior, then dropsy, in some form or degree, is very apt to arise. The aqueous liquid thus detained in the blood-vessels, seeks and at length finds some unnatural and inward vent, and is poured forth into the cellular tissue, or into the cavities bounded by the serous membranes.

Dropsy of one part sometimes supervenes suddenly upon the rapid disappearance of a watery collection from another part. It is no uncommon thing to see the swollen unwieldy legs and thighs of an anasarcous patient quickly unload themselves, and resume their natural bulk and symmetry. His friends congratulate him, and each other, that his disease is leaving him ; but as his legs are emptying, he becomes drowsy, forgetful, comatose, apoplectic ; and after his death we find the ventricles of the brain distended with serous fluid.

Or the dropsical accumulation may be transferred from its place through a safer channel. The best instance of this that occurs to my recollection I heard related by Dr. Farre. A gouty individual had hydrocele ; dropsy of the tunica vaginalis. After the disease had lasted for some time he got very drunk one evening, with rack punch, which greatly disordered his alimentary canal, and brought on a kind of cholera. He had profuse vomiting and purging, which quite

exhausted him : and at length he fell asleep. When he awoke in the morning he found that his hydrocele, which had been a large one, was gone : and it never returned. Such an accidental cure is most instructive.

If water be injected, in some quantity, into the blood-vessels of a living animal, the animal soon perishes ; dying generally by coma, or by suffocation : and when the carcass is examined, the lungs are found to be charged with serous liquid, or water is discovered in the cellular tissue of some other part, or in the shut serous membranes. If, however, the animal be first bled, and then a quantity of water be injected equal to the quantity of blood abstracted, the injection is followed by no serious consequences.

Facts like these throw, as it seems to me, a strong light upon a confessedly obscure part of pathology. It appears that under various circumstances the blood-vessels may receive a considerable and unwonted accession of watery fluid ; and that they are very prone to get rid of the redundance. When they empty themselves through some free surface, their preternatural distension is relieved by a flux : if, on the other hand, the surface be that of a shut sac, in discharging their superfluity they cause a dropsy. Why sometimes this organ, and sometimes that, is selected as the channel by which the superabundant water shall be thrown out of the vessels, we can seldom tell. We often find it difficult to determine which of the two facts in question is to be considered the antecedent, and which the consequent. For not only is it true that when the blood-vessels become overloaded with serous fluid, they readily deposit a part of it ; but also that when they are in the opposite condition of comparative emptiness, when they contain less blood than is natural, they are equally ready to replenish themselves by absorbing fluids from any source to which they can find access. In the case of the man who was cured of his hydrocele upon the occurrence of profuse watery discharges from the stomach and bowels, it seems clear that the expenditure of serous liquid from one part led to its absorption into the blood from another. When anasarca suddenly leaves the extremities, and fatal coma follows, it appears probable that the absorption is the first of the changes, and the effusion the second : and had this effusion been determined to the mucous membrane of the intestines, to the skin, or to the kidneys, it would have brought relief and safety to the patient, instead of causing his death.

We have obtained, then, a glimpse of one or two most important principles in respect to the pathology of dropsy. The blood-vessels, when preternaturally full of aqueous fluid, have a strong tendency to empty themselves ; when preternaturally empty, they readily drink up watery fluid wherever they come in contact with it. From the discharge of their superfluity of water arises a dropsy, or a flux. The cause, and the cure, of many dropsies, lie in these propositions.

The application of these principles to the supposed case of active dropsy must be obvious. No doubt, in some such cases, actual inflammation takes place ; but in many of them there is merely the dropsical effusion, without any other trace or evidence of inflammatory action. The two facts which it chiefly concerns us to remark are these—first, that the aqueous portion of the blood, which in health is habitually carried off to a very considerable amount by the skin, is suddenly diverted from that tissue ; the perspiration, sensible and insensible, is suppressed : and secondly, that the cellular tissue, or the large serous bags, or both, become filled with serosity.

It is not by any necessity, however, that the vicarious excretion is turned upon these serous surfaces. In truth, the intercepted perspiration more often escapes, or labours to escape, from some free surface ; and then we have, not a dropsy, but a flux. Diarrhœa, for example, is more common, under the supposed circumstances, than anasarca or ascites : apparently because there is a closer analogy of structure, and a more direct consent or agreement in function, and a stronger reciprocal influence between the skin and the mucous membrane of the alimentary canal, than between the skin and the serous tissues.

Brief allusion has been made to a large class of chronic dropsies, connected with and dependant upon a peculiar renal disease. This important species of dropsy will require a detailed examination hereafter. It is more complex, and of more obscure pathology, perhaps, than *cardiac* dropsy. It certainly has a more direct relation also to what I have just been describing as active dropsy : of which it may almost be regarded as the chronic form. Sometimes the kidney disease, of which the dropsy is an incidental and not an essential symptom, springs up silently, and without obvious cause. Sometimes it may distinctly be traced back to its origin in an attack of acute dropsy ; in which complaint the kidney always and manifestly labours, its functions being violently deranged, and the urine being small in quantity, and mixed with blood.

In this chronic and renal dropsy, the watery accumulation is accounted for by the deficient excretion through the customary channels. The blood-vessels deposit that excretion in a wrong place. The urine, in the outset of the dropsy at least, is scanty. The skin is almost always dry, harsh, and unperspiring. The anasarca usually increases

or decreases, as the quantity of urine diminishes or augments. Remarkable alterations take place also in the qualities and composition of the urine itself : it has a very low specific gravity, contains albumen, and is deficient in urea. The blood degenerates too ; and other organs of the body, and especially the heart, are apt to fall into disease. The suppression of perspiration, and the appearance in the urine of blood or serum, unchanged by the secerning power of the kidney, form striking links of connexion between acute and renal dropsy.

In the sketch that I have been endeavouring to give you of the pathology of dropsy, I have taken extreme cases to elucidate the two varieties of that disease which have been respectively denominated active and passive. Let me once more present to you, in a summary view, the points of resemblance, and the points of distinction between them.

They resemble each other in the result ; namely, in the collection of serous liquid in the circumscribed cavities and vacuities of the body. They differ in the rate at which the collection augments.

In the well-marked acute dropsies the liquid is rapidly effused, in quantity much beyond the natural amount of exhalation. In the well-marked passive dropsies the exhalation goes on as usual, but the fluid exhaled is not taken back again into the circulating vessels with sufficient facility. In the one case the circulation is disturbed and tumultuous ; in the other, it remains tranquil. It is probable that in the more acute forms, the serum transudes through the coats of the arteries, or of the capillary vessels next adjacent to the arteries. In the completely chronic and cardiac forms, there is a defect of absorption by the veins. Active dropsies are sometimes spoken of as belonging to the left side of the heart ; passive dropsies to the right.

But there are intermediate degrees, in which the full veins are not only unable to admit any addition of aqueous liquid, but also to retain that which they already hold ; and serosity gradually exudes through their parietes.

What connects all these forms of dropsy is a preternatural fulness in some part, or the whole, of the hydraulic machine. And this seems to be the grand key to the entire pathology, as well as to the remedial management of the disease.

I scarcely need point out to you the fact, that the water of dropsy is liable to change its place, in obedience to the force of gravity. In general anasarca, when the serous accumulation slowly augments, it first becomes visible about the feet and ankles. There are two causes for this ; the one occasional in its operation, the other general. The veins of the lower extremities are apt, when the patient is erect, to be more turgid than other veins ; for unless the action of their valves be quite perfect, those vessels sustain the weight of a large superincumbent column of blood, which concurs with other causes to retard the upward current, and to keep the depending capillaries unduly full. Under such circumstances the effusion, or the arrest of absorption, may *take place* around the insteps earlier than in any other part. But in general it is not so. In most cases, the truer and simpler reason of the earlier manifestation of dropsical swelling about the ankles, is merely that the serous liquid which fails to be removed from the cellular tissue in all parts of the body, gravitates towards the *lowest* part ; and being thus collected into a comparatively small space, is rendered more perceptible. During the night, when the horizontal posture is maintained for several hours, the œdema of the ankles disappears, but the neck and face, perhaps, become bloated and puffy. And it is obvious why, in these cases, the feet, towards evening, swell more than the hands. The hands receive the serous fluid from the cellular tissue of the arms alone ; the feet, that which sinks down, not only from the legs and thighs, but from the head and trunk also. The limbs may be looked upon as bags, which fill up in proportion to the quantity of liquid detained. And the lungs are similarly bags : and in these cases we commonly may hear the crepitation of pulmonary œdema in their lowermost portions.

I mentioned an instance in which one-half only of the body was anasarcous, and that the upper half. The descent of the dropsical fluid was prevented by the dress of the patient ; the waistband of his trowsers having compressed the cellular tissue through which alone the gravitating liquid could seek a passage. So, sometimes, it is stopped at a lower point of its descent by tight garters, and the thighs swell earlier than the insteps. It is not at all uncommon to see persons who, in the daytime at least, and in the erect posture, are anasarcous in the lower half only of the body. We do not so often meet with anasarca of one moiety of the body, the division being made by an imaginary plane drawn through its axis. Yet this does occasionally happen. This curious phenomenon is usually the result of a mere accident, the anasarcous patient being unable to leave his bed, or to lie at all except on one side ; and then the accumulating liquid gravitates to that side. I have, however, seen one case to which this explanation would not apply. I believe that some local obstruction to a large vein in the neighbourhood of the shoulder caused œdema there, and the fluid sunk down and filled the cellular

tissue of that side alone. As the man recovered, I had no means of verifying the truth of this conjecture.

Cæteris paribus those parts of the body become the most loaded with serous fluid, and shew the anasarca the plainest, of which the cellular tissue is plentiful and loose; as the eyelids, and the scrotum. But in extreme cases the liquid pervades the cellular tissue, where it is much more dense and compact: as where, for example, it is sub jacent to mucous membranes. In the examination of a dropsical corpse, the mucous coat of the intestines may sometimes be seen to be elevated by the water collected beneath it. It then looks like jelly, and the *valvulæ conniventes*, which are flat and thin in their ordinary state, become round and convex. Dropsy of the submucous tissue of the air-passages is frequently a cause of death.

Many persons seem disposed to ascribe these anasarcous swellings, especially when they make their appearance suddenly, to inflammation; and much is said about the frequency of *inflammatory dropsy*. But the facts we have just been considering sufficiently refute this theory. If the serous liquid be the product of inflammation, what is the part inflamed? It cannot be, as some appear to think, the distended cellular tissue itself; for if so, the inflammation must shift its quarters under the influence of gravity. The term inflammatory dropsy may not perhaps be indefensible when applied to that class of dropsical affections that have been spoken of under the head of active dropsy. I am far from denying the frequent agency of inflammation in producing changes which, in their turn, lead to dropsy; but we shall do well not to confound those collections of serum mixed with blood or with coagulable lymph, which are distinctly events or products of inflammation, with other collections of serum which resemble the former in that respect only, but differ entirely from them in every other particular. To the class denominated active, which occur suddenly, from defect of some one or more of the usual channels of aqueous excretion, and which are usually attended with much disturbance of the whole system, the epithet *febrile* would not be inappropriate. There may be some few cases in which it is impossible to determine whether the effusion be inflammatory in its origin or not. If the serum be turbid, if we can discover in it the smallest admixture of pus, or of flakes of lymph, or if the disease has been marked by the ordinary signs of internal inflammation, we need not hesitate in our opinion. One of the latest systematic writers on dropsy in this country holds that all dropsies are more or less inflammatory. We can see one reason for this mistake (for a mistake it surely is) in the relief and amendment which often ensue

upon the employment of bloodletting in dropsy. And this brings me to a very few final remarks concerning the principles upon which dropsies are to be treated.

Treatment of Dropsies.—Of course the first object is to get rid of the preternatural accumulation of watery fluid: and the second object is to prevent its collecting again; in other words, to remedy the diseased conditions which gave rise to the dropsy. Indeed, if we can accomplish this second object without delay, the dropsy will generally disappear of its own accord. In what has been called active or febrile anasarca, general bloodletting is advantageous in several ways. It helps to relieve the congestion, akin to inflammation, upon which the effusion depends: it tends to abate the undue action of the heart: and by emptying the blood-vessels, it facilitates the reabsorption of the effused liquid, and its ultimate ejection from the system.

But although bloodletting is the most direct and certain way of unburdening the loaded veins, and therefore, in many instances, the most effectual remedy for the dropsy, it is by no means adapted to all, nor even to many forms of the malady. It will always indeed remove a portion of the aqueous ingredient of the blood, but it expends at the same time its fibrin and its red particles. It impoverishes the circulating fluid, and so enfeebles the patient more than the indirect measures, to be mentioned presently, for evacuating the collected liquid. Perhaps, by rendering the blood more watery, venæsection may indirectly favour the transudation of its serum outwards whenever the venous current happens to be retarded. It certainly weakens the central organ of the circulation; and to muscular debility of the heart we have already seen that certain forms of general dropsy may owe their origin: and thus it is that ill-timed or excessive bleeding may be the cause of dropsy. In these forms of anasarca, instead of robbing the veins of their blood, we seek to repair the quality and richness of that fluid, and so to restore the deficient tone and vigour of all the muscles, and of the heart among the rest.

In many cases then it is inexpedient to let blood; and we endeavour to empty the vessels indirectly, and in such a manner as to withdraw from them the more watery parts only of their contents. In other words, it becomes our object to augment the discharge of watery fluid from one or more of the secreting surfaces of the body: but it must not be the inner surface of a shut sac.

I noticed before the close analogy that obtains between dropsies and fluxes. Dropsy is a flux into a closed cavity. Fluxes would be dropsies if the fluid poured forth did not escape. And you are to observe that we

frequently try to cure a dropsy by producing a flux.

By what surface or channel this artificial drain shall be attempted, is often a matter of great nicety and importance. In some cases we strive to promote the discharge of the superabundant water by the way of the kidneys : in others by the mucous lining of the alimentary canal : in others by the external skin. The circumstances by which our choice must be determined will come under review hereafter.

Passive dropsies are much more difficult of cure than active, and will often baffle our best-directed efforts. You are not, however, to regard those passive dropsies that depend upon the obliteration of a large vein as necessarily incurable ; because, if a collateral venous circulation be accomplished, the dropsy will permanently disappear. But we must give nature the credit of the cure in such cases. Time is the best remedy ; and all that we can sometimes do is to alleviate in the meanwhile the most distressing or threatening of the symptoms.

I mentioned, in the outset of the lecture, that the presence of the dropsical fluid may constitute nearly all the suffering of the patient, as well as much of his danger. Now, when we cannot get rid of the water by bleeding, or by internal remedies which excite serous discharges, we may often afford great present comfort to our patient, and prolong his days, by letting the water out by a slight mechanical operation. *Paracentesis* is the scientific, and *tapping* the vulgar name for this proceeding. It has been performed successfully, by means of a small trocar, to evacuate the water from the brain in chronic hydrocephalus : it is often resorted to for the purpose of emptying the peritoneal cavity, and the tunica vaginalis testis ; and it is not seldom practised to let out the fluid of anasarca ; for *acupuncture* of the legs and thighs and scrotum is only another form of tapping.

In the local variety of dropsy that is called *hydrocele*, the reaccumulation of the liquid is sometimes prevented by exciting just so much inflammation of the membrane as may cause its opposite surfaces to cohere ; whereby the cavity itself being abolished, any return of the disease is rendered impossible.

This is an expedient which we do not dare to employ in other species of dropsy ; in ascites, for example : 1st, because the inflammation itself would place the patient's existence in imminent peril ; and secondly, because, if it could be safely conducted, the adhesion and obliteration would seriously embarrass and impede the functions of important organs.

The circumstances which require and justify this mechanical remedy ; the rules and

precautions to be observed in its performance ; and the measures to be adopted for preventing the recurrence of the accumulation, by the removal of its efficient cause, will all be considered in detail when we come to treat of the special forms of dropsy.

NOTE ON THE PRESENT EPIDEMIC OF SMALL-POX,
AND ON THE
NECESSITY OF ARRESTING ITS RAVAGES.

By WILLIAM FARR.*

THE last epidemic of small-pox began early in 1837, and attained its greatest height in 1838. The number of deaths registered from small-pox in the two and a half years, ending Dec. 31st, 1839, were 30,819 in England, and 5186 (or one-sixth of the number) in the metropolis. Its termination was thus described :—" The epidemic [which had be-" gun in the towns on the eastern side of the " island] subsided on the western shore ; and " in the summer of 1839, only 1533 died of " small-pox in the kingdom ; 65 cases of " small-pox were registered in London. In " the autumn of 1839, signs of a second epi-" demic appeared at Liverpool, Bath, and " other towns ; the deaths in the kingdom " rose to 1730."—*App. to Second Report of the Registrar-General*, p. 17.

The disease in the metropolis was then at the lowest ebb ; the deaths from small-pox were only 60 in the three months, October, November, December, 1839. But the tables of mortality have displayed a rapid weekly increase down to the present time ; and it may be interesting to compare the rate of increase with that which obtained in the previous epidemic. The comparison will render it probable that if unchecked, the mortality has not yet attained its height.

The deaths registered in the metropolis were as follows, in 1837, 1838, 1839 :—

Quarters.		Deaths from Small-pox.
1	1837. July, Aug., Sept. - - -	257
2	Oct., Nov., Dec. - - -	506
3	1838. Jan., Feb., March - - -	753
4	April, May, June - - -	1145
5	July, Aug., Sept. - - -	1061
6	Oct., Nov., Dec. - - -	868
7	1839. Jan., Feb., March - -	364
8	April, May, June - - -	117
9	July, Aug., Sept. - - -	65
10	Oct., Nov., Dec. - - -	60
	Total. - - - - - - - - - - -	5116

The quarterly deaths rose from 257 to 1145. The increase was 445 per cent., or more than fourfold, in the period of *three*

---

* From the Lancet, Nov. 28.

quarters, extending from the middle of August, 1837, to the middle of May, 1838. The increase was in a geometrical progression; and the *quarterly* rate of increase was, therefore, the cube root of $4.45 = 1.65$; or 65 per cent.

The deaths by small-pox in the metropolis were 60 in the last quarter of 1839; but 104 deaths were registered in the first quarter of 1840. Another epidemic had commenced, and there was an opportunity of observing the disease at a much earlier stage than in the previous epidemic. The rate 1.65 regulated the rise of the former epidemic, after the deaths were 259 quarterly: would the same rate apply to the epidemic of 1840, and regulate its course? Could the future number of deaths have been predicted, with the degree of probability, in April, 1840? With only one series of accurate observations, it would have been rash to hazard any prediction of the kind. But if the prediction had been hazarded, it would have been found accurate. The rate 1.65 has hitherto regulate the course of the present epidemic, and has thus confirmed the view taken of this class of diseases, and of the laws of their progress.

The following table exhibits the quarterly deaths registered, and the numbers deduced from the first (60) by successively multiplying by 1.65 :—

	Registered.	Series of Numbers produced by 1.65, the Rate of Increase in the Epidemic of 1837-8.
13 weeks (Oct. 1 to Dec. 31, 1839) - - -	60	60
13 weeks (Jan. 5 to April 4, 1840) - - -	104	99
13 weeks (April 5 to July 4) - - - - - - -	170	163
13 weeks (July 5 to Oct. 3) - - - - - - -	258	297
Total - - - - - - - - - - - - - -	587	597

The deaths in the quarter which has commenced would be 440; in the quaarter following, 724, at the same rate. But it will be observed, that the present series of numbers ends precisely at the point where the registration of the former epidemic commenced. The deaths registered in the quarter ending Sept. 30, 1837, were 257; and in the quarter ending Oct. 3, 1840, they were 253.

At another time I will discuss certain slight corrections which are required in these calculations, and will show how the rata of increase for days, weeks, and any multiple of these elementary periods, may be deduced. It is now of more importance to show the practical bearing of the facts. What is the prospect before us? It may be seen in the previous tables. The deaths of hundreds, nay thousands, of children, are, probably, about to take place in the metropolis by small-pox; and the fatality of small-pox may be prevented by means of a discovery made by Jenner at the end of the last century. The epidemic *may* subside spontaneously, or it *may* spread its ravages to an unexampled extent; but it is more probable, that, if left to itself, it will increase at the present rate, and we may again see 500, and 750, and 1140, fall its victims in successive seasons. From the deaths (266) within the last six weeks, it may be inferred that the disease is spreading at least as rapidly as it did in former years.

It will not, I believe, be disputed by those acquainted with the subject, that if every unvaccinated person in the metropolis were vaccinated *within the next week*, the epidemic would at once be arrested; particu-

larly if, at the same time, the miserable courts and streets, which it is now devastating, were thoroughly cleansed, the houses whitewashed, and the comforts of the inmates, on the approach of winter, attended to, to a moderate extent.

Is not a case for public interference, then, clearly made out? Should not an energetic effort be made to save these lives, amounting to *several thousands*, from small-pox? They are helpless children, the great majority of them have not numbered fifteen years; but that can be no reason for abandoning them to their fate,—to the hot fever, the blistering pains, the defacing hands, of this sad malady. They are, in many instances, the neglected offspring of the poor,—which again only gives them a stronger claim on humanity, justice, and protection of society.

I am perfectly aware that some steps have been taken to extend the practice of vaccination; but those steps have been slow, and the measures appear by no means equal to the exigencies of the case. *Five children, at the very least, are destroyed daily by small-pox* in the metropolis alone; and what has been done, or is doing, to put a stop to this tremendous sacrifice of human life, and the sufferings of the sick and dying? For the last four weeks the Tables of Mortality have repeated 35 persons died of small-pox, 54 died of small-pox, 60 died of small-pox, 58 died of small-pox, in the week. They will reiterate nearly the same emphatic facts week after week through the year, the number rising progressively. Vary the statement slightly, and what would be the effect of the announcement in the Times or the Morning Chronicle :—five children will be thrown from

London-bridge daily during the next week—the next twelve months—and the number will be raised to six, seven, and eight daily in the next season. The very supposition is revolting. Yet it gives but a faint idea of the reality. Instead of dying suddenly, with little pain, and in a few minutes, the unprotected sufferers linger many days, ere they perish ; and the survivors escape as from the fire, with faces cicatrised, deformed irreparably, and perhaps blinded for life.

The lives can be saved in the actual, almost as certainly as they could in the imagined case ; but their salvation demands a little trouble, and some expense. The parents are ill-informed ; they do not know the danger of their children ; they are not aware that nearly all who die have not been vaccinated ; and that vaccination, producing a modified small-pox, is an effectual protection against the natural disease ; they must be visited, talked to, reasoned with, and " compelled to come in," as Dr. Chalmers would compel people to go to church and heaven.

With the facts before them the people of this country can come to but one conclusion, that the entire population should be forthwith vaccinated, and that no trouble or expense should be spared to prevent the threatened sacrifice of life. The Legislature, last session, emphatically asserted this principle ; and though the Small-pox Prevention Bill, introduced by Mr. Wakley, and supported by the voice of all parties in the medical profession, was set aside by Sir James Graham's Vaccination-Extension Bill, so much good was incorporated in the latter measure in committee, as to lead to the belief that the benevolent intentions of the Legislature, the government, and, in fact, of all parties, would not be entirely defeated. The Act has not, however, worked well ; perhaps it has not had a fair trial. I shall not now enter into the controvesy, in which the poor-law commissioners and the vestries appear to me to have been clearly wrong, and the medical profession right ; but cannot some compromise be come to, to meet the present emergency ? Five persons are dying daily of small-pox in the metropolis, and they die because the poor-law authorities have determined not to give more than eighteenpence for every life that is saved—for every child that is vaccinated—by the members of the medical profession, who discovered vaccination, and who not only deprive themselves of innumerable patients by the operation, but bestow more professional advice gratuitously than any other learned profession in the kingdom

All the medical practitioners of the country should be induced to vaccinate under the Act, and proper persons should be engaged immediately to go from house to house

to ascertain how many persons have and how many have not been vaccinated. The unprotected should be vaccinated as rapidly as lymph could be procured. Small-pox may thus be arrested.

The arguments for vaccination are met by one objection among very ignorant and very philosophical people. It is, that while vaccination saves from small-pox, it exposes the person vaccinated to other diseases. That if he do not die of small pox he will die of something else, is unquestionable ; but if this argument be good for anything, why save people from drowning, from fire, from any death whatever, from the murderer's guilty hand? Vaccination does not, it is true, like death by small-pox, exempt from other diseases ; but there is not a shadow of proof, that a person who has had the modified, vaccinated small-pox, is more liable to other diseases than a person covered with scars of the natural disease.

Dr. Baron, in his Life of Jenner, relates the case of a country parish which obstinately held back for some time, and refused vaccination at the doctor's hands. All at once the people brought their children in great numbers. An epidemic had proved extremely fatal in the previous year ; and the churchwardens discovering that the cost of coffins for those who died of small-pox formed a formidable item in the annual accounts, immediately exerted their influence, and induced the people to accept Jenner's kind offer. This story could only be true—and, in fact, could only be told of overseers, churchwardens, or poor-law authorities ; but for the satisfaction of the persons who see no merit in anything but a reduction of the rates, it may be stated, that in the last epidemic the coffins for the victims of small-pox, at only £1 each, must have cost £30,000.

The middle and higher classes are protected by vaccination from small-pox ; but when small-pox becomes epidemic and very virulent, experience has proved that a certain number of persons, in good circumstances, are attacked after vaccination, and a few die even of a second attack of small-pox. The rich are thus directly interested in the health of the poor. If the poor be swept off by an epidemic, the atmosphere is poisoned, and the rich are not always spared. For their own sakes, as well as from higher and more generous motives, the wealthy tradespeople, merchants, and inhabitants of the metropolis, should then surely exert themselves to suppress the contagious disease. The epidemic is now in Westminster and Marylebone ; it is spreading in the West-end, and is likely to be at the height just in the season when the families of the aristocracy are in town. They would naturally feel less apprehension for the safety of their

children, if instead of eighty or ninety dying in the streets around them, the malady were extinguished ; and as the votes of both houses of Parliament showed last year, would from pure humanity and an enlightened regard for the welfare of the community, sanction any efficient plan for the extension of vaccination.

The epidemic has already made considerable progress : many have perished irretrievably ; but no further arguments are, I hope, necessary to induce all classes to unite in saving four thousand lives in the metropolis, and six times that number in England and Wales.

Nov. 20, 1840.

ON THE

TREATMENT OF ULCERS OF THE LOWER EXTREMITIES.

By Joseph Bell, Surgeon, Barrhead.

[For the London Medical Gazette.]

I intend in the present communication to place before the readers of the Medical Gazette a few cases of ulcers treated principally on that excellent plan which Mr. Baynton brought under the notice of the profession many years ago : a plan which, I am sorry to say, has now almost fallen into disuse. I trust that the following cases will have some effect, however trivial, in rescuing it from being lost to suffering humanity.

Case I. — Jan. 2, 1838. E. M'E——, æt. 30 years, an unhealthy looking female about middle stature, dark complexion. On the internal aspect of left leg, about its middle, there is a large ulcer, measuring in length 4 inches, in breadth $2\frac{1}{2}$ inches at the upper part, and $3\frac{1}{4}$ inches at the lower ; is nearly an inch deep ; it is filled with black decayed cellular substance, and exudes a dark fœtid discharge, along with considerable quantities of blood ; edges of sore rigid, callous, and slightly everted, having a line of a greyish colour around their margin ; leg and foot much swollen, particularly about sore, around which, for the extent of four inches, the integuments are of a fiery red appearance, hot, hard, and unyielding to the touch. The integuments at the upper margin of the sore are undermined nearly half an inch ; pain of sore very acute, particularly at night, when she can obtain no sleep ; painfulness also prevents walking. Pulse 80 ; tongue white ; bowels said to be regular, as is also catamenia.   Sore commenced about three weeks

ago, in consequence of falling against a chair, by which the skin was abraded.

    Admov. Nitras. Argent. ulceri, et utat. mod. Baynton.   Habt. Pil. Plummeri, omni noct.

3d. Redness, hardness, around sore, nearly gone ; swelling less ; pain greatly relieved ; slept a little during the night ; the cellular substance which filled sore coming away. Cont.

4th. Pain, swelling, and redness gone ; granulations commencing to spring up at bottom of sore ; some purulent discharge over its surface.   Cont.

6th. Sore granulating beautifully, and is much less in size ; sleeps well, and is going about her usual avocations.   Cont.

8th. Ulcer filling up rapidly, and is beginning to cicatrize around margins.   Cont.

12th. Sore about size of a shilling, and is cicatrizing with rapidity.   Cont.

21st. Sore healed, and in its place a firm cicatrix about the size of a halfpenny.

Case II.—April 11, 1838. John Findly, æt. 25 years, of a ruddy complexion, fair hair, blue eyes ; pulse 68 ; tongue slightly furred. On external aspect of left leg, about its middle, are two ulcers excavated, of a round shape, with hardened edges, and covered with a thin acrid discharge ; circumference of each $3\frac{1}{2}$ inches, depth $\frac{3}{8}$ of an inch. A little lower down, and more to the back of the leg, there is a smaller sore, of a similar character and depth : sores very painful, and the integuments around them, to the extent of a hand's breadth, are painful, red, and tender ; considerable pain and swelling along anterior margin of tibia, extending four inches above sores, and two and a half inches below them ; bowels said to be regular.   Sores commenced a month since ; at first they had the appearance of small pimples, but have gradually assumed their present aspect. About 18 months since he had a similar ulcer on ankle of same leg. It was healed by Baynton's system.

Utat. mod. Baynton, et habt. Pil. Plumm. j. om. noct.

13th. Sores are now looking healthy, and discharging laudable pus ; pain nearly gone, as is also the redness and tumefaction which surround the sores ; has slept soundly last night, which he has not done for some months.   Cont.

May 3d. Sores healed.

Case III.—August 22, 1839. C. M., æt. 25 years, of a dark complexion, middle stature, full habit ; pulse 70 ; tongue clean ; has on the outer side of left leg, about three inches from malleolus, four ulcerated spots ; the largest is about the size of a halfpenny, its edges are hard, irregular, and elevated, about a quarter of an inch deep, and its surface

is covered with a layer of dirty yellow matter; discharge is thin and acrid; two of the others are about the size of a silver fourpenny piece, and the remaining one is rather larger than a sixpence; these resemble the first in their character, except the last, which is much deeper: integuments around sores very red, swollen; cuticle abraded, and very painful: the whole leg and foot is very much swollen; bowels and catamenia regular. Sores of fourteen months' duration; were caused by a fall against a piece of wood; has been under the treatment of several medical men. One dressed the leg nightly for several months with small pieces of adhesive plaster laid across sores.

Utat. mod. Baynton, et habt. Pil. Plum. j. om. noct.

24th. Sores greatly improved, are discharging healthy pus, and are granulating rapidly; inflammatory appearance of sk around sores gone, as is also pain. Cont.

27th. Sores cicatrizing, are nearly reduced one-half in size; no pain. Cont.

Sept. 2d. The three small sores healed; large one nearly so. Cont.

10th. Sore healed.

Case IV.—Feb. 22, 1838. A. B., a healthy-looking man, æt. 30 years, by trade a baker: tongue white and furred; pulse 86; appetite indifferent. On posterior aspect of right leg, over the gastrocnemii muscles, are two ulcerated spots of an oval shape, separated by a narrow band of integument; do not communicate; each about $4\frac{1}{2}$ inches in circumference; edges irregular, and surfaces covered with a black thin fœtid matter, which is copiously discharged. On inner side of leg, in a line with these, there is another ulcer rather less, but of the same irritable appearance as the others; skin around sores to the extent of six inches, of a very deep red colour, exceedingly painful when touched; leg swollen: he is unable to stand from excessive pain; bowels said to be costive. About a year ago a varicose vein burst and discharged a considerable quantity of blood; this was succeeded by the two ulcerated spots on back of leg; the other sore made its appearance about eight months since. Has undergone, previous to appearance of present complaint, several courses of mercury for diseased liver; has applied innumerable remedies to sores without effect; was confined to bed by one medical man for three weeks, with no improvement.

Utat. mod. Baynton, et habt. Pil. Plum. om. noct. et bibat Decoct. Sarsæ lbss. b. d.

25th. Sores were very painful for about fifteen minutes after two first dressings, but was free from it at the last. Great improvement in sores; pain nearly gone; integuments resuming their natural appearance; sores granu-

lating healthily, and laudable pus secreted: is able, since 23d, to walk about with freedom, and to attend his work. Cont.

March 1st. Sores cicatrizing rapidly; surrounding skin natural; no pain nor inconvenience from leg. Cont.

13th. Sores healed; general health improved.

Admov. fascia. et intermitt. alia.

Case V.—Jan. 20, 1838. J. R., æt. 18 years, a healthy-looking young woman, of fair complexion; pulse 72; tongue clean. She has an ulcer $2\frac{1}{2}$ inches long, by $1\frac{3}{4}$ inch broad, on outer side of right foot; edges of sores irregular and elevated; foot swollen, and skin of a fiery-red appearance and very painful. Sore is the consequence of a burn which she received ten weeks ago. She has been using—

Liniment Ol. Lini. c. Aq. Calcis, and poultices of bread.

Admov. Nit. Argent Ule. et utat. mod. Baynton.

Feb. 2d. Redness and swelling of foot nearly gone; pain relieved; edges reduced, and sore granulating healthily; is able to walk about. Cont.

8th. Sore has cicatrized, except about the size of a shilling, which is healthy; pain is totally gone.

16th. Ulcer healed.

Case VI.—April 1, 1840. Mrs. G., æt. 80 years, of a leucophlegmatic appearance: pulse 90; tongue furred. Has had an angry looking ulcer, about the size of a shilling, on outer side of dorsum of right foot, an inch from lower margin of external malleolus; surface of sore dark colour; slight discharge of sanies; surrounding skin inflamed and tender; veins of ankle and foot varicose. Sore of two months' duration, and is exceedingly painful, particularly at night.

Curat. Ulc. mod. Baynton, et habt. Pil. Plum. om. noct.

6th. Sore greatly better; pain gone; redness nearly so. Cont.

21st. Sore healed; integuments have resumed their natural appearance.

Cont. fascia. sed. intermitt. alia.

Case VII.—Sept. 15, 1839. J. C., æt. 24 years, a stout Highland girl, of dark complexion, rather above ordinary stature: tongue clean; pulse 76; appetite good. On right leg, over gastrocnemii muscles, there are two round-shaped ulcers about size of a shilling, quarter of an inch deep, edges callous, and a dark fœtid matter is discharged from them. On each side of inner malleolus there are two others, much larger and deeper, of a darker aspect, and discharging fœtid matter; leg and foot much swollen; integuments all around sores of a dark red ap-

pearance; very tender and painful; as is also sores, which are of seven months' duration; Bowels said to be regular; but has had no catamenial discharge for the last six months; is not pregnant. Has been using a bandage and some ointment to sores, without any relief.

Curat ulc. mod. Baynton m. s. et habt. Pil. Plum. om. noct.

18th. Sores on upper part of leg are healing rapidly; those on ankle are looking much better; surrounding redness and swelling completely gone; has had no pain since second dressing (16th). Cont.

26th. Two upper sores healed; others greatly improved; reduced nearly to one-half their extent. Cont.

Oct. 14th. Sores healed; catamenia returned about six days after.

CASE VIII.—Nov. 3, 1839. J. M'L., æt. 42 years, a stout man of middle stature; dark complexion; by trade a calico-printer; pulse 66; tongue clean; appetite good; has on inner aspect of left leg, two inches from malleolus, an ulcer of an oval shape; size, an inch and a half in circumference, five-eighths of an inch deep; surface dark, and exudes a thin discharge of a very offensive smell; edges irregular and callous; surrounding skin of a dark red colour; painful when pressed; considerable swelling of lower third of leg; and some of the veins enlarged, though not to any great extent; pain of sore very severe, particularly at night; bowels said to be regular; ulcer commenced about three months since; he has used a great variety of ointments without benefit. The same place ulcerated about eighteen months ago, and was healed in about six months by application of

Nitras Argent. and Cerate. utat.mod. Baynton, et habt. Pil. Plum. j. om. noct.

5th. Pain gone; skin around sore has lost its inflamed appearance; healthy looking granulations springing up on surface of sore; discharge is now of a healthy character; swelling nearly gone. Cont.

9th. Granulations are now level with edges of sore, which is cicatrized to a considerable extent; no pain.

12th. Sore healing rapidly. Cont.

21st. Sore healed.

Cont. fasc. sed intermitt. alia.

CASE IX.—Dec. 9, 1837. Ag. R. æt 14 years, of a weakly habit; fair complexion; pulse 86. On right leg, over edge of tibia, is an excavated ulcer about the size of a halfpenny, and half an inch deep; bone not bare; surface of sore of a dark brownish appearance; it discharges a thin fœtid matter: around sore the skin to the extent of twelve inches in circumference is of a deep red colour; is slightly œdematous; ankle and foot swollen and œdematous; pain of sore intense;

bowels regular; catamenia has not yet made its appearance. About eight days ago her leg came in contact with a piece of wood; the cuticle was abraded, and the present sore is the result.

Curat. ulc. mod. Baynton.

10th. Sore looks much better; discharge less fœtid and more purulent; surrounding inflammation nearly gone, as is also œdema; pain mitigated. Cont.

13th. Sore granulating in a healthy manner, pain and tenderness gone. Cont.

22nd. Sore healed.

CASE X.—June 19, 1839. J. B., æt. 19, a stout lad; on right leg, about its middle, there is a dark unhealthy ulcer on the inner edge of tibia, about the size of a half-crown piece, three-quarters of an inch to one-eighth in depth; discharge dark, thin, and of very offensive smell. Around edges of sore (which are elevated and callous) integuments discoloured; red, and at some spots livid; sore painful; it is the consequence of a scratch received from a nail about eight months ago. General health in different; tongue furred; pulse 70; bowels regular.

Curat. ulc. mod. Baynton, et habt. Pil. Plum. j. om. secund. noct.

20th. Sore looks better; discharge is decreased, and has assumed a more purulent character; surrounding discoloration less; pain greatly relieved. Cont.

22nd. Sore continues to improve; is filling up with healthy granulations. Cont.

Jan. 19. 1838. Sore healed.

CASE XI.—Sept. 6, 1838. Jas. S., æt. 62 years, a stout old man, by trade a carpenter; he is in the enjoyment of good health, and is able to follow his occupation. Pulse 70; tongue white. On the internal and posterior aspect of left leg, five inches from head of tibia, there is a large excavated ulcer of an oval shape, eleven inches and a half in circumference; edges ragged, elevated, and callous; surface of sore of a very unhealthy appearance; discharge thin and acrid, abrading surrounding cuticle; depth varies from $\frac{1}{8}$th of an inch to one inch; around circumference of sore, an inch in breadth, the integuments are hard and red, and painful to the touch; surrounding skin of a fiery appearance, and abraded at several points; he suffers great pain from sore; bowels costive. Sore commenced about three years ago: during that period he has employed a great many plans to effect a cure; such as ointment, nitrate of silver, pressure by a bandage and lead, &c.; from some of these means he obtained a temporary benefit, whilst others had no good effect.

Curat. ulc. mod. Baynton, et habt. Pil. Plum. j. om. noct.

7th. Feels sore easier; redness of skin less. Cont.

8th. Considerable improvement; edges of sore less elevated ; some healthy granulations making their appearance at its bottom ; sore less in size ; circumference ten inches. Cont.

12th. Sore granulating beautifully ; discharge healthy ; no pain ; circumference is now eight inches. Cont.

20th. Sore nearly filled up with healthy granulations; is cicatrizing round edges. Cont.

29th. Cicatrization going on rapidly; sore not half its original size. Cont.

Oct. 10. About the size of a shilling is all that remains to be healed. Cont.

21. Sore healed.

Cont. fasc. sed intermitt. alia.

Case XII. June 8, 1839. M. M'F., æt. 21 years, of a ruddy complexion, stout make; has on dorsum of right foot two deeply ulcerated spots of an oval shape, each about three quarters of an inch in circumference ; irregular, elevated, and callous margins. There is a third sore on outer side of malleolus ; it measures in circumference seven inches, and on outside of leg, about two and a half inches from head of fibula, there is another, which is not quite so large as the last. Surface of sores is covered with a brownish layer of matter ; discharge dark-coloured and fœtid ; integuments immediately around sores hard and unyielding, and for a considerable space they are inflamed and painful to the touch ; is unable to attend his work from pain. Pulse 76 ; tongue clean ; appetite good ; bowels regular. Ulcers of two years' duration ; are the consequence of a severe burn ; were at first dressed with

Liniment Ol. Lini, c. Aq. Calcis.

He has used different ointments, and has also got them dressed with small pieces of emplast. adhesiv. over which a bandage was applied. Nitras. argent. was also freely used, but no benefit followed any of these means.

Curat. Ulcus. Mod. Baynton, et habt. Pil. Plum. om. noct.

12th. Sores have now assumed a healthy aspect ; are filling up with florid granulations; pain gone, as is also elevation and hardness of edges ; is at his work (bleaching calico).

17th. Continues to improve; cicatrization has commenced. Cont.

20th. Sores on dorsum of foot healed ; the others cicatrizing rapidly. Cont.

26th. Sores on upper part of leg well ; that on ankle is now the size of a sixpence. Cont.

July 9. Sore healed ; only complains of a little stiffness of ankle-joint.

The preceding cases may be considered as affording a fair example of the results which have taken place in my

hands, from using the mode of dressing ulcers recommended by Mr. Baynton.

To explain at any length the method of this celebrated surgeon, may seem to some superfluous. It is, however, my decided conviction, that the majority of practitioners are either ignorant of it, or do not put it into practice. Dr. Hannay, of Glasgow, is the only medical man that I either have seen using it, or heard recommending its employment. If the present article should fall under his observation, I trust it will cause him to publish his extensive experience on the subject. No notice whatever is taken of this admirable plan in some of the most recent publications on surgery. In Lizars' " Practical Surgery," and in Burns' " Principles of Surgery," it is not mentioned. Both the authors recommend the use of a bandage and strips of adhesive plaster in indolent ulcers, in the manner described by Baynton ; but they overlook the most important part of his system, viz. the application of cold water, which, in my opinion, is of the greatest moment to our success, as, without it, in many instances of irritable sores, the plaster and bandage will prove injurious. Mr. Phillips, in his excellent Lectures on Surgery, lately published in the Medical Gazette, in speaking of the treatment of varicose ulcers, observes, " It is by giving support that the strapping system of Baynton, and others, procures the rapid cicatrization of these ulcers ; but although the cure is rapid, the relapse is also rapid. Baynton was accustomed to apply the straps completely round the limbs, commencing an inch below, and extending an inch above, the ulcer, and now and then they were intended to act like ligatures; at present, when this means is employed, the strap only partially surrounds the limb. . . . Even then it will often irritate the skin." (Vide Medical Gazette, vol. xxv., N. S., p. 424.)

In this quotation we have sufficient evidence that the Bayntonian system is fast falling into disuse ; nay, that such is already the case. I hold that it is unfair to blame it with procuring only a temporary cure, when, according to the Lecturer's own showing, the plan under consideration is not properly applied. The object which Baynton had in view, in applying the straps around the limb, was to procure

a small and fine cicatrix, in order to obviate the danger of a relapse. Again, we have no mention made of the cold water, which would, without doubt, destroy the irritation of the skin alluded to. Thus we observe that two of the parts of Mr. Baynton's plan are now become obsolete—the very steps which were peculiarly his own. The third particular, namely, the application of a bandage, cannot be called his discovery.

Baynton's system consists of three parts:—First, straps of adhesive plaster from two to three inches broad, and of sufficient length to surround the limb, and to overlap a few inches. These straps are to be applied by placing the centre of the strap exactly opposite the ulcer, over which the free ends are to be crossed, pulling them as tight as the feelings of the patient will permit. The first strap is to be placed a little below the lower margin of the sore ; the second is to overlap it a little ; the third to overlap the second a little ; and so on till the ulcer is completely covered : a soft piece of cloth is then to be placed over ulcer : but I frequently dispense with this. Secondly, a bandage is to be applied, from the extremity of the limb to the articulation above sore. Thirdly, this bandage is to be kept constantly wet with cold water. The dressing to be changed every day, or every second day, according to the quantity of discharge and irritability of ulcer.* Such, then, is the Bayntonian system, which, when properly applied, is competent to cure, speedily and effectually, the irritable or inflamed, and the varicose, as well as the indolent or callous ulcer ; proper attention, of course, being paid to the improvement of the general health—a *sine qua non* in every plan of treatment. I trust the cases which I have narrated in the preceding pages will tend to prove the truth of this assertion.

In selecting the cases from my notes, I chose chiefly those which come under the denomination of "irritable ulcers," and those that are called varicose ; because even the authors who speak most highly of Baynton's plan consider it inadmissible in the treatment of ulcers of this description,

and view it as merely applicable to the ures of indolent sores ; or in cases where all inflammatory appearance has been subdued.* S. Cooper, Burns, Lizars, and many others, affirm that depletion, poultices, and absolute rest, are essential to the cure of irritable or inflamed sores. The cases which I have related I think at least will show that such does not always hold good ; but, on the contrary, that the simple plan which I have used is quite sufficient to effect a cure, and, at the same time, to allow the patient to follow his usual avocation.

In the absence of all practical experience on the matter, the system strikes us as admirably suited for " irritable ulcers," which differ chiefly from those of an indolent nature in an inflammatory state of the integuments, with infiltration into the adjoining cellular substance. No better means can be employed to remove these conditions than the bandage and cold water. The pressure removes the inflammation, empties and supports the overloaded and enfeebled capillaries. The cold water is a powerful agent in the removal of the cutaneous inflammation : by decreasing the high temperature of the part, it produces a sedative effect. But these are not the only benefits derived from the bandage and water : they also act as stimulants to the ulcer, and thus establish a new and healthy action in the sore, which is at the same time kept constantly clean. I humbly submit, if this be not as rational a plan to remove the inflammatory condition which surrounds these ulcers, as either leeching or poulticing ; and then it has this very great advantage, that the patient can walk about during the time his sore is healing.

In the treatment of ulcers there is one point of great importance, viz. to obtain a small and firm cicatrix, in order to prevent a relapse. In the plan under consideration we have a most powerful means of effecting this desirable object, in the strapping with adhesive plaster. At each dressing the edges of the sore are brought nearer together, to a degree which no other plan can effect. This drawing also promotes cicatrization, as must be evident from taking a glance at the man-

---

* Vide Descriptive Account of a new method of treating old Ulcers of the Legs. 2nd Edition, 1799 ; and also Article "Ulcer," in Cooper's Surgical Dictionary.

* See Cooper's Surgical Dictionary, Article " Ulcer," and his First Lines of Surgery, p. 74 — 77. Sixth Edition, 1836.

ner in which this process is performed. The above circumstance makes the system well calculated for varicose ulcers, in which cases I order the bandage to be worn after the ulcer is healed (see Cases IV. VI. VIII.) The more that we consider the system, the more we are struck with its philosophic character. A more scientific piece of practice does not obtain within the whole range of surgery. In the bandage and cold water we have the most rational means of removing the inflammatory action which is established round the sore, aggravating the process of ulceration, and preventing a cure. We have also their stimulating effects upon the sore itself; and thirdly, by the plaster we can lessen most effectually the size of the cicatrix.

Cases V. and XII. are instances of burns. I have treated several severe cases of this kind with equal success. M. Velpeau details sixteen cases of ulcers arising from burns, treated by the bandage and strap applied as Baynton directed, with the most astonishing results*. He does not, however, seem to have used the cold water, which would to a certainty have shortened the duration of his cases, and relieved the sufferings of his patients.

In conclusion, I would merely remark, that if the system of Baynton were properly practised, we would be saved the sight of those disgusting sores which meet the eye in the wards of our public hospitals, and the *opprobria medicorum* would be deprived of one of their most fertile contributors.

STRUCTURE OF CARTILAGE.

To the Editor of the Medical Gazette.
Sir,

We have been taught since the days of William Hunter, that articular cartilage consists of fibres placed perpendicular to the surface of the bone ; and it is well known that if the articular end of a bone be macerated carefully for a sufficient length of time, its cartilage will become really soft and velvety. I have been in the habit of illustrating this to my class, by having a bit of white velvet

* Vide Revue Médicale, Française et Etranger, Juin—Juillet, 1835 ; or Brit. and For. Rev. Vol. i. p. 582.

gummed on the head of the humerus. But the other day, in making a perpendicular section of the knee-joint, similar to what is delineated in Dr. Todd's Cyclopædia (Articulation), I accidentally got a beautiful view of the structure of the cartilaginous crust of the patella. I had made a perpendicular section of this bone from the front, and having stopped sawing just at the cartilage, I *tore* the two pieces asunder. The perpendicular fibres of the cartilage were now beautifully seen.

Perhaps this notice may be acceptable to your anatomical readers, as I have not seen this method of demonstrating the cartilages described in any of the works on the subject.—I am, sir,

Your obedient servant,
JAMES DOUGLAS.

SEVERE INJURY OF THE HEAD.

To the Editor of the Medical Gazette.
Sir,

The following case of recovery after the removal of considerable portions of the cranium, with loss of substance of the brain (occurring in the practice of Mr. Lawrence, of Brighton), may not be considered unworthy a place in your widely circulated journal.—I am, sir,

Your obedient servant,
EDMUND J. FURNER.

Brighton, Dec. 25, 1840.

Late in the evening of the 25th of last April, Mr. Lawrence was summoned by Mr. Camac, surgeon, of Seaford, to meet him in consultation upon a case of fractured skull. He arrived about twelve o'clock at night, myself and his son accompanying him, when we received the following account of the case :—The patient, William Coombs, sixteen years of age, in the employ of the Rev. James Carnegie, residing at Seaford, about six hours before our arrival had been thrown from a horse upon a hard road, and struck by the horse's feet on the left side of the head. He was taken up in a state of insensibility, and removed to his father's house, where Mr. Camac found him, perfectly insensible, with a very feeble pulse, and dilated pupils. Upon examining the head there was discovered an extensive laceration of the scalp, with

fracture and depression of the temporal and parietal bones, to a very considerable extent, involving the squamous suture.

Mr. Camac, after removing two small loose pieces of fractured bone, requested that Mr. Lawrence might be sent for, the case being one of extreme danger.

Mr. Lawrence, having enlarged the wound of the scalp, was enabled, by the aid of the elevator, to remove five pieces more of depressed bone, some of which, from being driven into the brain, had forced a considerable quantity of cerebral substance, leaving a cavity, into which the finger could be passed to the depth of an inch or more : during the operation the patient cried out lustily, but became more sensible after it was completed, and soon fell into a natural sleep. The wound was carefully dressed by Mr. Camac, who has favoured me with the subsequent report of the case, and on whose skilful management the successful result must have greatly depended.

April 26th, nine o'clock, A.M.—The patient is sensible, and complains of pain in the head; reaction has taken place ; pulse 100; skin hot : bowels have not been opened ; eight leeches to be applied to the forehead : to take four grains of calomel directly, and an ounce of castor-oil after an hour, with a dose of mixture (containing a solution of Epsom salts) every four hours ; cold lotion to be constantly applied to the head ; low diet.

Five o'clock P.M. — Bowels freely moved, with a slight improvement in all the other symptoms.

27th.—Has passed a good night, and is decidedly better to-day : pain in the head partially relieved; pulse 96; skin cooler : the wound looking favourably : to have six leeches to the forehead, and continue the mixture and lotion as yesterday. The above treatment was continued with but slight alteration up to the 3d of May; the patient gradually improving.

May 3d.—The symptoms to-day have assumed a more unfavourable character, from the lad not being kept sufficiently quiet. He complains of darting pains in the head ; skin hot and dry ; pulse 100; the bowels open, with a healthy discharge from the wound. To be bled in the arm to six ounces ; to take four grains of calomel directly ; and continue the mixture, with the

addition of fifteen minims of antimonial wine to each dose every four hours. The head to be shaved, and the cold lotion applied.

4th.—Passed a good night, and all the symptoms decidedly relieved : bowels freely moved; pain in the head much abated ; pulse 94, and soft ; skin more comfortable : a small blister to be applied to the nape of the neck, and continue the mixture every six hours. From this time he continued to improve : the wound was daily dressed with spermaceti ointment ; the hair being kept closely cut. The granulations rapidly formed, and after a few weeks dressings were discontinued for straps of adhesive plaster, and the occasional application of the nitrate of silver, the cold lotion being continued. The pain in the head having subsided, and the appetite returned to its natural standard, a more generous diet was allowed, with the moderate use of exercise in the open air.

November.—The wound has been for several weeks healed, but he wears, as a protection to the part, a plaster composed of equal parts of adhesive and soap plaster, and is directed to take an occasional asperient, avoiding all stimulating diet. His health and strength are perfectly restored, and his intellects not at all impaired.

DISLOCATION OF THE TIBIA INWARDS

WITH THE ASTRAGALUS, AND FRACTURE OF THE FIBULA.

To the Editor of the Medical Gazette.

Sir,

I HAVE the honour to communicate to you the following case, in the hope it may be deemed of sufficient interest to merit insertion in your journal. I have refrained from entering into any lengthened statements upon the case, contenting myself with simply recording the facts, partly as they were related to me, and partly from my own personal observation.—I remain, sir,

Your obedient servant,
R. G. COOMBE.

Newcastle, Staffordshire,
Dec. 17, 1840.

Robert Middleditch, æt. 24, on December the 5th, fell off the vat in the brewery of Messrs. Combe, Delafield,

and Co.; a height of sixty feet. His fall was unbroken, and he cannot describe the manner in which he alighted, as regards the position of the injured foot. Almost immediately after the accident he was conveyed to the Charing Cross Hospital, and notwithstanding the very short space of time that had elapsed from the receipt of the injury, the swelling which had supervened was very considerable. The nature of the accident was, however, easily discernible. There was a remarkable projection at the inner side of the ankle-joint, evidently caused by the dislocation of the tibia and the astragalus, with the lower fragments of the fibula attached to them; all the bones holding their relative position to each other, as was evidenced by the ability to perform flexion and extension of the foot with tolerable ease. A corresponding depression upon the opposite side of the foot existed, and about three inches above this point the fibula was fractured. The inner side of the foot was slightly inclined towards the ground, and the sole turned upwards and outwards to the same extent.

Immediately upon the patient being brought into the hospital several persevering attempts were made by Mr. Hancock to reduce the dislocation in the usual way, due attention being paid to the relaxation of the great muscles of the calf, without success. The limb was then placed in a comfortable position, a few leeches being applied, which were followed by cold lotions; and as the patient was accustomed to drink large quantities of beer, a pint of it was ordered him daily.

Nothing further was attempted up to Dec. 10th, on which day, the patient's system having been previously well relaxed by repeated doses of tartar emetic, another futile attempt was made by Mr. Hancock, assisted by Mr. Guthrie, to reduce it with the pulleys.

This attempt was only continued for a little more than a quarter of an hour, for as the extending power was being made equally from the dorsum of the foot, and from a little above the os calcis, it was thought that the cavity from which the astragalus was removed being situated between these two points, would thus be compressed, and the return of the astragalus into it be prevented. To remedy this it was determined to have a strap so constructed as, by having more purchase upon the os calcis,

to allow extension to be made principally from that point. This was accordingly done, and on the following day the pulleys were again applied by Mr. Hancock and Mr. Guthrie, and gradually increased extension having been steadily maintained for upwards of an hour, the dislocation was reduced. Sloughing of the integuments over the inner ankle subsequently took place, exposing that apophysis. This case I believe to be the only one of a similar nature on record. I have in vain searched numerous surgical works, and have made inquiries of many professional men of considerable experience, with a view of ascertaining the existence of a parallel one. It seems to me to be very difficult indeed to give any explanation, in an anatomical point of view, how such an accident could occur, when we consider the great depth of the articulation between the astragalus and the scaphoid bones; the great number, strength, and elasticity of the ligaments connecting the bones engaged in this dislocation; and the very beautiful and excellent provision against separation of the bones of the foot from each other, derived from the arch which these bones collectively form. It is true it may be said that the very great violence which would be applied by a fall from so great a height as sixty feet, aided perhaps by some particular position of the foot as the patient came in contact with the ground, might rupture all the ligaments connecting the tibia, the fibula, and the astragalus, to the os calcis and the scaphoid bones: but if this were the case, would not the reduction have been comparatively easy to the great difficulty that seems to have been experienced?

ANALYSES AND NOTICES OF BOOKS.

The Anatomy of the Arteries of the Human Body, with its Applications to Pathology and Operative Surgery, in Lithographic Drawings, with Practical Commentaries. By RICHARD QUAIN, Professor of Anatomy in University College, and Surgeon to University College Hospital. The Delineations by JOSEPH MACLISE, Esq., Surgeon.

THIS publication is one of those splendid and original works, which at once

do honour to the fine arts of the countries in which they are published, and to their respective authors for the share which they have had in contributing to the advancement of anatomical and surgical science. Such publications, from the rare talent and industry, as well as the great expense necessary for their completion, are not to be looked for often : we may, therefore, congratulate ourselves on the appearance, at the present time, and in our own country, of a production meriting, as we sincerely believe, to be classed with undertakings of this high description.

The author of the work before us has enjoyed, as must be well-known to the majority of our readers, abundant opportunities for practical observation of the subjects which he proposes to treat of; and, that he has fully availed himself of the advantages presented to him as the Professor of Anatomy in a large medical school, is satisfactorily proved, by the unexampled extent to which he has carried his inquiries, which have been founded, as he himself informs us, on an examination of more than nine hundred bodies.

" Several years," Mr. Quain says, " have elapsed since I became impressed with the belief, that the difficulties which have often occurred in the performance of those surgical operations, in which the larger arteries are concerned, have arisen in great part from want of sufficient acquaintance with the differences in anatomical disposition to which these vessels are subject—not merely those deviations in the origin of large branches, which are usually named varieties, but other peculiarities of various kinds which are liable to occur; such as those which affect the length, position, or direction of the vessels. Under that impression I was led to observe these circumstances more closely, and finally determined to obtain a record of the condition, whatever it might be, of the more important vessels in a considerable number of cases,—a record to be made especially with a view to points bearing on practical surgery.

" With this view, I examined with more or less attention the bodies which were received during a series of years for the study of anatomy in the School of Medicine in University College. These bodies, to the number of 930, were, with rare exception, so inspected

with reference to the subject of my inquiries, that any thing unusual could not escape notice ; and, in order to insure accuracy, when other occupations allowed, the arteries were carefully examined, and their condition noted at the time ; attention being always particularly directed to those vessels, and to the points in their history, which seemed to be of importance in the practice of surgery.

" This detailed investigation was continued until the number of cases observed appeared such as would afford grounds for reasonable conclusions, both as to the limits of the deviations from the ordinary standard, and as to the relative frequency of their occurrence.

" At the same time that the observations thus made were written down, drawings were obtained of all the important peculiarities which presented themselves ; and when it was practicable, the preparations were preserved.

" The varieties in the arrangement of the blood-vessels thus noted grew, as may be supposed, to be very numerous ; but instead of difficulties multiplying with the number of observations, it was usually found that, as the facts accumulated, the transition from one state to a very different one ceased to be abrupt or without method, for others from time to time interposed, which served to link them together.

" Originally these observations were intended exclusively for the benefit of my class ; but as the number and connection seemed likely to render them more extensively useful, I resolved to publish them. On examining with a view to publication, the materials which I had collected, it became obvious that their utility would be very limited, unless as a part of a full history of the arteries, with adequate delineations. In consequence a series of drawings, showing the arteries according to their usual arrangement, has been prepared, and to these are appended the observations previously alluded to. The work has thus grown under my hands, and has gradually assumed its present form."

There cannot be any doubt in the minds of those who consider the subject as attentively as its importance demands, that there is no other division of anatomy which has greater claims upon the attention of the practical surgeon than that which embraces the

history of the blood-vessels; since, in reality, it is the consideration how these important structures may be implicated in his proceedings, that principally occupies the thoughts of the surgeon previously to undertaking any operation of consequence. Indeed, unless he has been enabled to form a clear judgment upon these points, he is prevented from advancing a single step without being harassed by the reflection that he is exposing himself to an imminent risk of failure in his attempt,—a failure which is almost certain to be productive of danger to the life of his patient, and injury to his own reputation. We are firmly convinced that there is no other hindrance than the dread of occasioning an uncontrollable hæmorrhage at each stroke of the knife, which prevents the greater number of surgeons from undertaking what, if it may not be termed the most difficult, or the most important, is, at all events, the most brilliant part of surgery, and the most striking in its results, viz. the performance of the great operations. With these feelings, we do not hesitate to express our belief that all teachers of anatomy or surgery; all hospital surgeons; and, indeed, all practitioners throughout this country, who are in the habit of performing operations, will gladly avail themselves of the invaluable assistance which a reference to the work before us is capable of affording them. By means of it, the surgeon, after long absence from the schools of dissection, will be enabled to refresh his fading recollection of the relative anatomy of the principal blood-vessels and nerves, and, for the first time, he will become acquainted with a greater number of possible deviations from the ordinary arrangement, than he could have learned from any other work extant.

It has long been regarded as a great objection to the valuable and expensive work of Tiedemann, that in it only the muscles and arteries are represented, whilst no notice is taken of the fasciæ, nerves, and veins—structures which are equally interesting to the surgeon. We are therefore inclined to regard it as one of the most important features of Mr. Quain's work, that in it we find all these structures depicted with equal care and exactness. In this respect, as well also as in the superior style of execution of the drawings, the present

publication has greatly the advantage over the work of the Heidelberg professor. Indeed, we are not acquainted with any other anatomical or surgical work in which the advantages resulting from the rare combination of faithful accuracy in the representation of nature, with great beauty and elegance in the design and execution of the engravings, are more strongly exemplified than in the work before us. Possessing these qualities, it richly deserves to be classed with the beautiful works of Cheselden, Camper, Wm. Hunter, and Scarpa.

The execution of the plates furnishes indisputable proof that Mr. Quain has been peculiarly fortunate in possessing the assistance of a gentleman, who knows himself to be not less skilful in delineating with his pencil, than he is conversant with the anatomy of the parts he is called upon to represent.

In conclusion, we venture to predict, that the accuracy, the originality, the sterling practical usefulness, and, comparatively speaking, the moderate price of this beautiful work, will soon place it, not only in every public medical library in the United Kingdom, but in that of every professional man who feels deeply interested in the progress of anatomical science, or in the efficiency and perfection of operative surgery.

A Retrospective Address, delivered at the eighth anniversary meeting of the Provincial Medical and Surgical Association, held at Southampton, July 22d and 23d, 1840. By R. WAKEFIELD, SCOTT, M.D., &c. Worcester, 1840. 8vo. pp. 98.

AMONG the points touched upon by Dr. Scott in his sensible and judicious address, are, the controversy concerning Sir C. Bell's discoveries in the nervous system; the physiology and pathology of the fluids; excretory ducts; the structure and functions of the spleen; and varicose capillaries. He thinks that "this condition of the capillaries was sufficiently familiar to Dr. Hake previously to his having seen the preparation of Mr. Kiernan, though it is questionable whether he would have extended the application of that knowledge so far as he has subsequently done, had it not been owing to the preparation shown him, accompanied by

the statement of Mr. Kiernan, that varicose capillaries were the basis of his investigations on the anatomy of cancerous formations." (p. 57-8.)

Dr. Scott next mentions the researches into the structure of mucous membranes; nutrition; and Jacquant on the follicular apparel [apparatus] of the intestinal canal. He then glances at some points in medical jurisprudence. Recent experiments have convinced him that the hydrated tritoxide of iron is really an antidote to arsenic. He speaks of an interesting case of suspected infanticide in France, where the viscera of the chest and abdomen were found to be quite healthy, but where two-thirds of the cavity of the cranium contained nothing but a serous fluid. "The only vestige of the cerebellum consisted in a little prominence at the upper part of the cavity. The two lobes of the cerebellum could be distinguished, but were in such a state of ramollissement as must evidently have resulted from disease. The tuber annulare and medulla oblongata were the only parts of the brain which were distinct and intact." (p. 64-5.)

In Materia Medica our author mentions the new moxas of Grafe: monesia; *cannabis Indica*, or Indian hemp; *gentiana cruciata*; &c. &c. Under the head of medicine. Dr. Scott touches on fever, phthisis pulmonalis, diseases of the urinary organs, &c.; and the essay terminates with the articles Medical Statistics, Bibliography, Biography, and a few concluding remarks.

Dr. Scott's address will have the effect of awakening the attention of many practitioners to the important fact, that medicine is an ever progressive art.

Memoranda regarding the Royal Lunatic Asylum, Infirmary, and Dispensary, of Montrose, &c. By RICHARD POOLE, M.D., &c. Montrose, 1841.

THE Lunatic Asylum of Montrose, the first of the kind in Scotland, was built in 1781, the chief founders having been Alexander Christie, the Provost of Montrose, and Mrs. Susan Carnegie, of Pitarrow. The work before us, drawn up by Dr. Poole, the medical superintendent of the asylum, is a minute history of the charity from its foundation to the present time. There is also a sufficient account of the Infirmary and

Dispensary. The Montrose Asylum contains between seventy and eighty lunatics, and is maintained partly by voluntary contributions, and partly by the sums paid by various parishes for the board of the paupers belonging to them. Before this asylum was built, says Dr. Poole, Lord Fountainhill's quaint *notandum*, written in 1681, was still in some measure applicable.

"Mr. Alexander Burton gave in a complaint to the Secret Council against his brother, for putting him in Hopkirk the chirurgeon's hand as if he had been a madman, &c. He answered (the allegations to that effect): They had his portion in their hands, and he was only asking his annual rents; and to refuse him his own, and thrust him *in ergastulo*, and treat him as a fool, would raise pepper and passion in any man's nose, and then they termed these acts fury, for *ira est brevis furor*. In Scotland, having no Bedlam, we commit the better sort of mad people to the cure and tameing of chirurgeons, and the inferior to the scourge." (p. 1-2.)

Our author urges, with great propriety, the erection of lunatic asylums in Scotland by compulsory assessment. He advocates the system of non-restraint most earnestly, and his theories are confirmed by the practice of the establishment over which he presides, as well as by that of others. Dr. Poole's work does credit to his humanity, and will be consulted with advantage by practitioners. In case he should rewrite, we wish he would subjoin a recapitulatory chapter, giving the essence of the book in some twenty pages, and also add running titles throughout the work.

MEDICAL GAZETTE.

Friday, January 8, 1841.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE MANAGEMENT OF THE INSANE.

THE question respecting the Management of the Insane, to which we alluded some time since, and upon which the opinion of the intelligent portion of the

public deserves nearly as much consideration as that of members of our profession, is that which relates to the measures that should be taken before a person can be placed under restraint as a lunatic, and deprived of the management of his affairs. In the decision of this question the impossible definition of lunacy or insanity is often asked for; but if it could be given, it could scarcely form a secure basis on which to determine whether or not the supposed lunatic should be removed from society; for, as we remarked on the occasion of the trial of Edward Oxford, the definition must always have respect to the condition of the individual, and the external circumstances in which he is placed. Indeed, the further history of that individual offers all the confirmation that our assertion needed; he is now in Bethlehem Hospital, and, as we are informed on good authority, evinces no disposition, and performs no act, which might not as well exist in, or proceed from, a thoroughly sane man—or, at least, one whom all the world would allow to act without restraint, upon his own personal responsibility. In short, the circumstances under which Oxford's insanity was evidenced, and on the existence of which it mainly depended, having ceased,—there being no applause or wonder to be excited by attempting mischief in Bedlam, and none but self-imagined queens to inflame his democratic notions,—he is become quiet and harmless, and, so long as he remains in his present abode, will continue so.

Now, in all Oxford's history there was nothing which required medical knowledge in order that it might be justly decided what his fate should be. The whole nation felt and said that it was the attempt of a madman—of one who did not weigh the consequences of his act—who appreciated rightly neither the enormity of his crime, nor the terror

of the punishment he must certainly draw down upon himself. But suppose his insanity had existed not in the motive (whatever it was) which impulsed him to fire at the Queen, but in some of the propensities which anticipating heirs are so apt to deplore, and anxious to restrain in their relatives—suppose he had been devoted to drinking, gambling, or any other foolish mode of spending his money, and had followed these pursuits with as much rashness, and as little reason or thought for the future, as guided him in firing at the Queen—would the nation have thought him mad, or demanded his being secured in Bedlam? Oh no! At the worst he would have been called by the prudent an idle silly fool, and by his companions a daring harebrained lad! but neither physician nor layman would ever have thought of restraining him from doing mischief either to himself or to others.

Yet it is evident that cases of this latter kind are just those in which the question of what should be done with a supposed lunatic is most often raised, and in which the public have an undoubted right to claim that the decision should not rest entirely with the members of our profession; for in these cases the question is not entirely a medical one, nor are the circumstances such as only one educated in medicine can judge of. The main question in a case of doubt of this kind is, is the person accused of insanity capable of managing his own affairs? and surely the old legal maxim, "cuique in suâ arte credendum" here merits application. Except that their habits, and the necessities of the study of their profession, make medical men, more than any other class, observers of the characters of those with whom they mix, and that they are thus more likely, in general, to detect the extravagances of thought that fill up the boundary between what the world

calls respectively eccentricity and madness—except for these circumstances, we cannot but think that, in a doubtful question of insanity, they ought not to be the only judges whether a man is capable of conducting his own business. For to form such a judgment requires not so much a knowledge of medicine as of the business in question. The activity which, displayed in one business, would be rashness and madness, in another becomes a laudable boldness; the speculations that in some circumstances a man may reasonably undertake, in others he would be deemed mad to engage in; the dissipation that one man might join in, and retain his character for sanity, another might be held mad for giving himself up to. Now who is likely to be the best judge in these cases, if not one who knows the various modes of undertaking business in general, or in particular that of the person whose sanity in the conduct of his affairs is called in question ? There are a hundred other cases of the same kind; but we will not now point them out. Some of them will immediately occur to the reader, and will convince him, if he will candidly consider them, that there are many instances of supposed insanity in which medical men are not the only, and, perhaps, not even the best judges, whether the patient, or, more properly speaking, the accused, is or is not capable of managing his own affairs.

But it may be said, what is the need of this disturbance of old systems ? the injury done to a man by a temporary confinement is but temporary, and is commonly of such excellent effect in curing him of his eccentricities, that he never afterwards runs any risk of being thought mad again; besides, he can apply for his discharge to visiting magistrates, and there is the commission *de lunatico inquirendo* to prevent all this mischief. This is all very well, and would be very wise if it were true. But those who would thus argue lose sight of the fact that when a man has been once confined in a lunatic asylum, or been under the care of a keeper, his character (at least for competency in business) is destroyed for ever among those with whom he formerly associated, so that he is usually compelled, when discharged " cured," either to remove far from his former home, or to remain there constantly distrusted. Besides, it cannot be agreeable for even the most sane man thus to be put upon his trial at a disadvantage, such as every one must labour under who has been once confined. When a young man, defending perfect freedom of inquiry and opinion on religious subjects, urged that they could, at least, do no harm, for that truth would always come out and shine brighter after every trial, Dr. Johnson said to him, " And pray, sir, how would you like, presuming you to be innocent, to be put on your trial for your life once a week ?" Something of the same kind might be said in this case. Who would like, having been, as he thinks, unlawfully committed to restraint as a lunatic, to be put on his trial to prove his sanity ? It is surely a trial that the wisest and the vainest might alike shrink from, and feel some distrust as to the result.

As to the commission *de lunatico inquirendo*, as a safe-guard against the unjust committal of lunatics, it is applicable only to a small portion of cases, and even in these is but of limited utility. The mention of it reminds us of another good saying. A young lawyer, full of his profession, thought to overwhelm one who was speaking of the difficulties the poor endured in endeavouring to find justice for their obvious claims, by saying, " There are the laws, sir; the law and the courts are open to all ; none are

excluded frem the law of England."
" True," it was answered, " and the
London Tavern is open in the same
way to all alike—who can pay for it."
And so it is with a commission *de
lunatico ;* its expenses are such as none
but the rich can bear, and such as none
expose themselves to but those who
have reason to hope for profit from its
result.

Besides, this commission is obtained
by application of those who are anxious
to prove the existence of lunacy; what
is wanted is something that should
serve as a resource for the one accused,
—some court in which the state of his
mind might be fairly judged of by a
sufficient number of competent and im-
partial persons. Such a court might be
open to the appeal of any lunatic who
chose to demand his freedom; and to
avoid the frequent, but vain claims of
those about whose insanity no doubt
could be entertained, a visiting magis-
trate, or any justice of the peace, might
first be required to certify that the case
of the petitioner deserved inquiry, of
which fact he might judge either by a
personal interview, or by the evidence
of a rationally written letter, or even by
the favourable testimony of witnesses.
As in the case of a common commis-
sion *de lunatico inquirendo,* the jury
should be twelve impartial, not profes-
sional, persons, and the court should
have the power of calling before them,
and ordering the payment of reasonable
fees to medical men, in all cases in
which their evidence was deemed ne-
cessary to confirm or weaken that of
other persons conversant with the ac-
cused, with his habits of life, the nature
of his business, and so on. In short,
there should be a court similar in nature
to that at present held under the Chan-
cellor's commission, but in which the
supposed lunatic should stand in the
relation of a plaintiff, and not in the

disadvantageous position of a defen-
dant.

Such a court, easily open to petition-
ers, and conducted with all possible
economy, and to which the truly neces-
sitous might appeal *in formâ pauperis,*
would remedy all the evils which are
reported to exist in the unnecessary
detention of lunatics after their cure is
perfected. But the main object of the
legislation, to which it is not at all im-
probable the recent excitement on the
subject of lunatic asylums may give
rise, should be to prevent the commit-
tal of any to restraint for whom it is not
absolutely required. Such an event is
a disgrace to any civilized country, and
its avoidance more merits the care of a
legislature than half the schemes that
have of late occupied the attention of
our senators do. The obvious means
of prevention would be not to allow a
person to be placed under restraint for
more than a few days in his own house,
or to be removed at all to an asylum,
except with a certificate, signed not
only by his medical attendants, but
by two or more magistrates, or other
respectable men, not interested in his
case, and who had personally visited
him : and to provide that in all
doubtful cases a person so restrained
might appeal within another week of
his confinement, upon obtaining the
certificate of some other magistrate that
his case deserved inquiry.

We mention these only as hints for
the formation of some plan, which
might be followed in order to obtain a
remedy of those glaring evils of unjust
and unnecessarily long confinement,
wherever they exist. Of course we do
not believe a tithe part of the accusations
that are popularly raised about them; yet
it is not improbable that they have their
foundation in some little truth. Whether
they have, or not, it matters little for the
interests of the profession, to which

suspicion is almost as injurious as proven guilt. The suspicions of the public are now actively awakened—the *Times* has admitted the question into its columns, and has given its sanction to the public excitement, and through its medium there is now scarcely a cottage in the land whose inhabitants have not learnt to suspect some ill of *mad-doctors*, and all who have to do with the insane. Let the medical profession, therefore, who are conscious of their own honesty and good intentions, be the first to petition for some new measures, which may place them beyond the reach of suspicion, though they may impose no greater restraint on their conduct than their consciences now do.

MIDDLESEX HOSPITAL.

CASE OF WOUND IN THE ORBIT.—FRACTURE OF THE ÆTHMOID BONE.

A middle aged man was admitted, late in the evening of the 28th of December, with a penetrating wound in the left orbit, and sudden loss of vision in the right eye. He stated that he met with the accident just a short time before, while assisting to raise a horse that had fallen, owing to the slippery state of the streets. He was close to the head of the horse, when the animal, unexpectedly making an effort to rise, struck him on the left eye with so much violence as to throw him to the ground, yet without his being stunned. He was taken immediately to a chemist's shop, when, besides having a deep incised wound between the left eye and the nose, he found that he was completely blind in the *right* eye. On describing the accident more minutely, he expressed his belief that it was not the horse's head which had inflicted the blow, but that the blinker, or some metal ornament on the bridle, must have struck him.

December 29th, 1 o'clock P.M. — The wound is situated at about a third of an inch from the inner commissure of the eyelids, and extends downwards from under the eyebrow for about an inch. It is apparent that the lachrymal canals, and also the tendo oculi, must have been divided. A probe was introduced to the depth of three-quarters of an inch into the wound, in the direction of the inner wall of the orbit, but without the bone being felt exposed. The blood which issues from the wound is thin, as if mixed with tears. There is a trifling degree of

ecchymosis in the eyelids, close to the wound; but the eye itself is uninjured. The most remarkable circumstance connected with the accident is the total loss of vision in the *right* eye, without there being any perceptible injury to that eye. Its sensibility, as well as all its different motions, is perfect; but he is absolutely blind on that side, and the pupil is dilated to the utmost. A lighted candle was held before the eye—so close that he said he felt the heat of it—but he could not distinguish the flame in the least degree, and the iris did not contract. He answers questions promptly and clearly, and evinces no symptom of injury extending to the brain, except that he complains of a little headache. The bones of the nose were carefully examined, but no crepitus could be felt; neither was there any ecchymosis to indicate injury on the right side.

The wound was dressed with adhesive strapping, and a compress. He was ordered, by Mr. Shaw, Jalap, gr. xvj. c. Hydr. Chlorid. gr. iv.: to be followed in four hours with salts and senna. After the operation of the purge he is to take Hydrarg. Chlorid. gr. ij. c. Pulv. Antimon. gr. iij. 6tis horis.

30th, 1 P.M.—He has been delirious during the night, and now lies insensible, or only to be roused with difficulty. The symptoms are those of inflammation affecting the membranes of the brain. The bowels have been frequently and copiously evacuated.

> The head to be shaved, and cold water applied. V. S. ad ʒxvj. The calomel and antimony to be given every four hours.

Half-past 10 P.M.—Up to six o'clock he remained much in the same condition as at the former visit. He is now convulsed, lying curled up on his left side, with the arm and leg flexed and stiff, and the right in rapid and constant motion. His breathing is laborious. The pupil of the right eye is now contracted. The calomel, without the antimony, to be laid on his tongue, as he cannot be made to swallow a pill. A blister to be applied to the nape of his neck.

31st.—There is no material change. The right eye does not move, although it retains its sensibility. He was ordered to continue the calomel, cold to the head, and to have the blister dressed with mercurial ointment.

Jan. 1st. — The breathing is stertorous and frequent. He now lies on his back. The spasm which affected the left side, and more especially the left arm, has subsided, and there is now hemiplegia of this side, the right side being tranquil. There being considerable heat in the head, eighteen leeches were ordered to the right temple. Sinapisms to his legs.

2nd.—He died early this morning, having,

by the nurse's account, become convulsed again on the left side, just before death.

Post-mortem examination. — Upon raising the calvarium, and removing the dura mater, an excessive degree of vascularity was observed, with a copious deposit of lymph between the archnoid membrane and pia mater, over both hemispheres. The brain, on being sliced down, was likewise unusually loaded with vessels. A large accumulation of serum, with purulent matter diffused in it, was found in both the lateral ventricles. When the anterior lobes were raised, they were found adherent in all their under surface to the dura mater, by means of coagulable lymph. Upon the optic nerves being exposed, that on the right side was seen to be torn completely through, or its ends only joined by delicate membrane, close to the optic foramen. The base of the brain, extending from the medulla oblongata to the commissure of the optic nerves, was thickly covered with a layer of lymph, which obscured the roots of the nerves. In the posterior part of the right anterior lobe, close to the injury of the optic nerve, the brain was bruised, softened, and ecchymosed, to the extent of about a square inch of its surface, and for the depth of half an inch, so as to approach close to the anterior cornu of the lateral ventricle. The cause of the laceration of the brain, and tearing across of the optic nerve, was found to be a fracture of the cerebral plate of the æthmoid bone, including part of the sphenoid, which forms the roof of the foramen opticum. A fragment, consisting of a thin plate of bone, was found insulated, or hanging loosely attached by dura mater, to the fore part of the sella turcica, above the right cavernous sinus; and it seemed obvious that this piece of bone, on being driven off, had torn the optic nerve, and caused the laceration of the brain. Upon more minutely examining the wound of the orbit, as by introducing a probe, it was found that the point could be made to pass, without any force, and by a slight degree of management, into the crushed part of the æthmoid bone, and to appear within the skull. It was accordingly evident that the object by which the blow was inflicted must have been pointed, and probably had an obtuse end; that it entered the orbit so as to strike the os planum and force it inwards; and the force being communicated in a direction upwards at the same time, the blow had the effect of fracturing the cerebral plate of the æthmoid bone, and lacerating the optic nerve on the opposite side.

NEW REMEDIES.

Lozenges of lactate of iron.—M. Cap recommends the following formula: an ounce of lactate of iron, an ounce and a half of sugar, and enough gum Arabic to make lozenges each weighing fourteen grains, and containing one grain of lactate of iron. From six to twelve are to be taken daily. To ascertain if the lozenges really contain the lactate of iron, dissolve one of them in water, and add a little tannin. The solution becomes black, if the preparation is well made; but if it remains colourless, it contains no lactate of iron. [But, surely, other salts of iron would give a black colour.—*Translator.*]

Johnson's Syrup.—The patent granted to the inventor for five years having expired, this syrup has become public property. It consists of an ounce of syrup of liquorice, forty six grains of the fresh juice of asparagus heads, and the same quantity of the syrup of mallow.

Paullinia. — Dr. Gavrelle, who passed many years in the Brazils, became acquainted there with a remedy called *Paullinia*, which when powdered and mixed with the chocolate nut, is used as a ptisan against diarrhœa and dysentery, and, generally, as a tonic. It is the fruit of a shrub of the same name (*Paullinia sorbilis*), and of the colour of the chocolate nut; it has a peculiar smell, and a bitter taste, resembling that of ratanhy. The seeds are taken out of the capsule, dried in the sun, and powdered. They contain gum, starch, a resinous matter, of a brownish red colour, an oil, tannin, and a crystallizable substance with the chemical properties of caffein. Dr. Gavrelle has used the remedy in France also, with advantage, in the diarrhœa of the phthisical, chlorosis, paralysis, migraine, long convalescence, &c. The most suitable preparation is the alcoholic extract made into lozenges, syrup, pills, powders, tincture, and ointment.

Pitch against piles. — Dr. Wardleworth assures us that he has used this remedy with advantage in many cases, both of external and internal piles. His usual formula consists in ordering $3\frac{1}{2}$ grains of pitch to be made into pills, two of which are to be taken every evening. The well-known efficacy of balsamic remedies in piles may perhaps serve to recommend these pitch-pills.—*Zeitschrift für die gesammte Medicin.* Sept. 1840.

ABSCESS OF THE LIVER,

WITH PERFORATION OF THE STOMACH AND ABODOMINAL PARIETES.—RECOVERY.

Dr. Kreig, of Merseberg, relates this case. —Mrs. Engelsardt, a tall brunette, æt. 31, mother of three children, the youngest of whom was 7 years of age, took ill in January, 1838, of the gastro-enterite, then epidemic here: with ulceration of the mucous membrane. Within three days the disease

began to decline; every day she appeared to get better, and was able to leave her bed for an hour at a time, when an exposure to cold suddenly gave her disease the following dangerous turn.

On the first examination of the abdomen, on the 8th of January, a tumour, the size of a fist, projecting forward, and irritable when pressed upon, somewhat elastic, was perceived in the epigastrium.—The patient declared that she had this tumour already six years, and she thought it had been caused by violent straining after an emetic; it gave her no uneasiness except a feeling of tightness after frequent or plentiful meals; it had not grown larger for many years, and annoyed her alone on this account, that she could not wear a girdle, and was obliged to wear her clothes quite loose. This being the case, the treatment was directed to the fever, and little attention was directed to the tumour, as it did not appear in any way to modify the course of the disease. The liver, however, seemed somewhat enlarged, and, as is usual in fever of this intermitting type here, where liver as well as spleen is commonly engaged, it was thought probable that the cause of the fever proceeded from it. No suspicions, however, were entertained of there being any more serious lesion, and we were unwilling to believe that the tumour could be a hernia of the stomach. However, on the 14th of February, a rigor came on in consequence of the cold above mentioned, which first occurred every day, then each evening, then in a slighter degree morning and evening, and ended each time by a hot and sweating stage. At the same time the right hypochondrium and the whole right side to the shoulder began to give great pain, a severe cough came on, and the skin assumed a jaundiced appearance; the urine was scanty and saturated with the phosphates, the bowels were constipated, and the abdomen and feet began to be dropsical. Three venesections, leeches, calomel, quina, and mercurial ointment, did not prevent the approach of hectic fever. Meanwhile the tumour in the epigastrium became more painful and irritable to the touch, and had acquired the size of half a head of cabbage. Percussing it caused a tone as though it contained much air; yet was it evident that there was a large abscess of the left lobe of the liver, to evacuate which must now be the object of treatment. Poultices were applied, and it was evident that the skin was becoming redder and redder. On the 7th March, after having eaten some soup, she was suddenly seized with a violent fit of continued sneezing, during which a highly disgusting smell mounted, "as if from the stomach," into the nostrils. After a few seconds, a shocking taste became perceptible in the mouth, and violent vomiting succeeded of a purulent

fluid, mingled with mucus, of a yellowish green colour, and most horrible stench, like the smell from the intestinal contents of a putrid body.* Shortly after discharges from the bowels of a similar nature occurred. On the succeeding days, a similar fit of ominous sneezing, accompanied by vomiting, and the same disturbance in the tumour as mentioned before, with violent coughing, causing rigors. Rigors also occurred after every attempt at taking food. The patient was now in a very melancholy condition. An access of hectic fever, morning and evening, extreme feebleness, the upper parts of the body emaciated, to the last degree, the abdomen and legs swollen, thirst and hunger to a painful degree, but not daring to gratify either on account of the dreadful vomiting, painful and disgusting to herself, and unendurable to those about her. There was nothing to be expected but death!

On the 25th March, Dr. King had the boldness to open the abscess. Much air rushed out, the tumour sank, and gradually a matter similar to what had been discharged by stools and vomiting was given exit to.

From this moment the condition of the patient improved. The discharge was kept up from the opening in the epigastrium by warm poultices; the irritability of the stomach decreased, vomiting gradually ceased, the alvine discharges still exhibited a yellowish brown pus mingled with fæces. Fresh buttermilk, given in increasing quantities, served both for food and medicine. The febrile attacks yielded, the urine flowed in considerable quantity, the œdema in abdomen and limbs decreased visibly, and sleep for many hours refreshed the patient.

The discharge from the opening was sometimes streaked, but not in other respects changed. The abscess healed towards the end of April. A few days after the patient was worse. There were fever, tendency to vomit, purging as heretofore, and dropsical swelling of the belly. The navel projected like a hernia, and increased in size to that of a child's fist. An incision was made, and under the application of poultices a large quantity of the yellowish green matter, not so offensive as before, was discharged. Every thing now proceeded better, convalescence was no more interrupted; the incision healed, and in July, the patient, though reduced to a skeleton, was able to leave her bed. Since then this patient has perfectly recovered, is able to eat any kind of food, and perform laborious tasks without any difficulty.— *Medicinische Zeitung*, No. 9, Feb. 1840; and *Dublin Journal*, Jan. 1841.

LATERAL CURVATURE.

To the Editor of the Medical Gazette.

SIR,

IN reply to Mr. Child's last communication, and in reference to division of the muscles of the back in spinal distortions, I beg leave to state that no very satisfactory result, or rather such as I could consider satisfactory, followed the operation in my case, although the mother of the patient thought him much improved. It is difficult to ascertain minor degrees of amendment, except by a series of casts, and these are not easily obtained. I ought to state, however, thet I had no opportunity of employing mechanical extension after the operation, as I proposed, and that I think division of the sacro-lumbalis was indicated in my case.

It is not a little singular that while accomplished anatomists and surgeons (e. g., Malgaigne) are demonstrating theoretically the utter impossibility of treating successfully the more severe cases of lateral curvature, practitioners are continually bringing forward instances to the contrary. It is to be hoped that M. Guérin's forthcoming work will remove the uncertainty in which we are left by these conflicting statements.

I am, sir,

Your obedient servant.

T. LAYCOCK, M.D.

York, Jan. 4, 1841.

ON THE

USE OF MERCURIAL PLASTER

("Emplâtre de Vigo.")

IN PREVENTING DEFORMITY AFTER SMALL-POX.

By M. CHOMEL.

A YOUNG girl is under M. Chomel, in the Hôtel Dieu, who has been vaccinated, but she says without effect. The variolous eruption, which is demiconfluent, was preceded by the ordinary symptoms. A mask, made with the plaster of Vigo, was applied to the face on the second day of the eruption. The patient tore it off within twenty-four hours, but, notwithstanding this, the result is very remarkable. On the neck, chest, and all the rest of the body, the variolous pustules were developed with all their distinguishing characters: opaque, umbilicated, and surrounded by a bright red areola. But on the face the course has been very different; instead of pustules we see acuminated vesicles, or solid papulæ. On some points where the plaster had not adhered, small pustules are perceived; where it had, we search for them in vain. It appears impossible, on the simple inspection of this patient, to state that mercury has not exercised a local

action, specific and advantageous; for the patient will not be scarred, and will be speedily convalescent.

In another ward is a patient already convalescent, who has been submitted to the same mercurial treatment, and the desquamation has followed its ordinary course, except on the face, where scales have not formed. In another bed in the same ward is a woman five months and a half advanced in pregnancy, in whom the plaster has entirely averted the eruption from the face : small whitish papulæ supplying the place of the pustules. Desquamation has not taken place, except on the lips and eyelids, where some pustules appeared ; but the mask of plaster did not extend to these parts. The treatment is well worthy of further trial.— *Bulletin Général de Therapeutique*, 15 et 30 *Août*, 1840 ; and *Brit. and For. Med. Rev.*

A storm of thunder and vivid lightning passed over this place about 7 o'clock A.M. of the 3d, accompanied with heavy and large hail stones ; the wind, which had been blowing in violent gusts two or three hours previously, ceased when the thunder storm commenced.

Rain fallen, ·215 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XVII.

Diseases of the Eye. Catarrhal ophthalmia. Purulent ophthalmia of Adults.

HAVING brought my observations on general pathology to a close, I next proceed to the consideration of individual diseases; and I shall take them up, one by one, in that anatomical order to which I adverted in the introductory lecture of this course. That is to say, I shall go *a capite ad calcem* : interpolating those disorders which, although they have a name, have as yet no ascertained local habitation, wherever it may seem most convenient to introduce them. I mentioned before one advantage, as it seems to me, of bringing together, in juxta-position, all the diseased conditions to which the same part, or the same neighbourhood, of the body is liable, namely, the facility thus afforded of comparing the phænomena by which they are characterized, and of discriminating one disorder from another. In taking the parts in succession from the head downwards, we adopt a sort of order, definite enough for the purpose of aiding the memory, and yet free from the trammels that belong to all attempts at arranging diseases according to their essential nature and affinities.

I propose then, in the first place, to speak of certain diseases of the organ of vision. Diseases of the eye occupy a sort of neutral ground, upon which the surgeon and the physician may both lawfully enter. For some of them there are no means of relief, but in manual operations of the most delicate

kind. On the other hand, many of the internal parts of the eye require, when diseased, exactly the same species of general treatment which the physician adopts in diseases of *other* internal parts. We seek to change the condition of a small portion of the body, by remedies that act upon and through the system at large. My real and only motive, however, for beginning with a few of the numerous morbid states to which this little part is liable, is this :—that we find, in the eye, more satisfactory and plain illustrations of the *general* facts and doctrines of pathology, as I have been endeavouring to set them before you, than in any other single organ of the body. " Here (to use the words of Dr. Latham, in his little volume on *Clinical Medicine*—a book which I strongly recommend you to study) – here you see almost all diseases in miniature : and from the peculiar structure of the eye, you see them as through a glass ; and you learn many of the little wonderful details in the nature of morbid processes, which, but for the observation of them in the eye, would not have been known at all."

" Within the small compass of the visual apparatus," says Mr. Lawrence, " we meet with a greater variety of *structures* than in any other part of the body. Indeed the eye, with its appendages, exhibits specimens of every one of the animal tissues. We find in it bone, cellular and adipous substance, and blood-vessels : mucous, fibrous, and serous membranes ; the conjunctiva exemplifying the first ; the sclerotica, the sheath of the optic nerve, and the lining of the orbit, the second ; the surfaces containing the aqueous humour, the third : muscular, nervous, and glandular parts : common integument, and hairs. Besides these, it contains several tissues of peculiar nature, to which there is nothing strictly analogous in other parts."

The eye itself, taking it apart from its appendages, the spheroidal eye*ball* itself, is scarcely an inch in its longest diameter.

Yet it seldom happens that disease of any kind, occupies the whole, even of this small space, at once. Inflammation, for example, is often confined to one of the tunics of the eye, external or internal ; and when it affects more, it is usually in consequence of the extension of the inflammatory process, from some one texture in which it took its rise. You will not expect me to treat of the vast number of disorders to which the several parts of the eye are liable. I shall bring, I repeat, a few of them only under your notice ; and I shall select those concerning which the physician is most frequently consulted ; which every one, whatever branch of the profession he may follow, ought to be competent to treat ; and, more particularly, which are calculated to elucidate other diseases, and, above all, other internal diseases, that are usually assigned to the care of the physician. With the anatomy and physiology of the organ, I may take for granted that you are already acquainted.

I will first briefly inquire into the inflammatory affections of what may be considered the mucous membrane of the eye, which, like other mucous membranes, forms a surface communicating with the external air. Some of these affections are very trifling : some are very severe.

There is a mild form of inflammation of the conjunctiva, which constitutes the most common disease of the eye to which adults are subject. It results, in most cases, from vicissitudes of temperature, or from certain conditions, or sudden variations, of the atmosphere. It is very apt to be excited by exposure to a stream or draft of air, especially in the night, and during sleep. It has a strong analogy – indeed it is the *same disease*, except in *situation* —with that moderate degree of inflammation, produced by the action of the same causes, in the mucous membrane of the nasal cavities, the throat, and the bronchi, which in common parlance we style a *cold* in the *head*, or in the *chest*, as the case may be : and accordingly the inflammation of the conjunctiva of which I speak is often called, by the unlearned, a *cold in the eye:* and the same analogy is expressed in its technical appellation : the cold in the head or chest is termed by nosologists a *catarrh ;* and the *cold in the eye* of the vulgar, is with them, *catarrhal ophthalmia.* The suddenness (sometimes) of its accession, has procured for it also the denomination of a *blight* in the eye.

The term ophthalmia is at present used to denote inflammation of the eye *generally :* it conveniently expresses in one word what would otherwise require more. Formerly, when the diseases of the eye were not so well understood in this country as they are at present, almost all the inflammatory conditions to which that organ is subject were lumped together under the common appellation of ophthalmia, or *the* ophthalmia. That word now requires some epithet to distinguish the seat or the kind of inflammation that is meant.

It can scarcely be otherwise than interesting to mark the phænomena which occur in catarrhal ophthalmia, when we know that in its cause and nature, it is the same with inflammation of a similar surface, in parts which we cannot so well inspect as we can the conjunctiva. This membrane, as you know, lines the eyelids, and covers about the third-part of the globe of the eye anteriorly. The inflammation, in catarrhal ophthalmia, is confined to the conjunctiva and the meibomian follicles. Its leading symptoms are *redness* of the surface of the eye ; *some pain* and uneasiness there ; an increased *discharge* from the affected membrane and the follicles ; and a *sticking together* of the *eyelashes and lids.*

The *redness* is worth notice, both in respect to its tint, and to the arrangement of the vessels in which it appears. It is *superficial ;* and of a *bright scarlet* colour ; and usually *irregular* or diffused in patches, some fasciculi of vessels being more distended than others. When, however, the inflammation is more intense, the whole surface, except that of the cornea, becomes of a scarlet red. The vessels of the conjunctiva, which are thus rendered visible by inflammation, anastomose continually with each other, and form a net-work ; and they can be slipped and dragged about over the subjacent surface by moving the eyelids with the finger. Frequently some of the meshes of this net-work are filled up with little patches of extravasated blood ; the eye is what is called blood-shot, or to speak learnedly, there is ecchymosis : and sometimes all distinction of separate vessels is nearly lost. In the commencement of the complaint the redness is confined to that part of the conjunctiva which lines the lids : and it afterwards advances gradually, from the angle where it is reflected over the eyeball, towards the cornea.

Now all these particulars are of consequence, since they are diagnostic of the seat of the disease ; and to show this I must mention, by anticipation, the appearance and the arrangement of vessels that are observed when inflammation affects some of the textures that lie deeper than the conjunctiva, and especially the sclerotica. The sclerotic redness is seen *through* the conjunctiva: it is of quite a different *tint* from that of the conjunctiva ; instead of shewing a *bright scarlet* colour, it is *pink*, or sometimes of a slight *violet* hue ; the vessels are much *smaller* and *finer* than those belonging to the conjunctiva, like hairs ; and they are *straight* also, and arranged regularly like the radii of a

circle; they lie in the sclerotic round the cornea like what is called a glory by painters, or like a halo, or zone surrounding the central cornea; and they *cannot be made to shift their place* by any dragging of the lids. These are very important distinctions. They are such as are easily recognized when two eyes are examined in which the two membranes in question are separately inflamed and vascular; and they are still more palpable perhaps when both membranes are simultaneously inflamed, as they often are, in the same eye. Then, unless the conjunctiva is so universally red as to prevent our seeing the sclerotica through it, the contrast between the larger, more tortuous, scarlet, and reticular vessels of the conjunctiva, and the fine, straight, rose-coloured, radiating vessels of the sclerotic, is exceedingly striking: and those of the conjunctiva, which lie naked on the loose mucous membrane, admit of being slipped about over the fixed zone of vascularity which is presented by those of the fibrous tunic.

The pain that attends catarrhal ophthalmia is slight and trifling. At the outset there is generally some uneasiness when the eye is exposed to the light; but there is no intolerance of light when the disease is fairly developed. The patient complains rather of a sensation of stiffness and dryness, and feels as though there were some foreign body in the eye, between the globe and the lids, especially when the eye is moved; a grain of sand, or gravel, or a little fly. So exact is the resemblance of this feeling, that you can with difficulty persuade the patient that there is nothing of that sort in his eye. No doubt this sensation is produced by the inequality and roughness of the surface consequent upon the irregular distension of the vessels of the inflamed membrane; irritating the organ mechanically, just as a piece of dust would irritate it.

Now in this respect, again, there is a marked difference between conjunctivitis and sclerotitis. In the latter disease, the pain is much more severe, of a dull aching character, with a sense of tightness: the part inflamed is denser, and less yielding than the conjunctiva. The pain is attended also, frequently, by throbbing, and it is felt, even more severely perhaps, in the surrounding parts, than in the eye itself; in the brow, temples, and head. It is a very remarkable circumstance, too, that the pain is distinctly aggravated towards night; increasing in violence from the evening till after midnight, abating towards morning, and ceasing in a great measure during the day, to be again renewed in the evening. I am speaking now particularly of inflammation of the *sclerotica* produced by the same *causes* as give rise to catarrhal ophthalmia: of what is generally called *rheumatic* ophthalmia.

The increased discharge that takes place from the eye in catarrhal ophthalmia is *not* a discharge of *tears*. In the beginning of the complaint there is sometimes a slight degree of lacrymation. But this soon ceases, and the mucous secretion from the surface of the membrane is augmented in quantity, and changed in quality. At first it is somewhat thin, but it soon becomes thicker, and it is often puriform; *i. e.* opaque and yellow: sometimes it retains more exactly the characters of mucus, is transparent and viscid; so that the eye looks moist to a bystander, while to the patient it feels gummy. The puriform secretion is not, in general, in any great abundance. You may see it lying in the angle between the eye and the lower lid, by pulling them apart: or it makes itself visible at the corner of the eye, or between the eyelashes along the edges of the lids, which it glues together at night. Sometimes however ever the discharge is more copious, so as to approximate to what is observed in the less severe forms of another disease I shall presently mention; viz. *purulent* ophthalmia.

There is seldom much swelling of the conjunctiva. If there be any, it results from an effusion of serous fluid into the meshes of the cellular tissue that connects the membrane with the subjacent sclerotica: by which effusion the conjunctiva is partially raised and separated. This kind of effusion often goes to a very great extent in purulent ophthalmia, or in violent inflammation of the external membranes, as I shall shew you by and by.

So much, then, for the symptoms, and causes, of catarrhal ophthalmia. It is necessary that you should be familiarly acquainted with them; not so much because the complaint is very *serious* in its nature, but because it is *common;* because you are sure to be again and again consulted about it, and because it is of great importance to distinguish it from other forms of ophthalmia, in order to adopt the proper treatment. A mistake of diagnosis might lead to mischievous activity on the one hand; or to still more pernicious inertness on the other.

When the inflammation does not extend beyond the mucous membrane, it will run a certain course, and then, under favourable circumstances, subside. But if it be improperly treated, or if the patient cannot guard himself against a repetition of its exciting causes, it may continue for weeks, and harass him a good deal, and even produce such a change in the inflamed lids as may prove a source of permanent irritation, and of chronic disease of the cornea over which they sweep.

Treatment.—Active general remedies are scarcely ever necessary. The patient should observe the main particulars of the antiphlogistic regimen, and avoid exposure to drafts or currents of air, and to cold and moisture

generally. When the external weather is inclement, he should remain in rooms of a uniform temperature. It will be right to purge him in the outset with calomel and jalap, or with calomel followed by a black dose.

If the system at large sympathizes with the local disease, it may become necessary to take blood from the arm, or to apply leeches; but neither of these measures are requisite, except the inflammation is unusually severe, or the disease has been neglected or mis-managed.

After the bowels have been thoroughly cleared by an active purgative or two, remedies which encourage moderate perspiration will be likely to forward the cure : such as warm diluent drinks : five grains of Dover's powder, and immersion of the feet in warm water, at bed-time ; and saline draughts containing 2 or 3 drachms of the liquor ammoniæ acetatis, taken at intervals during the day.

But in this complaint *local* measures are of greater importance than those which are addressed to the general system : stimulating or astringent applications to the affected membrane itself. Almost all modern writers on diseases of the eye agree in this. Dr. Mackenzie, of Glasgow, states it as the result of his observation on Beer's practice in Vienna, and of his own subsequent experience, on an extensive scale, at the Glasgow Eye Infirmary, that " general remedies in this disease are inferior to local ones ; that *violent* general remedies are worse than useless ; and that a local stimulant treatment may almost entirely be relied on." Mr. Melin, in a report of ocular diseases at the General Hospital, Fort Pitt, states that he had treated nearly 300 cases, some of them severe, upon the same principle, without either local or general bleeding; and that he had satisfied himself of the efficacy of this plan of management. And Mr. Lawrence, who for ten years was one of the surgeons to the Ophthalmic Infirmary, in Moorfields, and who during that period had ample opportunities of studying *this* disease of the eye as well as others, says that it is one to which the use of strong astringents is more particularly applicable. In dis rders that have a strong natural tendency to terminate in recovery, it is only by taking advantage of the conclusions derived from extensive observation that we can be quite sure of our ground ; and when the same result is reached by different and independent observers, we may safely place confidence in their concurrent testimony.

Dr. Mackenzie and Mr. Melin both employ and recommend the same application ; viz. a solution of the nitrate of silver in distilled water, in the proportion of four grains to the ounce. A large drop of this solution is to be applied to the membrane once or twice, or three times, in the course of the day. If the patient recline his head backwards, and the drop be placed in the hollow formed by the internal angle of the eye, it will be diffused over the globe upon the separation and subsequent winking of the lids. After a minute or two this causes a pricking or smarting sensation, which subsides in from ten to twenty minutes, and the eye then feels much easier than it did before the drop was applied. Dr. Mackenzie says that the feeling as if of sand in the eye, is uniformly relieved, and the inflammation abated by the use of this solution, which he speaks of as a remedy of sovereign utility in the puro-mucous inflammations of the conjunctiva. The eye continues easy, after its application, for five or six hours perhaps ; and when the symptoms return, they are again to be met by the introduction of another drop. As the disease subsides the remedy gives less and less pain, till at last it is scarcely felt. He tells us that " he has sometimes alarmed other practitioners by proposing to drop upon the surface of an eye highly vascular, affected with a feeling as if broken pieces of glass were rolling under the eyelids, and evidently secreting puriform matter, a solution of lunar caustic; and that he has been not a little pleased and amazed at their surprise when, next day, they have found all the symptoms much abated by the use of this application." He declares also that the acetate of lead, and the sulphate of zinc, substances which are much used in what are called *collyria*, or *eye-washes*, are greatly inferior, as local applications, to the nitrate of silver, in this disease.

There is another expedient that requires to be attended to in these cases. When the eyelids are gummed together by the viscid discharge, much hurtful irritation is often produced by the attempts made by the patient to separate them. Now all this may be obviated by greasing their tarsal edges at bed-time with any mild ointment ; the spermaceti ointment, or a bit of lard. There is no necessity, as I believe, in this form of disease, to use medicated or stimulating salves : the object is to prevent the mutual adhesion of the lids ; and this is accomplished by simple grease.

Purulent Ophthalmia—is another disease of the conjunctiva ; differing from catarrhal ophthalmia in degree, in the severity of its symptoms, in the danger which it implies to the sense of vision, and in its exciting causes. It takes its name from the profuse discharge of pus, or of altered mucus which cannot be distinguished from pus, that pours from the inflamed surface. There are three remarkable varieties of purulent ophthalmia ; called respectively—1, purulent ophthalmia of newly born children ; 2, purulent ophthal-

mia of adults, or Egyptian ophthalmia,
or contagious ophthalmia ; and 3, gonor-
rhœal ophthalmia.

The symptoms of the two last-mentioned
varieties, especially in their severer forms,
are so much the same, that it would involve
us in mere repetition if I did not take them
together. In truth it appears to me much
the simpler and better mode to look upon
purulent ophthalmia as one disease ; and to
specify, as we go on, the differences by which
its several forms are characterized : and not
to split it into three different diseases, and
to give a separate description of each.

Although purulent ophthalmia is inflam-
mation of the very same part that is inflamed
in catarrhal ophthalmia, and differs from it
chiefly in degree, it is a hideous complaint,
either to suffer or to treat ; on account of
the rapid progress it frequently makes, and
its destructive tendency. The inflammation
is *greatly* more intense, the surface becomes,
in the worst cases, highly vascular through-
out. A copious discharge of thick, yellow,
puriform matter speedily establishes itself :
this flows out from between the swollen lids,
and runs over the cheek, which it often
excoriates. At the same time considerable
effusion takes place into the cellular tissue
that connects the sclerotica and the conjunc-
tiva. You are aware that the conjunctiva
extends over the whole anterior face of the
globe; but that it adheres so much more
closely to the cornea than to the sclerotica,
that we might doubt at first whether it did
not stop at its margin. This close and firm
adhesion over the cornea, and the looser
attachment to the sclerotica, give rise to a
very singular phænomenon. The conjunctiva
is raised to some distance from the subjacent
sclerotica by the effusion that takes place
between them ; and it projects around the
cornea in the shape of a large thick ring,
leaving the cornea buried, as it were, in a pit :
nay, sometimes the swollen and prominent
membrane will lap over, so as nearly to ex-
clude the cornea from our sight. The same
kind of effusion takes place also, sometimes
with great rapidity, into the cellular tissue
connecting the conjunctiva with the palpebræ,
producing great external tumefaction, and a
livid red appearance of the eyelids, which
project forwards in large convex masses, and
often prevent our seeing the globe of the eye
at all : the upper lid especially becoming
hard and stiff, and completely overhanging
the lower. This swelling from effusion into
the subconjunctival tissue is of a pale red,
fleshy colour, sometimes marked here and
there with patches of extravasated blood.
The appearance is called *chemosis* : not
ecchymosis, as the similarity of the sound
has led some erroneously to suppose, but
chemosis. Ecchymosis is a barbarous term
of modern fabrication, from εκχεω, effundo;

and signifies an effusion, and by common
consent among medical writers, an effusion
of blood. χημωσις is a genuine Greek word,
the root of which is χημα, hiatus ; and it
means a gap or hollow.

Now this puriform or purulent inflamma-
tion, so long as it is confined to that part of
the membrane which lines the eyelid, is not
of any serious importance ; but it is prone
to extend itself to the cornea, and the whole
anterior surface of the eye, causing ulcera-
tion or sloughing of the cornea, either in
consequence of the actual inflammation of
that part, or in consequence of the pressure
made upon and around it by the swelling of
chemosis. Frequently, when the cornea
remains visible, a furrow or trench of
ulceration may be seen at its margin ; some-
times forming a complete circle, some-
times portions of a circle, sometimes going
quite through ; and when this happens, or
when the cornea bursts, from the effects of
deeper-seated inflammation, the aqueous
humour is evacuated, and the iris protrudes
through the aperture. And even when these
horrible consequences do not take place, the
eye is often as effectually spoiled for the
purposes of vision by an interstitial deposit
between the laminæ of the cornea, rendering
it opaque, and permanently excluding the
passage of light to the retina.

And when neither of these lamentable
effects of the inflammation are produced, it
is apt to leave behind it a chronic and very
troublesome condition of the membrane.
The conjunctiva that lines the lids remains
thickened and granular, and hard and
rough, instead of regaining its natural
smoothness and softness, and polish. And
the consequence of this is a perpetual irrita-
tion of the surface of the cornea, by the me-
chanical friction of the rough and hard lid in
opening and closing the eye, and in the
various motions of the eyeball. The con-
tinuance of this irritation leads at length to
haziness or opacity of the cornea, which be-
comes traversed also by visible red vessels.
Chronic inflammation of its investing mem-
brane is produced, and kept up.

The most severe forms of this disease are
attended, at length, with a good deal of
pain ; doubtless because the inflammation
penetrates to the deeper-seated textures of
the organ. The pain then presents those
characters which I mentioned before as be-
longing to certain inflammations of the scle-
rotica : *i. e.* it is pulsative ; and sometimes
sharp and lancinating, sometimes dull and
aching ; and it is intermittent, or, if constant,
it is aggravated by paroxysms ; the paroxysms
coming on at night, and abating towards
morning ; and it is not confined to the eye
itself, but extends to the parts around it.
This circumorbital pain is characteristic of
inflammation of the sclerotica and cornea,

and of the internal tunics, the choroid and
iris. When the eye is not visible, from the
swelling, we may conclude that the inflam-
mation is as yet confined to the *conjunctiva*,
when the pain is only scalding or "sandy;"
and that it has extended to the sclerotica and
cornea when the pain is severe, throbbing,
and paroxysmal. In the cases in which the
latter kind of pain is felt, the cornea generally
gives way; and sometimes this circumstance
brings relief to the pain, and sometimes the
pain continues to return after the bursting
of the cornea. It is curious that with all
this, there is seldom much intolerance of
light manifested.

In the earlier stages of this malady, it is
entirely local: the system at large is scarcely
disturbed at all. But the constitution begins
to sympathize and suffer when the local
symptoms increase in severity: the pulse
becomes frequent, and the tongue white,
but there is seldom much thirst or fever;
and when blood is drawn from a vein, it does
not, in general, exhibit the buffy coat. A
good deal of variety in these respects has
been noticed however in different cases.
Children appear to suffer more constitutional
disturbance when labouring under purulent
ophthalmia than adults. If there be not much
fever, there is always much uneasiness and
irritation, and the sleep is broken by the
nocturnal accessions of pain.

Such being the general features and course
of the disease, at least as it occurs in adults,
or in patients beyond the period of infancy,
we may next inquire into the circumstances
under which it has been observed to occur.

Purulent ophthalmia has been ascertained
to be a common disease in hot climates: in
India, Persia, and Egypt. It was brought
into England, from the latter country, by our
troops in the beginning of the present cen-
tury, after the celebrated struggle which
there took place between our army and the
French under Napoleon. In this way it got
the name of the *Egyptian* ophthalmia. It
naturally excited very great attention at that
time, and it does not appear to have been
accurately described before.

To give you some notion of its prevalence
in certain places and at certain periods, and
of its serious nature, I may state that it was
ascertained, by returns made from the Mili-
tary Hospitals at Chelsea and Kilmainham,
that on the 1st of December, 1810, there
were no less than 2317 soldiers a burden
upon the public from blindness in conse-
quence of ophthalmia; and that in this num-
ber those soldiers who had lost the sight of
one eye only were not included.

Again, in the year 1804, within nine
months, *i. e.* from April to December, nearly
460 cases of purulent ophthalmia occurred at
the Royal Military Asylum; and within six
years from that time, without including re-

lapses, upwards of 900 cases had taken place
in the same establishment.

You will find these statements in a paper
in the third volume of the "*Transactions of
a Society for the improvement of Medical
and Chirurgical Knowledge*," by the late
Sir Patrick Macgregor. Many of our best
regiments were for a time crippled and ren-
dered unfit for service by this disease; which
they carried from Egypt to other foreign
stations as well as to this country, especially
to Sicily, Malta, and Gibraltar. Nor were
the French troops less extensively affected by
it. Assalini, who wrote an account of the
ophthalmia of Egypt, states that two-thirds of
the French army were labouring under it at
one time. It occurs also, but fortunately
not to such an extent, in civil life. It broke
out some years ago, in a large boys' school
in Yorkshire; and blindness of one or both
eyes, or serious injury to sight, from opacity
of the cornea, and other consequences, took
place in nearly 20 cases.

You perceive, therefore, that this formid-
able complaint has been ascertained, within
the last forty years, to have prevailed as an
epidemic; attacking great numbers of persons
living under the same circumstances, and
having constant communication with each
other. And one of the first questions that natu-
rally arises in one's mind, is whether it is capa-
ble of being propagated or not from one person
to another by *contagion*. Much difference of
opinion has existed on this subject. For my
own part I cannot imagine how any one can
doubt its contagious properties.

I will give you a case or two, as related by
Sir Patrick Macgregor, proving two very
important facts; first, that the disease is
capable of being excited in the eye of a per-
son, previously healthy, by the direct appli-
cation of the puriform discharge from an eye
affected with this ophthalmia; and secondly,
the very rapid operation of the poison so
applied.

One of the nurses employed at the Mili-
tary Asylum, while syringing the eye of a
boy who had much purulent discharge, found
that a considerable quantity of the matter
had spurted into her right eye. This was at
4 o'clock in the afternoon: she felt little or
no smarting at the time; but towards 9 o'clock
the same evening, her right eye became red
and somewhat painful, and when she awoke
the next morning, the eyelids were swelled,
there was purulent discharge, and she com-
plained of pain in the eyeball. The usual
remedies were begun in the morning, and she
recovered in the space of three weeks or a
month. The left eye (into which none of
the matter had gone) remained free from
disease.

A precisely similar accident happened on
another occasion to another of the nurses,
except that the matter spurted into her *left*

eye, about nine in the morning, Sir P. Macgregor happened to be in the hospital at the time when the accident occurred. He desired the nurse to bathe her eye immediately with luke-warm water, and she did so for several minutes ; but notwithstanding this early precaution, about seven o'clock in the evening the left eye began to itch to such a degree, that she could not refrain from rubbing it. When she awoke next morning the eye was considerably inflamed, the lids were swelled, and when she moved the eyeball she had a sensation as if some sand was lodged beneath the eyelid. In the course of the same day purulent fluid issued from the eye, and other symptoms followed which were similar to those of the children under her care. The disease subsided under the usual treatment in 14 days. In this case also the other eye remained sound.

Another of the nurses in the same institution did not come off so well. She was sponging, with warm water, the eyes of a boy suffering severely from purulent ophthalmia ; and she inadvertently applied the sponge she was using to her right eye. This happened at 8 o'clock in the morning. She mentioned the circumstance to the other nurses, but she took no means to prevent infection. Between 3 and 4 o'clock of the afternoon of the same day, great itching of the right eye came on ; and before she went to bed it was considerably inflamed. Next morning her eyelids were swollen, she complained of pain in moving them, and the whole anterior surface of the eyeball was much inflamed ; and a purulent discharge began to trickle down the cheeks from the inner canthus. The symptoms increased in severity in spite of all the means employed to check them, and on the fourth day the eyeball burst. The sight of the eye was irrecoverably lost, and the inflammation continued for upwards of three months. The left eye did not suffer.

These were cases in which the poisonous matter was *accidentally* applied. But a similar application has been made *intentionally*, and by way of *experiment*, and *with the same results*. Dr. Guillié, of Paris, introduced the puriform secretion, which was furnished by some children affected with purulent ophthalmia, under the eyelids of four other children belonging to another institution ; an institution for the blind. These four children were amaurotic, but the external surface of their eyes was healthy and entire. In each instance a regular attack of purulent ophthalmia followed the introduction of the matter.

Facts of this kind, I say, prove, beyond the possibility of question, that the disease may be propagated from a diseased to a healthy eye by actual contact of the puriform matter. Here we have not one case (which

might be considered as an accidental coincidence), but several : the morbid secretion is applied to one eye only; the symptoms of inflammation commence, and the regular form of the disease is fully developed within a few hours after the first application of the pus; and that eye only is affected. It is impossible to get over evidence of this kind.

The only questions therefore that can be raised are, whether the disease is ever produced in any *other* way than by contagion; whether it can be occasioned through the medium of the atmosphere impregnated with the specific effluvia proceeding from the diseased part, without any actual contact of the pus in substance ; and supposing that the complaint does not always result from contagion, how it is originally produced ?

I ought to observe, that independently of such isolated examples of the direct communication of the complaint, by contact with the diseased matter, as I have just laid before you, the history and progress of ophthalmia, since it has been noticed in Europe, are very strongly indicative of its contagious nature. I have already stated that it was not known in Europe till the commencement of the present century—till after the Egyptian campaign, in fact. It is not alluded to by any of the authors on diseases of the eye who wrote previously to that period ; although some of the Italian physicians and surgeons, and many of the Germans, had paid great attention to that class of diseases. It spread from Egypt both to France and to this country, and to other places in which detachments of the Egyptian force were subsequently stationed : in Sicily, to wit, and in Gibraltar and Malta. Whenever it has prevailed among our troops at home, *this* circumstance has been *uniformly observed :* that it first broke out in soldiers who had come from Egypt, or had been in communication with regiments that had been in Egypt. In all cases its origin could be traced to the introduction of fresh troops into the regiment or the barracks.

Again, the manner in which it spreads is exceedingly instructive on this point. It extends itself rapidly, when once introduced, in places where a considerable number of persons are collected together ; especially under circumstances favourable to the propagation of contagious maladies ; as among soldiers assembled in barracks, where many of the men live in the same apartments, and use the same towels ; while the officers, who live in larger and better ventilated rooms, and apart from each other, generally escape. And the good effect, in checking the farther extension of the disease, of separating the healthy from the sick, and of confining every one to his own washing utensils, and clothes, and towels and sponges, leads to the same conclusion. Rust, a German author, men-

tions this striking fact in corroboration of what I have just been saying. The disease broke out in the town of Mayence. This place was garrisoned by Prussian and Austrian troops. The ophthalmia began to spread extensively among the Prussian soldiery ; while the Austrians, who were stationed in separate barracks from the Prussians, in another quarter of the town, remained quite free from it.

Those persons who deny, or who doubt, the contagious nature of purulent ophthalmia, rest their opinions upon some such considerations as these. They hold, in the first place, that the peculiarities of the atmosphere, in Egypt, where the disease has been found so common, are *sufficient* in themselves to account for it. That the inhabitants of that country never dream of its being caused by contagion. Assalini, who saw the complaint raging in the French army, professes his belief that it did not arise or spread by contagion. He remarks that the atmospheric conditions which are known to occasion *catarrhal* affections, are very frequent and powerful in Egypt : the days are very hot, the nights chilly, and attended with heavy dews ; and the eyes are perpetually exposed, in the day time, to a dazzling glare of light from the white sandy surface, while the air is full of floating particles of hot sand, which are raised from the ground by the slightest breeze. His opinion therefore, and that of others who saw the disease as it prevailed in that country, was, that it consisted simply of acute catarrhal inflammation of the conjunctiva ; and that it affected those persons most who were most exposed to the exciting causes of such inflammation : the common soldiers, therefore, more frequently than the officers.

Other circumstances adduced by the disbelievers, or sceptics in respect to contagion, are that many who have intercourse with the sick escape the disease ; and that when bodies of men, among whom purulent ophthalmia has been prevailing to a great extent, are broken up and dispersed, the complaint is not thereby disseminated, as they say it ought to be, supposing it to be communicable from one person to another ; that, in fact, this dispersion, the disbanding of troops for instance, and sending them to their friends and families all over the country, is the surest way of stopping the disorder.

Again, many ineffectual attempts have been made to inoculate the eyes of animals with the matter of purulent ophthalmia. Müller, a German, with that care and industry for which the Germans are so remarkable, took matter from the eyes of patients labouring under purulent ophthalmia early in the morning, before they had washed them, collected it on a camel's hair pencil, and in-

serted it under both the lids of each eye, in a great number of animals, leaving the pencil there for a few seconds, and then pressing it so as to squeeze the matter out. He also smeared the pus copiously and repeatedly along the edges of the lids. He served in this way five cats, ten dogs, two rabbits, two squirrels, two blackbirds, a starling, a yellow-hammer, and a cock. And in none of them did the inoculation produce the slightest effect.

It is a sufficient answer to these *negative* experiments, however, that other persons were more successful in producing the disease in this manner. Vasani and Gräfe have both excited it repeatedly in dogs and cats, by the application to their eyes of matter taken from human patients. And I have already informed you of many instances in which the disease was generated in men by accidental, and even by intentional, inoculation. No amount of negative evidence can do away with positive testimony so often repeated.

And with respect to the other objections, and especially the *main* objection, that persons may associate and hold close intercourse with individuals labouring under purulent ophthalmia without contracting the disease ; I would have you remark that this is no more than what continually happens in regard to diseases that are acknowledged on all hands to be contagious, and to have no other source at present, however they might have originated at first, *but* contagion : the small-pox for example. I think there is good reason for believing, from the facts which I have been relating, that purulent ophthalmia, like the small-pox, is capable of being communicated from one person to another, not only by positive contact, but by transmission of the specific poison somehow for a short distance through the air. But many persons exposed to the contagion of small-pox escape it altogether ; and more persons still, perhaps, fail to be affected, though fully exposed, at one time, and yet readily accept the disease at another time, even when the exposure may seem much more slight than on previous occasions. Now what is true of the small-pox may be presumed to be likely, although perhaps in a different degree, of purulent ophthalmia.

As to the circumstance that the disbanding of a regiment infected with the disease prevents instead of favouring its dissemination, that circumstance is really no argument at all against our belief in its contagious nature. We shall see hereafter, that when fever patients are collected in numbers in distinct wards, or in fever hospitals, *that* disease is very apt to be communicated to the nurses and medical attendants of the sick ; whereas when such patients are distributed here and there among others, in a *general* hospital, the disease is

scarcely ever known to spread. In the one case the poison is *concentrated* and *effective*, in the other it is *diluted* and *harmless*.

Dr. Mackenzie indeed has come to the conclusion, from what he has himself observed, that the discharge in *catarrhal* ophthalmia, especially when it is distinctly puriform, if conveyed from the eyes of the patient to those of others by the fingers, or by towels, and so forth, is capable of exciting inflammation of the conjunctiva, still more severe, more distinctly puriform, and more dangerous, than was the original ophthalmia. And with respect to the disease which I have been speaking of as purulent ophthalmia, or Egyptian ophthalmia, this author calls it, *contagious* ophthalmia ; he holds that the inflammation of the conjunctiva, whether in the mild or more severe form, may and often does originate from common atmospheric influences, but that when so caused it may be communicated from person to person, especially when it is attended with a puriform discharge.

And this is an opinion which, I think, is fully warranted by the facts which we are in possession of upon this subject. There is a strange reluctance, which I have never been able to account for, in some medical men, to admit of the operation of contagion, as a cause of disease. There are undoubtedly some difficulties belonging to the doctrine of contagion, and I hope in the progress of the course, and especially when I come to speak of fever, to give that subject the careful attention which its great importance demands ; and to enable you to make up your minds respecting it. At present I will only remark, that there is nothing absurd, or unlikely, in the supposition, that diseases may first arise from some other source, and then become capable of spreading by contagion ; and that in all cases, even when the contagious principle is most manifest, there seems to be something else required besides the presence of contagious matter ; there must be a power of receiving it, a susceptibility of its influence, on the part of the person exposed to it : a predisposition which is less common in regard to some diseases than to others ; but without the presence of which there is scarcely any complaint that can be so propagated.

At any rate I would desire to impress upon you the expedience and propriety of *acting*, whatever your doubts or your belief may be, *upon the safe side*. We are bound to proceed, in all questionable cases of this kind, upon the most unfavourable supposition. Very great discredit and loss of reputation have befallen practitioners who, having themselves no belief that a given complaint was contagious, have neglected those precautions which, under a contrary impression, they would have thought necessary. Perhaps

they may have sometimes suffered unjustly : but you had better not commit yourselves, especially while you are young in years and in experience, by strong assertions of the noncontagiousness of any disease, the mode of propagation of which is at all questionable. And as for the disease that we are now concerned with, you will do well to act as though it were certainly contagious ; whether you meet with it as a sporadic or as an epidemic complaint, whether it be severe in its symptoms, or mild. You should forbid the use of your patient's towels and washing vessels by other members of the family ; you should avoid employing the same instruments or sponges to any sound eye which you have been using for one that is affected with this complaint ; and you should take care to wash your own hands, after handling a diseased eye, before you apply your fingers to another that is yet, in this respect, healthy.

LECTURES

ON

MORTIFICATION,

Delivered at the Medical Theatre of St. George's Hospital.

By Sir Benjamin C. Brodie, Bart. F.R.S. &c.

Lecture III.—Dec. 12, 1840.

Destruction of parts by Caustics.

</div>

Parts may be destroyed by the application of various substances, which exercise a chemical action on the materials of which their organization is composed. We call these substances *caustics*, and sometimes *escharotics*. This is a subject of especial interest in practical surgery : and in considering it I shall not confine myself to the *modus operandi* of caustics, but I shall extend my observations to the modes of using them, and explain some of the principal occasions on which you may, in the treatment of diseases, have recourse to them with advantage. I have no scruple in doing this, as I am not restricted by the rules of a systematic course of lectures, and need have no object in view, except that of making these discourses as useful to you as possible.

I have said that caustics act chemically, destroying in this manner the organization of the parts to which they are applied. If there be any exception to this general rule, it is in the case of *arsenic*, in the operation of which there seems to be something peculiar. I make this observation, because it has appeared to me, that while other caustics have a manifest action on the dead body, it is not so with arsenic. I very much suspect that arsenic acts merely on the fluids, while ordinary caustics act on the fluids and solids also. However, I offer this to you as a conjecture, and

as a matter deserving of further inquiry, and not as a well-established fact. All other caustics which I have made the subject of experiment produce a distinct alteration in the condition of the dead body, though different in appearance from what they produce on the living, in which they operate on the fluids as well as on the solids, and in which the blood moving in the small vessels conveys their influence beyond the surface to which they are actually applied.

A great variety of chemical agents may be employed as caustics. It would be an endless task for me to describe all of those with which I am myself acquainted ; and if I were to do so, a multitude of others would be left unnoticed, of which I have no experience. I shall only speak of those which we are in the common habit of employing, and the right use of which will, if I am not mistaken, enable you to accomplish all that can be accomplished in this way.

There is some difference in the action of different caustics,some act slowly,others rapidly; some produce much pain, others comparatively little pain : the pain caused by some is very severe for a short time, by others less severe, but of longer duration : some destroy a part to a much greater extent than others : the slough made by one kind of caustic will separate much sooner than that made by another. The period occupied by the separation of the slough seems to depend on the quantity of surrounding inflammation. If the inflammation of the margin be considerable, the slough is soon thrown off; whereas, if it be trifling, it may remain attached for a long time. If the caustic be applied merely to granulations, the slough separates much sooner than if it be applied to the skin or to other parts of original structure.

There is no class of cases in which you will have such frequent occasion to apply caustic, as those of exuberant granulations, such as are commonly called *proud flesh*. In some cases, in which there is little disposition to form new skin, the granulations rising above the level of the skin in the neighbourhood, it is important that they should be destroyed. On these occasions we commonly use the nitrate of silver, and it is quite a sufficient caustic for this purpose. You rub the part with it pretty freely, and the next day the exuberant granulations have disappeared, partly by sloughing, and partly by absorption. There are, however, occasions on which you will find a great irregular mass of unhealthy granulations beyond what the nitrate of silver will easily destroy. Such granulations as those to which I now allude are frequently generated over an old carious surface of bone, and you will then find that the ointment which I am going to mention makes an excellent caustic application for them. It is a very old prescription, but not

the worse on that account. The ointment consists of verdigris, sulphate of copper, nitric oxide of mercury, of each two drachms, oxymuriate of mercury one drachm, with as much hog's lard as is necessary to blend them together. This may be spread on lint, and one or two applications will be sufficient to destroy a very large mass of fungous granulations.

One mode of making an issue is by means of caustic, and for this purpose we generally employ caustic potash (potassa fusa), or strong nitric acid. The former may be rubbed on the part until it has penetrated through the skin, and that is enough. If you continue rubbing it afterwards it goes deeper than is necessary, and generally gives rise to considerable bleeding. This caustic continues to spread after you have ceased to apply it, and you must make an allowance for this when you use it, otherwise you make too large a slough. The concentrated nitric acid spreads a little after it has been applied, but not so much as the caustic potash. The nitric acid is applied by means of lint on the end of a probe dipped in the acid, and rubbed for several minutes on the surface. I have seen issues made by the nitrate of silver made into an ointment and laid upon the part. It makes a slough of the skin, and, as far as the mere issue is concerned, will do very well ; but it is very slow in its action, and causes ten times the pain produced by other caustics.

When an issue is open you want to keep it so, while perhaps it has a tendency to heal ; and there are other occasions on which something is required to prevent sores or the orifice of a sinus from healing. A man may have a small abscess by the side of the anus. If the orifice heals the matter collects within, and a large abscess is formed, which should be prevented if possible. In these cases the best thing that can be done is to touch the margin of the issue, or the orifice of the sinus, now and then with the caustic potash. It makes a slough which takes some time to come away, and the application of it once in ten days or a fortnight will answer that purpose. I have seen the nitrate of silver frequently used with the same intention ; but in fact it promotes cicatrization, and heals the sore or the sinus, instead of keeping it open.

There is an occasion on which you will not unfrequently have occasion to apply caustic, and where it is very material indeed that it should be done in a careful and scientific manner. I refer to cases in which a person has been bitten by a rabid dog, or a dog supposed to be rabid. It is evident that in either case the treatment must be just the same. On these occasions it is better to excise the part thoroughly, and to take out a good deal of the surrounding parts. But it sometimes happens that this cannot be very

easily accomplished. A person, for instance, is bitten in the palm of the hand, ; the dog's tooth penetrates into it, and it would be a very serious thing to cut out tendons, nerves, and every thing else drawn to the metacarpal bones. Or it may be that you had supposed that you had cut out the part completely, and yet find on examination that the tooth has penetrated further, where you cannot very easily follow it with the knife. On these and similar occasions, you can do nothing better than trust to the application of caustics. Mr. Youatt, the veterinary surgeon, who has had great dealings with rabid dogs, tells me that when he has been bitten he has always applied the nitrate of silver, and he is alive and well now : so that in his case this kind of caustic has answered the intended purpose. But, then, he applies it at the very instant when he is bitten ; whereas very few of your patients have the nitrate of silver in their pocket, or could apply it if they had. The best caustic, I apprehend, to use on these occasions is the caustic potash ; and for this reason ; that it dissolves the parts with which it comes in contact, and that then the dissolved caustic penetrates still further, beyond the part to which it has been actually applied. If the tooth penetrate to the cellular membrane, some of the saliva may have gone into the cells beyond ; and if you apply the nitrate of silver, or the nitric acid, these will coagulate the fluids and harden the solids, and they will diffuse themselves, like the caustic potash. A convenient way of applying the latter on these and some other occasions is this—melt some of the caustic potash in a silver or platina spoon, and when melted dip into it the blunt end of a probe, and it will come out with a varnish of the caustic upon it : dip it in again and again, until a button of caustic of sufficient size is formed upon it. By means of a probe thus armed you may carry the caustic into a narrow wound, so that you are sure it will penetrate wherever the dog's tooth has penetrated : and then, from the particular nature of the caustic, (as I have explained) you may be certain that it will penetrate still further, and as far as the saliva can have reached.

Caustics may often be used very advantageously for the purpose of distroying diseased lymphatic glands. A man has chronic inflammation and enlargement of the glands in the groin, forming a considerable tumor. The skin over them ulcerates, forming at last a large ill-conditioned ulcer, which will not heal. What is the reason of this ? Because no ulcer will heal unless it has a healthy basis, and here the basis is a mass of diseased glands. These diseased glands may take a long time to recover themselves—not merely months, but one or two years, and as there are plenty of glands to spare there is no harm in destroying them.

You may effect this by the caustic patash, but not very well ; you want some kind of caustic which will lie in the substance of the diseased glands and destroy their inner structure as well as their outer surface. The form of caustic I am going to mention was used by the late Mr. Pearson, from whom I had the prescription. It consists of one ounce of crumb of bread, two drachms of oxymuriate of mercury, one drachm of red oxide of lead. These are to be mixed together, kneaded with the fingers, and formed into a sort of paste. The paste should be rolled into little conical troches, and these, if left to dry, become hard like bread seals. These troches may be stuck into the enlarged gland like pins into a pincushion. They produce no effect at first, but in the course of a little time they begin to act, and the patient knows this by the pain produced. This lasts for some hours, and, if a sufficient number of the troches be employed, the whole of the gland is at once destroyed. If any portion remains not destroyed it is easy to effect it by repeating the process. I do not know whether the red-lead answers any useful purpose ; I suppose not, but I found it in the original prescription, and on all occasions, where I find a particular prescription to do just what is wanted, I am unwilling to alter it.

Caustic may be applied to various morbid growths ; and I am inclined on the whole, when these can be easily destroyed by caustics, to use them in preference to the knife, and for these reasons :—*First,* the former are on the whole much less formidable to the patient ; *secondly,* if I am not very much mistaken, there is less chance of any ill consequences from the application of caustic than from even a small operation with a knife. For example, you very seldom find an attack of erysipelas follow the use of caustic, certainly much less frequently than after the use of the knife. Again ; the slightest wound in certain constitutions will be followed by that diffuse inflammation of the cellular membrane, terminating in gangrene, which I noticed in a former lecture. But I do not recollect that I ever saw the same thing to happen after the use of caustic. The cases, however, to which caustic are applicable, are only those in which the morbid growth is of small size, and placed quite superficially. Undoubtedly it would cause too great a shock to the constitution, and too much suffering to the patient, for him to have a morbid growth of very large size destroyed in this manner.

There is a very common kind of morbid growth ; in the form of warts and condylomata, which occur in women about the pudenda, and in men on the glans penis and about the anus. These are very easily destroyed by caustic. The nitrate of silver will destroy warts on the glans penis very

well, if they are of imitel extent, but not when they are collected in large masses. In such cases as these strong nitric acid may be employed. Rub the warts with it, and repeat the application from time to time till the whole are destroyed. The following application will answer the purpose very well in cases where the warts are not very extensive—a drachm of muriatic acid, added to three drachms of muriatic tincture of iron. This destroys the warts very well, but not very rapidly. The application must be repeated every day for some time, till the warts shrivel, decay, and drop off. There is a very common escharotic, and a very useful one for warts, on the glans penis or pudenda, where they do not exist to a great extent — namely, equal parts of powdered savine and verdigris. This being sprinkled on the warts destroys them, partly by making them slough, and partly by promoting their absorption. Another excellent caustic on this, and some other occasions, is this : take half an ounce of strong nitric acid, add to it half a drachm of white oxide of arsenic. It makes a beautiful blue solution consisting of the nitrate of arsenic dissolved in nitric acid. This may be applied to the warts by means of a probe armed with lint ; and it has a double operation. The nitric acid acts immediately, and, when it has done acting, the slough contains a certain quantity of arsenic, which continues to operate afterwards. Having this double action you may suppose that it is a very efficient caustic.

On this occasion, as on many others, on which you use nitric acid, without care, you will be in danger of burning the neighbouring textures. A woman who has warts on the pudenda wishes to have them destroyed, but she has no desire that the skin in the neighbourhood should be burned. This, however, will happen, unless you take care to prevent it. If you use nitric acid you should have at hand a solution of the bicarbonate of potash, by applying which you may neutralise the acid as it flows beyond the surface on which it is intended to act, and stop its operation. I may observe here, once for all, that there are many occasions when it is necessary to use similar precautions. Indeed, almost always when you use a caustic it is prudent to have some counter-agent at hand to stop its action if it goes on a wrong part. Acids may be neutralised by alkalies; caustic potash may be neutralised by vinegar. If you are afraid of nitrate of silver burning the neighbouring parts, its action may be neutralised by common olive oil ; a solution of the bicarbonate of potash will decompose chloride of zinc—and so with other caustics.

Caustic may be used with great advantage in many cases for destroying the congenital vascular tumors which we see so frequently in children—nævi, as they are sometimes termed.

There are small vascular spots, not exactly congenital, though they occur in early life, which present themselves on the face of children, and which not unfrequently are objects of some anxiety, especially in the higher classes of society; as they form rather ugly red specks on the face. On examining one of them with a lens you see one large vessel in the centre, and small branches radiating from it. These spots, in most instances, if let alone will disappear spontaneously. If however this does not happen, you may destroy them in the following manner. The principal vessel is near the surface. Touch it through the cuticle for an instant with strong nitric acid, and it will contract and become obliterated. This is best done by means of a pointed piece of glass, which they sell as a sort of toy under the name of a glass pen. It is in truth as bad a pen as possible, but it answers this purpose, and some other purposes in surgery, extremely well. If the acid flows over the check you may neutralise it by a little bicarbonate of potash. But this will not destroy these vascular stars in every instance : and there is another and a still more certain method of proceeding. Puncture the principal vessel, from which the others radiate, with a lancet, and then introduce into the puncture, merely for a single instant, a very fine piece, scraped like a pencil, so as to have a sharp point of the caustic potash. Touch it for a moment only : that will be quite sufficient. But even after so slight an application, you will see that the caustic has also burned the margin of the skin, and unless you adopt other measures a trifling mark will be left. For this nothing is required but the application of a small piece of lint soaked in vinegar.

There are some congenital nævi which are altogether cutaneous. There is a very intricate plexus of little vessels filled with scarlet blood in the skin, which being elevated above the surface of the surrounding skin assumes an appearance which may be compared to that of a raspberry. If a nævus of this kind be of large size it must be removed by the knife or by a ligature, but if it be small you may destroy it very well with caustic. You should not employ the caustic potash, for that would produce bleeding, but rather have recourse to nitric acid, which destroys the nævus sufficiently, while at the same time it coagulates the blood in the small vessels, rendering the nævus more solid than it was before. With a bit of stick, or a probe armed with lint, and dipped in the strong nitric acid, paint the surface of the nævus, taking care that you include the whole,

but that you do not burn the neighbouring parts. This makes a slough of the surface of the nævus, and destroys it at the same time that it coagulates the blood in the small vessels below, and thus renders them impervious. But, as I stated, just now this method is applicable only where the nævi are of small size.

There are subcutaneous nævi formed by vascular tumors in the texture *under* the skin, and not *in* the skin itself. These put on a different appearance from the cutaneous nævi before mentioned. The blood here is seen not of a scarlet, but of a purple colour, because the skin lies over it. These may be destroyed by caustic when they are of small size; and even when they are of large size, if it be a great object to avoid the scar which must exist after the removal of them by the knife or by ligature. These vascular nævi have sometimes been cured by vaccination. Half a dozen punctures have been made with a lancet armed with vaccine lymph. The pustules being crowded together in the nævus, a good deal of inflammation has ensued, with some degree of sloughing, and altogether the nævus has been cured. But you cannot depend on this method—at least so I am informed by those who have practised it, for I have not tried it much myself. But you may on the same principles very easily cure a nævus of this kind by caustic. For this purpose I have a very narrow lancet, perhaps about the eighth of an inch in width: I introduce it into the middle of the nævus, and move it in different directions, so as to cut to pieces, as it were, its vascular structure. I then have a probe armed by dipping the round end into the nitrate of silver melted in a platina spoon. This is to be introduced into the puncture made by the narrow lancet, and moved about, so that wherever the lancet has divided the bloodvessels this may penetrate. It causes inflammation and sloughing, at the same time obliterating the vessels beyond the margin of the slough. When the slough is separated there is a slight discharge of pus for a few days, and if the tumor be of small size you will find that it is cured; but if it be large the application must be repeated. I have used this on several occasions with great advantage, especially when the tumor has been on the face, where it was a great object not to destroy the skin. If you remove one of these tumors either by the knife or by ligature, you must in either case leave a large cicatrix. But by applying the caustic in the way which I have mentioned you save the skin that lies above it. I was last year called to see a little child that had one of these subcutaneous nævi at the end of the nose, which gave it a very ugly appearance. A good part of the alæ of the nose was involved in the tumor, and to have

cut it out would have disfigured the child for life. I treated it according to the method which I have just explained. Several operations were required, but they succeeded perfectly; the child is quite cured of the nævus, and I will not say that you see no mark at the end of the nose, but there is so little, that, unless your attention were called to it, you would not know that any thing had happened. I have destroyed an extensive nævus covering a very large portion of the face in the same manner, there being very little or no scar afterwards.

There is another class of cases which may be very conveniently treated with caustic, and in general much better than with the knife. I mean those tumors which I have been in the habit of calling half malignant, and which occur on the face chiefly of elderly people. A man has a soft tumor upon the face, covered by a smooth skin, and not exactly a wart. On cutting into it you find it consists of a brown solid substance, not very highly organised. A tumor of this kind may remain on the face unaltered for years, and then when the patient gets old it may begin to ulcerate. The ulcer spreads slowly but constantly, and if it be left alone it may destroy the whole of the cheek, the bones of the face, and ultimately the patient's life; but it may take some years to run this course. So far these tumors in the face, and these ulcers, are to be considered as malignant. Nevertheless they are not like fungus hæmatodes or cancer, and for this reason: that the disease is entirely local. It does not affect the lymphatic glands, nor do similar tumors appear in other parts of the body. I have generally been in the habit of destroying these tumors with caustic, and when they are of small size I prefer caustic to the knife, for the reasons I have formerly mentioned. If a patient applies to you with one of these tumors as large as a pea or a horse-bean, not ulcerated, but beginning to increase in size, you may proceed in the following manner. First, make a crucial incision through the substance of the tumor with a lancet. Then, as soon as the hæmorrhage has ceased, apply the caustic potash in the incision. You may destroy the tumor if you please by letting the caustic act on the skin without using a lancet, but its destruction is much more easily accomplished in the manner which I have suggested. One application is generally sufficient; the slough comes away, and the sore heals. Perhaps it will be asked—Is there not this objection to the use of caustic; namely, that some time is necessary for the slough to come away—then a further time for the healing of the wound? and does not all this make the process of cure more tedious than it would be if the knife were used instead? The fact is, that a wound always heals much

more readily after the application of caustic, than after the use of the knife. Take two cases—if you destroy one tumor of a given size by the knife, and then the other, supposed to be of the same size, by caustic, in spite of the time occupied by the separation of the slough, the sore in the former case will be healed sooner than that in the latter.

If the tumor be ulcerated, this is favourable rather than otherwise to the use of the caustic, because it saves the trouble of dividing the part with a lancet. When, however, the tumor has been of long standing, and has produced an extensive ulceration, the caustic potash will not well answer the purpose. There will be so much bleeding from the large surface that the caustic will expend its action on the blood, and will produce but little effect on the disease. You may then destroy the tumor with nitric acid, but the best applications, according to my experience, are the chloride of zinc or arsenic. There is, however, one very serious objection to arsenical caustics applied to a large surface ; the arsenic is sometimes absorbed, producing severe constitutional symptoms. There was in former times a Miss Plunkett, a quack, who pretended to cure cancer, and it was known afterwards that her secret consisted in the application of arsenical caustics. An old medical practitioner, whom I knew in the early part of my professional life, informed me that it had fallen to his lot to see many of Miss Plunkett's patients, and that after the application of her caustics many of them died, from what seemed to be inflammation of the bowels. It is indeed notorious that the topical application of caustic to a great extent is very likely to produce the same poisonous effects as arise from an absorption of arsenic from the alimentary canal. The chloride of zinc acts merely locally ; it is not absorbed into the constitution, and its use is not attended with any constitutional disturbance, nor productive of the smallest danger. I generally use the chloride of zinc by mixing it with an equal quantity of flour. It deliquesces from the moisture of the atmosphere, or you may add a little water to make it into a paste, which is to be spread on lint. If you want a deep slough spread the paste thick ; if a thin one, spread it as thin as you please. The depth of the slough depends on the thickness of the paste, and the thicker it is the longer the action of it continues. The application of the chloride gives the patient a good deal of pain, which you must make him endure as well as you can by giving him opium. Some patients suffer much more than others ; some will not require any opium at all, others will require it in great abundance ; but when the action of the caustic has ceased there is an end to the pain, and the slough comes

away in a few days. If the ulcerated surface be of large size, and the disease of much depth, a second application may be required. When the disease is situated over a bone, I generally like to procure a thin exfoliation of the latter, and the caustic accomplishes this very well, acting on the bone, but not to any great depth. The exfoliation takes place in a few weeks, and when the thin layer of dead bone has come away, healthy granulations are seen beneath. Sometimes, after having destroyed a great part of an ulcerated tumor with chloride of zinc, a small portion of it may be left here and there, to which you may apply the caustic potash, or or solution of arsenic in nitric acid. This solution of arsenic, or any other preparation of arsenic, may be applied to a small surface very safely. Observe that what I object to is its application to a very large surface.

Ulcerated tumors, similar to those which occur on the face, are sometimes met with on the scalp, and these too may be destroyed with caustic. You must, however, apply it in these cases with great caution, and for this reason—if you destroy at once a large piece of the pericranium, the destruction of it is likely to produce a separation of the dura mater from inside the bone. A case of this kind which I saw long ago made a great impression on my mind. A surgeon applied the caustic potash to the scalp with a view to make an ssue in a man's head, who was labouring under a headache, and nothing else. He made a slough down the bone, and exposed a piece of the occiput as large as half a crown, or larger. The patient was soon seized with a set of strange symptoms, and died. It was found that the dura mater had become detached from the inside of the bone just opposite the part where the pericranium was destroyed on the outside ; and it was clear that the sloughing of the dura mater was the cause of the man's death. I mention this case to shew that you must be cautious in the use of caustic when you apply it to the scalp ; but you may apply it in that situation, nevertheless, if you proceed in a prudent manner. I had lately a very successful case of one of these half malignant tumors of the scalp, which was much ulcerated, and had been going on for some years. I applied caustic to the different parts in succession, not making a fresh application until the slough made by the former one had come away. By proceeding in this manner the bone was not killed, except a very thin layer on the surface, and the patient was cured.

You may with proper precaution apply caustics to parts situated internally, even to the inside of the mouth, and to the inside of the female urethra. In that disease which we call *epulis*, a red tumor that looks like the gum, and which becomes connected with

it, (though I believe that it really has its
origin in one of the alveoli,) you may use
caustics with great advantage. It is in vain
to destroy the outer part of such a tumor,
that is, the part connected with the gum,
unless you also destroy the inner part where
it originates in the alveolar process also ; and
from the surgeon not being aware of this cir-
cumstance, I have in several instances known
repeated operations with the knife, as well as
the application of hot iron, and caustics fail.
The caustic which I find in general to be
most convenient in these particular cases, is
the caustic potash. You must fix it at a right
angle to the end of a pair of dressing forceps,
and secure it well by tying thread round it.
The caustic should be scraped small enough to
enter the alveolus, the teeth having been pre-
viously removed. Having thus destroyed
the disease where it originated, you may
apply the caustic to that portion which is
outside, and connected with the gum. But
you will say that it will burn the tongue or
the cheek ; and so it will, if you are not
careful. You must let your assistant hold
open the cheek, and while you apply the
caustic he must have at hand a brush
dipped in vinegar, which he is to apply
whenever the caustic spreads beyond where
it ought to be applied. I do not recommend
this kind of treatment in the case of a large
epulis, in which it will probably be necessary
to take out a portion of the jaw ; but it is
perfectly applicable to many cases in the
early stage of the disease. With a somewhat
similar precaution you may apply caustic to
destroy the vascular excrescence, to which I
have before referred, of the female urethra—
a disease first described by Sir Charles Clarke,
and of which you will find some account also
in my lectures on Diseases of the Urinary
Organs. For these cases you should be pro-
vided with a silver tube or shield closed at
one end, and open on one side. Introduce
this into the female urethra, so that the vas-
cular fungus may project into the open side
of the tube, and there apply the caustic.
Here also you must trust to your assistant
dabbing the neighbouring parts with some
liquid which will act as an antidote to the
caustic ; a solution of bicarbonate of potash
if you use the nitric acid, or vinegar if you
use the caustic potash. In general, in these
cases, it is better before you use the caustic
to remove as much of the excrescence as
you can with a pair of scissors.

I have spoken of the application of caustics
to some cases of what I have called half
malignant disease : but occasionally they may
be employed in cases of true malignant disease :
such as scirrhus and fungus hæmatodes. If
one of these tumors is of large size it is better
to use the knife ; in fact you cannot remove
it otherwise. But there are instances of

smaller tumors in which you may use caustic
with great advantage. I will give you an
example. A lady consulted me concerning
a scirrhous tumor of the breast. The tumor
was very small, but there was a scirrhous
gland in the axilla, and where there is one
scirrhous gland you may be nearly certain
that there are several others, though you can-
not perceive them through the skin. I did not
therefore recommend an operation. She
came to town a year afterwards ; the tumor
had ulcerated, and there was severe and in-
deed almost intolerable pain. I applied to
the ulcerated surface of the tumor a paste of
flour with the chloride of zinc. The tumor
was apparently destroyed, and the sore cica-
trized. She continued well for a consider-
able time. Another tumor then shewed
itself in the neighbourhood of the cicatrix,
which was also attended with excessive pain,
and that was destroyed in the same manner,
as was a third tumor that appeared afterwards.
By this treatment her life was prolonged a
full year and a half ; and during this time she
was in a state not of misery, but of compara-
tive comfort, being generally free from pain.
She died at last of effusion of fluid into the
chest.

A lady, whom I attended last winter, had
a fungous growth over the head of the tibia.
It had all the appearance of malignant dis-
ease, was of considerable size, and was partly
ulcerated. There had been a tumor there
before, and her country surgeon had re-
moved it, but the disease had returned. I
removed it a second time with the knife, and,
as far as I could see, I removed not only the
diseased structure, but the parts beyond to
a considerable extent. The wound appeared
quite healthy, and went on healing favoura-
bly. Just, however, as it was healed, and
when the patient had fixed the day for going
out of town, there appeared on the margin
of the wound, where there had been nothing
before, a tubercle, which seemed to be pre-
cisely similar to what the other tumor had
been in its origin. I destroyed this tubercle
with caustic, and the sore thus made healed.
A second and a third appeared, which were
also destroyed in the same manner. No
others have since shewn themselves, and I
cannot but entertain some hopes that the
disease is really eradicated.

I must not recommend you to use the
chloride of zinc without giving you this
caution respecting it. Never apply it ex-
cept where there is an ulcerated surface. If
you apply it to the skin, you must first put
on a blister to remove the cutis, as otherwise
it will scarcely act at all. But even when
the cuticle is removed, it will not act for
the first twenty-four hours ; and it will then
begin to produce intolerable pain, which
will continue for four or five days. When

the tumor is covered with skin, you must use the caustic potash, or nitric acid, first ; and when the superficial slough has come away, if the further use of caustic is indicated, the chloride of zinc may be had recourse to.

ON
PHLEBITIS OF THE CEREBRAL SINUSES,

AS A RESULT OF PURULENT OTORRHŒA*.

By James Bruce, M.D., Liverpool,

Formerly House Surgeon to the Glasgow Royal Infirmary.

[For the Medical Gazette.]

PURULENT OTORRHŒA is sometimes the result of an acute inflammation of the middle ear, but is more frequently observed as one of the sequelæ of variola and scarlatina in children of a strumous constitution. It is likewise observed about the critical period of fevers of the typhoid type, where the cerebral symptoms have been prominent during the course of the disease ; but in such cases, I have some reason to doubt whether the acute symptoms, which follow the suppression of a chronic otorrhœa, are not often confounded with those occurring during the advanced stages of typhus.

The discharge commonly takes place from the external meatus, by an ulcerated aperture in the membrana tympani : it is liable to vary in quantity, and its physical qualities are materially influenced by derangement of the digestive functions. When neglected, or badly treated, the discharge increases in quantity, becomes fœtid and sanious, and communicates a brownish or violet tinge to silver instruments : this peculiar change in the character of the secretion constitutes the principal distinction between chronic otorrhœa and internal otitis, and is supposed to afford a certain indication of ulceration of the mucous membrane of the middle ear. When the inflammation extends from the mucous membrane of the cavity of the tympanum to the subjacent cellular tissue and periosteum, it speedily reaches the bony parietes, and the ossicular auditus are usually expelled, together with small quantities of osseous

debris. Itard* observes that the ossicula may remain for some time in the cavity of the tympanum, after being detached from their situation, owing to the small size of the opening in the membrane ; and while thus detained they become incrusted with matter ; their expulsion becoming difficult, or next to impossible, till the whole of the membrana tympani is destroyed. The mastoid cells, from the delicacy of their structure, are generally attacked by the inflammation at an early period of the disease : disorganization proceeds rapidly in this situation, and an abscess frequently forms in the integuments covering the mastoid process. When the abscess bursts externally, a communication is sometimes established between the fistulous opening and the cavity of the ear ; whilst, in other cases, instead of opening, the abscess allows its contents to become infiltrated with the subjacent cellular tissue, and to penetrate between the muscles of the neck as far as the theca of the spinal cord†. The whole of the petrous portion of the temporal bone is liable to carious disorganization during the course of a chronic otorrhœa ; but all parts are not affected by it in an equal degree. According to Lallemand, it most commonly attacks the part of the petrous body containing the semi-circular canals : it has often also its seat in the partition marked by the groove for the lateral sinus, and sometimes makes its way into the cranium, under the tentorium cerebelli, by the aqueduct of the cochlea. In a case which occurred in the Glasgow Fever Hospital, under the care of my friend Dr. A. Anderson, the upper half of the petrous body, as far as the base of the cranium, was extensively carious, and of a dirty-grey colour ; it was almost completely detached from the squamous portion of the bone, and, when the concha and integuments were removed, it was seen through a carious aperture above the external meatus.

The discharge from the ear is liable to suppression from various causes. This may depend upon the increased viscidity of the secretion, or may be occasioned by the changes which take place at puberty and during pregnancy ; and also by

* Traité sur les Mal. de l'Oreille, t. i. p. 208.
† Pilcher on Structure and Diseases of the Ear, p. 198.

pathological changes in other organs, giving rise to discharges which appear to become vicarious of the otorrhœa. Lallemand* has remarked the alternation of the purulent discharge with attacks of rheumatism, catarrhus vesicæ, and leucorrhœa.

The most frequent and dangerous complication of purulent otorrhœa is that which arises from metastasis of the inflammation to the brain or its membranes. It is usually preceded by cessation of the discharge from the ear, and the pain, originally confined to that organ, gives place to a severe general headache; fever, stupor, delirium, and symptoms of meningitis, supervene, and the patient may die suddenly in convulsions, without any appreciable traces of morbid action being discovered in the brain or its meninges. In cases of longer standing, the substance of the brain is sometimes found softened in the vicinity of the temporal bone; pus may have been effused between the layers of the arachnoid; or an abscess formed in the substance of the hemispheres, not unfrequently in that opposite to the affected ear—a circumstance which proves that in such cases the inflammation is transferred to the brain by metastasis, and not by continuity of tissue.

When the caries of the temporal bone has extended to the cavity of the cranium, the dura mater and arachnoid, and sometimes the brain itself, are attacked by inflammation; the dura mater becomes partially detached, and a small quantity of puriform matter is usually deposited between it and the diseased bone. In some rare instances the carious opening in the petrous body has become the channel of communication between the cavity of the tympanum and an abscess in the corresponding lobe of the brain; whilst in other cases, more recently observed, the sinuses of the dura mater have been found extensively inflamed, and their cavities filled with pus and false membrane: death evidently resulting from the formation of secondary abscesses in the lungs, and the deposition of pus and lymph in the pleural cavities.

I have thus briefly passed in review the series of pathological changes that usually take place during the progress of a purulent otorrhœa. With the exception of those last enumerated, the anatomical characters of the disease were well understood and described by Morgagni*; but sensible, as that distinguished pathologist undoubtedly was, of the manner in which the inflammatory action is extended from the ear to the brain, he entertained the singular idea that the pus secreted in the ear found its way into the cranium, and that its passage into the skull was favoured by the position of the patient's head, as well as by the carious openings in the temporal bone. Although observation has abundantly disproved the hypothesis of Morgagni, the question relating to the organ primarily affected in co-existing suppuration of the ear and the brain, has given rise to much discussion. M. Itard†, in his excellent monograph on diseases of the ear, has adopted the opinion originally maintained by Laubius, that purulent otorrhœa is in many cases merely symptomatic of disease in the brain. He believes that a primitive cerebral otorrhœa exists whenever suppuration takes place within the cranium, and penetrates into the ear by the carious openings in the temporal bone, or by the natural foramina; or, in other words, he considers the otorrhœa, in many instances, as the critical termination of an encephalitis. M. Itard has adduced several ingenious arguments in support of this opinion, but they appear to me to be completely overturned by the reasoning of Lallemand‡, who has almost succeeded in demonstrating that the lesion of the ear invariably precedes that of the brain. It would occupy too much of our time on the present occasion to examine this question in detail; but I may be permitted to observe, that the argument deduced by Itard from the anatomical position of the temporal bone at the base of the cranium, is perhaps the most conclusive that could have been advanced against his own hypothesis. Lallemand naturally inquires why the purulent matter, presuming it to possess corrosive properties, never effects its escape through any other bone besides the temporal, although there are some which occupy a lower position in the

cranium, and which are thinner and less compact in their structure. What is the cause of this predilection for the temporal bone? Are we not justified in ascribing it to a primary disease of the ear, which recognizes, as one of its most frequent and dangerous complications, a carious condition of the temporal bone?

Another argument, which has been overlooked by this able pathologist, might be deduced from the appearance of the carious openings on the cranial aspect of the bone. Where the disease has attacked several parts in succession, the patient generally dies before the process of perforation is completed in them all, and the caries can thus be observed in various stages of its progress. I lately witnessed a case of this description, where the patient died in consequence of a perforation of the posterior wall of the petrous body; in another point on its superior surface, where the disease was less advanced, the bone was slightly discoloured, thin, and diaphanous, evidently shewing that the caries had commenced in the ear, and that the destruction of this bony lamella was all that was wanting to complete the communication between the cavities of the ear and the cranium.

In the foregoing pages I have endeavoured to give a rapid sketch of the morbid anatomy of the middle ear, and I have also briefly adverted to those lesions of adjoining structures most commonly observed in connection with long-continued disease of that organ. There is still another complication of purulent otorrhœa, to which I have casually alluded, and which appears to have been almost entirely neglected by writers on diseases of the ear. The complication to which I allude is inflammation of the cerebral sinuses. That these vessels should occasionally become affected during the carious disorganization of the temporal bone, we might almost have concluded *à priori* from their anatomical relations to the petrous body. When we reflect on the relation of the petrosal sinuses to the superior angle of the bone; when we see the lateral sinus lodged in a deep sulcus on its posterior aspect, and separated from the mastoid cells and cavity of the tympanum only by a thin osseous partition; and when we observe how invariably the dura mater becomes inflamed, either from sympathy with

disease of the ear, or extension of the carious disorganization to the brain, we are at a loss to conceive how this lesion of the sinuses should have been so rarely described as one of the morbid complications of purulent otorrhœa. I attribute this, in some measure, to the carelessness with which our dissections are usually conducted: we are too apt to be influenced in our examination of diseased structures by our pathological tenets, and our investigations are either limited to the organ in which disease is presumed to exist, or terminated by the discovery of any single lesion sufficient to account for death. Even our best pathological writers are too often guilty of this partial mode of investigation. Kramer justly reproaches Abercrombie with having omitted, in the history of his cases of cerebral disease consequent upon otorrhœa, the indispensable local examination of the affected ear; and likewise, with having paid little and quite inadequate attention to that organ at the post-mortem examination. Within the last few years I have witnessed three cases of inflammation of the sinuses in conjunction with disease of the ear; and in confirmation of the opinion I have just expressed, it is worthy of notice, that in the last of these cases this remarkable lesion was not at first detected, although the temporal bone was carious, and the external wall of the lateral sinus slightly eroded. My attention was particularly directed to this singular affection by the following case, which occurred in the Glasgow Royal Infirmary during the time I was house-surgeon to that institution.

CASE I.—John Britton, æt. 9, was admitted on Tuesday, March 1, 1837, for an immense abscess, occupying nearly the whole of the left side of the head. The abscess extended upwards as far as the vertex, and involved the whole of the integuments of the left side of the cranium, from the occipital tuberosity to within an inch of the external angle of the orbit. It formed a considerable prominence laterally, and fluctuation was distinct every where except in the immediate vicinity of the mastoid process, where the swollen parts were firm, of purplish colour, and acutely painful on pressure. Left side of face was greatly swollen, and there was complete closure of the eye, from

the œdematous condition of the eyelids. The pupil was of natural appearance, and sensible to light. The face appeared somewhat distorted, but it was difficult to determine whether this depended on the partial œdema, or on paralysis of the facial nerve. The patient complained much of his head, and seemed unusually drowsy, and inclined to dose. He generally lay in a state bordering on stupor, and was extremely fretful and peevish when roused, although sensible when spoken to. He sometimes got up out of bed without assistance during an intense exacerbation of headache, and seated himself by the fireside, moaning loudly, and pressing his hands against his forehead. His pulse was 120, weak and fluttering. Breathing seemed slightly oppressed, but he never complained of his chest. The abscess was punctured above the ear, and more than twelve ounces of thick fœtid pus were evacuated. He felt greatly relieved after the abscess was opened, and the œdema of the eyelids almost entirely disappeared. The abscess continued to discharge freely. His appetite, which had been voracious when he entered the Infirmary, now became impaired. He remained in the same lethargic state, constantly moaning, yet quite sensible when roused, till the Friday evening, when delirium supervened, and his left forearm and leg became affected, with rapid convulsive motions, bearing a close resemblance to a paroxysm of chorea. This convulsive agitation of the left side of the body came on repeatedly during the night, and each paroxysm lasted about ten minutes. The patient died next morning at 6 A.M.

The parents of the boy, who were unusually intelligent for persons in their condition of life, informed me that when about four years of age he was attacked with severe headache and pain in left ear. The pain continued, without intermission, for several days; and during that time he cried almost incessantly, and seemed drowsy and stupid. A discharge then took place from the ear, at first small in quantity, but afterwards rather abundant, and followed by a gradual mitigation of all the symptoms. He had afterwards attacks of the same kind nearly every three weeks, and during the suppression of the discharge he was quite deaf in

the affected ear; but on the subsidence of the acute symptoms he gradually recovered his hearing. His last illness commenced about five weeks before he entered the hospital, and was preceded by the usual premonitory symptoms. The discharge did not appear at the usual time; but nearly eight days from the commencement of the attack a hard painful swelling was observed behind the left ear : it seemed to proceed from the mastoid process, and slowly extended upwards, forming the abscess already described. The swelling and apparent distortion of the face were observed only a few days before he came under my care.

Inspection, forty-eight hours after death.—On laying open the abscess, the squamous portion of the temporal bone, posteriorly, was found denuded of its pericranium. When the calvarium was removed, the dura mater in the vicinity of the left ear was thickened, spongy, and of a dirty greenish colour : some purulent matter was deposited between it and the bone, and internally the arachnoid could not be detached from it. This thickened portion of the dura mater appeared slightly concave on its cerebral aspect, and the concavity corresponded to an ulcer on the left hemisphere of the brain, at the junction of the middle with the posterior lobe. The ulcer was nearly circular, with ragged edges, and almost the size of a fourpenny-piece. It was quite superficial, coated with a puriform secretion, and surrounded, to the extent of several lines, by a faint ash-coloured areola. There was no apparent alteration of the cerebral substance. At the superior extremity of the fossa, in which the lateral sinus is lodged, there was a carious opening in the temporal bone, of an elliptical form ; it was filled with thick purulent matter, and communicated with the cavity of the ear. The left lateral sinus was filled with puriform matter, and lined with a yellowish semi-organized false membrane. Near the termination of the sinus, at the jugular fossa, its cavity was obliterated by a coagulum which was slender and pale at its origin, but thicker, and of a deeper red colour, where it dipped down into the jugular vein. The pseudo-membranous substance was interposed between the coagulum and the walls of the sinus. The canal be-

came completely impervious at the tor-
cular Herophili, from the quantity of
lymph thrown out by its parietes. The
rest of the brain was healthy. Quan-
tity of fluid in ventricles natural. On
sawing open the cavity of the tym-
panum it was found completely divested
of its lining membrane, and containing
a quantity of thick purulent matter.
The ossicula auditus were gone, as
well as the membrana tympani. The
mastoid cells were completely destroyed,
and the internal auditory canals were
full of caseous pus. The veins of the
diplöe appeared healthy. Nearly a pint
of whey-coloured flaky serosity was
found in each pleural cavity. The lower
lobes of both lungs were congested,
and studded with purulent deposits of
various sizes. Both pleural sacs were
coated internally with a thin layer of
shaggy lymph, evidently of very recent
formation. Other viscera sound

There are various important consi-
derations connected with the history
of the preceding case. It is impossible
to doubt that the affection of the ear
was the first link in the chain of mor-
bid phenomena, and that the caries of
the temporal bone was a consequence
of the extension of the disease to adja-
cent structures. The external abscess
was evidently the result of the suppu-
ration within the mastoid cells, and
was probably simultaneous in its origin
with the caries of the posterior wall of
the tympanum, which eventually led
to meningitis, ulceration of the brain,
and phlebitis of the lateral sinus. The
secondary abscesses in the lungs were
probably the immediate cause of death,
as in cases of traumatic phlebitis.

Ulceration of the surface of the brain
is a very uncommon appearance, al-
though distinctly described by several
writers. Abercrombie* has only seen
one instance of it. It is perhaps most
frequently observed as a result of other
lesions of the cerebral substance, and
is so commonly associated with them,
that it becomes difficult to determine
how far the chief symptoms depend
upon the ulceration alone. In the case
just related there is a close analogy
between the symptoms preceding death
and those which have been observed in
other examples of this rare affection, by
writers on cerebral disease. The sin-

gular convulsive motions, resembling
chorea, were observed in a case related
by Dr. Powel,* in which there were
large irregular patches of ulceration on
the anterior lobes of both hemispheres.
Dr. Abercrombie† also alludes to the
case of a lady mentioned by Dr.
Anderson, of Leith, where the patient
was seized with a convulsive affection
of the left arm and leg, occurring in
paroxysms several times a-day, and
generally continuing half an hour at a
time. She was liable to attacks of
coma, and died at last of gradual ex-
haustion. At the upper part of right
hemisphere there was an ulceration two
and a half inches long, one and a half
broad and nearly an inch in depth.
Similar involuntary motions of the
extremities on one side of the body,
occurring in paroxysms, were also ob-
served in the cases of ulceration of the
brain recorded by Dalmas and Scou-
tetten;‡ in the former case the forearm
was principally affected, and in the
latter the face was œdematous, and the
patient could be roused to consciousness
till within a few hours of death. In
another case related by Bricheteau,§
where the ulceration co-existed with
otorrhœa and caries of the temporal
bone, death was preceded by furious
delirium and convulsions. I have ad-
verted to these examples of this affec-
tion, not with the view of proving that
certain symptoms are invariably ob-
served in every case of ulceration of the
brain, and are therefore to be consi-
dered as pathognomonic of that disease,
but merely to show that the peculiar
character of the convulsions in the case
related above is strikingly analogous to
that observed by some authors in con-
nection with similar lesions.

The condition of the lateral sinus,
which was apparently unaccompanied
by inflammation of the other sinuses, or
of the cerebral and diploic veins, fur-
nishes us with an explanation of the
remarkable lesions of the thoracic vis-
cera. The latter appearances belong
to a class which many of our best pa-
thologists believe to have their depen-
dence on the diseased state of the
veins immediately adjacent to the seat

of a primary affection. The lesions observed, however, in the preceding case, do not exactly coincide with the views of certain writers, and I shall have occasion to advert to this want of coincidence hereafter, in tracing the connection between phlebitis of the sinuses and the pathology of secondary abscess.

[To be continued.]

ON THE
COAGULATION OF THE BLOOD AFTER DEATH.

By James Paget, Esq., M.R.C.S.

Demonstrator of Morbid Anatomy, and Honorary Curator of the Museum, at St. Bartholomew's Hospital.

(For the Medical Gazette.)

An apology may be deemed necessary for the publication of observations similar to any which have been already recorded, and from which correct conclusions have been already drawn. Probably, such a proceeding will be considered justified, if the previous reords have been so far forgotten or overlooked that the general opinion is at utter variance with them and with the conclusions to which they certainly lead.

When the facts which I propose now to detail were first noticed by me, I imagined that none similar to them were on record, for they were not familiar to any to whom they were mentioned; but on looking over some of the many treatises that were written on *Polypus of the Heart*, during the 17th and 18th centuries, I found in one by Joseph Pasta *, the greater part of the same facts set forth with an admirable accuracy, and made the groundwork of nearly the same conclusions as I had drawn from them. Perhaps similar observations were made by others of the same period; but as far as I can learn none noticed them before Andrew Pasta, the cousin and preceptor of the author already quoted, who is said to have described many of them in two epistles, *(De Motu Sanguinis post Mortem*, and *De Cordis Polypo in-dubium revocato*), published in 1737. Since the

* De Sanguine et de Sanguinis Concretionibus per Anatomen indagatis et pro causis morborum habitis Quæstiones Medicæ. — Bergomi, 1786, 8vo.

time of the younger Pasta, who tells us that his own work was written chiefly for the purpose of restoring his cousin's neglected observations, the facts have been again forgotten, or have been quoted only for the sake of contradicting them; probably because both these authors mixed them with many errors, and drew from them many other conclusions besides the true ones. Except in the article *Blood, Anormal Conditions of*, in the Cyclopædia of Anatomy, by Dr. Babington, in which they are very briefly mentioned, I do not think there is any modern work in which these facts are recorded, although they seem to be the only ones that can guide to a correct judgment of the period at which the coagulation of the blood in the heart and vessels has taken place. But whether there be or not, the apology already offered for relating them again ought to be deemed sufficient, for there can be no doubt that the prevalent opinion is, that the large masses of fibrine, which contain little or none of the colouring matter of the blood, and adhere firmly to the walls of the heart, are formed some time previously to death.

This opinion is expressed more or less distinctly in all the most esteemed works on the diseases of the heart, from that of Corvisart onwards. It has lately been very strongly advocated by M. Bouillaud, both in a special paper on the subject, and in his great Traité des Maladies du Cœur, and more recently in two articles in L'Experience *; and he not only states the auscultatory and other symptoms which these supposed polypi of the heart produce, but he gives a full account of their causes, and describes the treatment which he has found most successful in removing them, and the stethoscopic and other signs by which their gradual disappearance from the interior of the heart may be recognized. The deservedly high reputation of M. Bouillaud gives such weight to his opinions, that when they are recorded on the side of an old error, I may reasonably fear whether the following facts, simple and conclusive as they seem, will be sufficient to establish the truth, which I believe to be, that the coagulation of the blood in the heart and large vessels during life is a very rare event, and had

* Mai et Juin, 1839.

not occurred in a great majority of the cases which are described as examples of it.

Having, without any definite object, taken accurate notes of the condition of the blood found after death in the principal parts of the circulatory system, of nearly 150 of the bodies which I had lately examined, I was anxious to discover whether an analysis of the numerous facts thus collected would lead to any general results. Among several of more or less interest was the following:—whenever in the coagula found after death in the heart and large blood-vessels the colouring matter has separated from the fibrine of the blood, so that a part of each coagulum is nearly colourless, and more or less similar to the buffy coat of blood drawn from a person labouring under an acute inflammation, the least coloured portion is always placed at that part of the clot, which, in the position in which the body has lain since death, is at the highest level.

In proof of this, if, in any case in which coagula are found in the heart, that organ be either examined as it lies in the chest, or be held in the position which it naturally occupies in the recumbent body, it will be constantly found that the uncoloured portion of each coagulum is placed uppermost, that is, in the part which in the body lies nearest to the sternum; and that as the distance below the sternum increases, either the coagulum becomes more and more deeply coloured, and less firm, or else at some definite lower level presents an exact plane of sepation between the uncoloured and coloured portions. A similar observation may be made in the long branched coagula that lie in the pulmonary arteries. In the trunk of the artery these coagula are rarely quite black; they are usually either colourless, or contain but a few of the blood-globules, and these placed at the most depending part. But however little colouring matter there may be in the part of the coagulum which lies in the trunk of the pulmonary artery, the extremities of its numerous ramifications, which are contained in the posterior branches of that vessel, are always more or less completely black. The same rule is observed in the coagula in the branches of the pulmonary veins, and in those which occupy the vena cava

superior, and its chief branches; in all of which the portion of the coagulum from which the blood-globules have separated is always that which lies on its uppermost (or, as the parts are usually described, its anterior,) surface. Again, a similar fact is evident in the coagulum usually contained in the longitudinal sinus : if that canal, at the vertex of the head, contain a colourless coagulum, it will constantly be found, on drawing it gently out, that it is black at that part where it passes down the occiput ; and whatever be the colour of the coagulum in the longitudinal sinus, the blood in the lateral sinuses is never, as far as I have seen, more than loosely coagulated in a soft black mass. In short, wherever the blood is examined, illustrations of the same rule are met with ; as, for further examples, in the invariable blackness and softness of the coagula, (if any have formed) in the vena azygos and vena semi-azygos ; in the blood of the renal veins, as compared with that of the vena cava inferior adjacent to them; in that of the descending branches of the internal iliac, compared with the firm, and often nearly colourless coagula in the external iliac and femoral veins ; in the soft black coagulum of the thoracic aorta, which lies low in the posterior curve of the spine, compared with that which in the same subject is often colourless in the abdominal aorta on the anterior lumbar curve.

It follows from these facts, which I have confirmed by the careful examination of a considerable number of subjects, that, regarding the cavities of the heart, and the large vessels leading to and from them, as one cavity, any quantity of blood contained in it at the instant of death coagulates according to the same method as it would if drawn from the body into a basin, or any other vessel; and that if its coagulation be sufficiently slow, or the proportion of fibrine large, the colouring particles always sink to the lower level, and leave a certain quantity of uncoloured fibrine above them. In different cases, this fibrine, as well as the rest of the coagulum, varies considerably in its general aspect, and in the degree of its adhesion to the walls of the heart; and according to the condition of the blood from which it is separated, presents nearly all the varieties which

have been described as unorganized, and slightly or partially organized polypi, or concretions, of the heart.

The rule applies equally whatever be the degree of coagulation of the blood. The best illustrations of it, however, are in the cases where the cavities of the heart are all filled with firm coagula, in which there has been almost a complete separation of the blood-globules from the fibrine, so that large white, yellow, or pinkish masses, of a firm, transparent, or glistening jelly-like substance, are found completely filling one or more of the cavities, and closely adhering to their walls, and in the interspaces of their muscular fasciculi. In these, which it is to be observed are the very cases upon which the opinion of the frequent coagulation of the blood during life is chiefly founded *, the vena cava inferior is full of soft black coagulum, without any trace of buffy coat. This is, on the one hand, continuous with a white or white and black coagulum, which fills a portion of the inferior cava lying on the lumbar vertebræ, and on the other, forms one mass with that in the right auricle, in which there is always a distinct level, above which all the coagulum is composed of more or less pure and firm fibrine, and below which it is quite black and much softer. The coagulum in the auricle is again continuous with that in the superior cava and its branches, in which there is usually the same degree of separation of the chief constituents of the blood as in the blood in the auricle, and always an equally distinct gravitation of the colouring particles to the lower or dorsal portion of the coagulum. Lastly, the coagulum in the right auricle is usually continued in one mass into that in the ventricle, where again similar characters may be remarked. The apex of the right ventricle being, in the recumbent posture of the body, the highest point of the heart, there the blood is never in these cases at all coloured; commonly the whole coagulum in this ventricle is white or yellow, but in many cases it exhibits a black layer at the most de-

pending part; that is, at that part which lies in contact with the posterior wall of the ventricle, behind the auriculo-ventricular opening, and just below the origin of the pulmonary artery. The coagulum in the right ventricle is continued into that in the pulmonary artery. In the latter there are usually three semilunar grooves of moderate depth, by which it is sometimes nearly cut through, and which show that it was modelled on the sigmoid valves. If there be any colouring matter at all in the *trunk* of this arterial coagulum, it is always situated at its dorsal or inferior aspect; but in cases of extreme separation of the blood it is quite colourless, for the natural course of the main trunk of the pulmonary artery is somewhat backwards as well as upwards and to the left. Tracing the branches of this coagulum, the largest are always those which lie in the posterior divisions of the artery; and in these the quantity of colouring matter constantly increases, but still occupies the same depending part of the coagulum, on which, at some distance towards the back of the lungs, the uncoloured fibrine is arranged in the form of only a thin riband-like superficial layer. At last, the coagulum becoming gradually softer, one arrives at branches of the artery near the back of the lungs, in which it is entirely black; and still further back than these, the arteries contain only fluid blood, or a deeply blood-stained serum. If, on the other hand, the coagulum be traced from the trunk of the pulmonary artery into its anterior or sternal branches, it is found in all these more adherent, smaller and drier, and containing scarcely a portion of the colouring matter of the blood.

On the opposite side similar appearances present themselves: the blood in the posterior pulmonary veins is fluid, or if coagulated is less firmly so than that in the anterior veins; that in the left auricle is less coagulated than that in the left ventricle; and so on according to the same rules as are observed in the venous system.

The few apparent exceptions to this rule that sometimes occur, will I believe always prove, on careful examination, to be examples of it. For instance, when the right auricle is very much dilated or distended, the separation of the colouring matter of the blood in its appendix and anterior part may be

* They occur most frequently, but not exclusively, in those who die of acute inflammations. I have seen such appearances in two persons, who died of hemorrhage, which was in neither preceded by any inflammation; and in the bodies of many who have died of perfectly chronic disease.

more complete than in the right ventricle ; and when the body has been placed immediately after death in some other than the recumbent posture, the level of the separation of the fibrine from the dark clot is correspondingly altered. Thus, in the body of a man who had suffered from excessive dyspnœa for several days, and having died while sitting up with his head resting on his knees, had remained in that position for three or four hours after death, the condition of the coagula was almost exactly the reverse of that usually observed ; so that I ventured to predict, before hearing the circumstances of his death, that the body had not been *laid out* in the usual manner. The blood was darker and softer in the ventricles than in the auricles, and there was less separation of fibrine in the auricles than in the superior cava, or the trunks and superior branches of the pulmonary vessels : the blood was also less coagulated in the inferior cava on the lumbar vertebræ, than in the same vein at the diaphragm, and more completely separated in the superior cava than in any other part of the circulatory system that I examined.

The close similarity which, it is evident from these facts, exists between the coagula of blood found in the heart and blood-vessels after death, and those which form when blood is drawn from the body during life, and left at rest, leaves no room for doubt that the process by which they are formed is in both cases essentially the same, and that the coagula found after death have resulted from the blood *while at rest* having separated into its constituent parts, of which the serum has gravitated into the lower parts of the body, and there, more or less stained with colouring matter, has been imbibed into the porous tissues, while the globules have slowly descended during the *setting* of the fibrine, and have left a greater or less quantity of uncoloured coagulum above them. There is no perceptible difference whatever, (except that of external form), between the coagula of blood found in the body after death, and that which is formed of blood drawn into a basin ; each has the shape of the cavity in which it is contained ; the one is simple, the other branched and complex in its form ; but in the disposition of their constituent parts they are identical.

If the coagulation, by which these *polypi* are formed, occurred during life, while the heart was still acting, and at least a part of the blood still moving, it is in the highest degree probable that the fibrine would be deposited in concentric layers on the interior of the heart and vessels, as it is in the sac of an aneurism, and that the parts of chief coagulation and separation would be the auricles, which are less forcibly moved than the ventricles. But the actual results of the coagulation are the very reverse of these, and are explicable only by supposing that the whole mass of blood was fluid, when at the time of death it all nearly at the same instant ceased to move and began to coagulate.

The coagula that do form in the heart and large vessels during life generally present characters by which they may be easily distinguished from the preceding. The simplest kind of this class are those which are deposited in concentric layers on the walls of the heart or blood-vessels, like the coagula in an aneurismal sac. Examples of these are very common in cases of gangrena senilis, in phlebitis, in those in which the veins adjacent to malignant growths become blocked up by coagula, in certain cases of granular kidney, which are probably accompanied by inflammation of the renal veins, in analogous cases of cirrhose, in pulmonary apoplexy, and in some other complaints. Similar coagula in the heart are more rare. I have found them in two cases of excessively dilated left auricles, where the lining membrane was diseased and rough— cases which might, perhaps, justly be called aneurisms of the auricles ;—in one or two cases of great dilatation of the left ventricle, and in cases of real aneurism of the same part. But in all these cases there can be no difficulty in determining that the fibrine was deposited during life. It is arranged in evident concentric layers, which are easily and definitely separable, and often have a thick fluid between them ; the portion nearest the axis of the cavity or vessel is least firm and darkest ; none of it is glistening or transparent, like the coagula formed after death, or the buffy coat ; but all is dull and opaque, of a reddish or brownish grey colour, grumous, and looking granular. In the heart the fibrine thus

deposited during life occupies not any large portion of the cavity, but only adheres to some particularly dilated or diseased part, and is quite separate from the coagula which have formed after death,* and which present all their usual characters. In short, as the origin and mode of formation of the coagula of the one kind are similar to those of inflammatory blood, with its buffy coat, and those of the other kind are similar to those of the layers of fibrine in an aneurismal sac,—so in all their important characters are they respectively similar; and hence the buffy coat, and the fibrine of the anuerismal sac, substances which are familiar to every pathologist, may be taken as certain standards, by a comparison with which a correct decision of the date of formation of coagula within the heart and large vessels may be always attained.

The other formations in the heart with which the white coagula formed after death have been confounded, are yet more different from them. One kind of these consists of those rounded hollow bodies that usually adhere among the columnæ carneæ, and are of an opaque yellowish colour, moderately firm consistence, and filled with softened fibrine,† and to which Laennec ‡ gave the name of vegetations globuleuses. About these, if the description that I have given of the other kind be observed, there can be little question ; the existence of the softened fibrine, which constitutes the puriform fluid in the middle of the mass, is sufficient proof that the clot was maintained for at least many hours at the natural temperature of the living body ; and all the characters of these masses, as far as I have seen or read of them, are widely different from those of the buffy coat.

As little doubt can exist respecting the nature of those actually vascular growths which are sometimes found attached to the walls of the heart, and

much more rarely to the interior of the arteries. These are never transparent or shining, or in any respect similar to the fibrine of the blood ; the heart usually contains, besides them, masses of common coagula ; they are attached as firmly to the walls from which they grow as their parts are to each other; they usually adhere by a base of less circumference than the rest of their mass ; and when a section is made through one of them and the wall of the heart, there is seldom any abrupt line of demarcation between them*.

The only kind of coagula about the period of formation of which I can now entertain any doubt, are the little shreds of fibrine that are sometimes found adhering to the chordæ tendineæ, and which are certainly very similar to these obtained by stirring the blood. It is not improbable that in the last period of life, as the blood passes among those fine tendinous strings, some of its fibrine may separate and adhere to them, under the influence of the same unknown force as that by which it is separated by sticks, or other small bodies, made to move in it. But this opinion can be accepted as only in the lowest degree probable.

If it be true that the cases are very rare in which coagulation of the blood takes place in the heart and vessels during life, and that the fibrine thus deposited can be easily distinguished from the coagula that form in the bodies of nearly all persons after death, and that the latter are formed after the same method as in blood drawn from the body during life and left at rest, it follows, that by the examination of the coagula in the heart and large vessels after death, a judgment may be formed of the condition in which the blood was during life, with at least as much certainty as by the general examination of that drawn in venesection. The researches of many observers, and especially those of MM. Andral and Gavarret, of which abstracts have been recently published†, prove that a knowledge of the relative proportions and respective characters of the main constituents of the blood forms an important feature in the history of each

---

* Sometimes one finds the black portion of a coagulum formed after death separated from the white. The latter, in these cases, always lies uppermost, and adheres to the anterior (upper) wall of the cavity. There can be no doubt the black part of the clot has fallen down from the white and firmer portion. I have seen such cases only when the dark part of the clot was soft and very easily broken.

† L'Expérience, Août 1840.

disease. I would, therefore, venture to suggest, that the general condition of the blood after death should be ascertained with as much care as that of each of the organs of the body, and that a description of it should form a part of each future record of post-mortem inspections. The notes which I have made of the last two hundred cases examined, already afford some conclusions of much interest, which, if I should be able to confirm them by some hundreds more of inspections, may grow to be important.

A notice of the condition of the co-agula of blood is absolutely necessary in those cases of medico-legal investigation in which it is required to know in what position the body was placed in the first hours after death. The case I have already mentioned, in which the condition of the blood was the reverse of that usually seen, because the dead body remained for some time in the erect posture, shows that in these cases the arrangement of the several portions of the clots would afford a most important part of the evidence.

In all cases it must be remembered that the coagulation that takes place in the body is much slower than that which ensues in blood drawn from it, either during life or after death; so that a quantity of uncoloured fibrine is found in the heart and uppermost vessels of the dead body in many cases in which it is most probable that had the blood been drawn during life it would not have presented a buffy coat. In the majority of cases the blood does not coagulate in the body for the first four hours after its rest has commenced; in many it remains fluid for six, eight, or more hours, and yet coagulates within a few minutes of its being let out of the vessels. But as this greater slowness of coagulation is common to all, it is not material in a comparison of the blood of many dead bodies, though it would require to be carefully estimated in a comparison of the blood of the dead with that of the living.

DOUBLE UVULA.

To the Editor of the Medical Gazette.

Sir,

May I request the favour of a place for the following extraordinary case in your valuable journal, which must prove interesting to the medical public, and to the physiological inquirer in particular. On the 2d of November I was called upon to see Mary O'Donnell, a peasant girl, aged eight years. She had an affection of the glands of the neck, for which I prescribed preparations of iodine, with gentle saline aperients, under which treatment she is now nearly well. Having had occasion to inspect her throat I perceived two *uvulas* projecting from the palate, perfectly distinct and of equal size, of which circumstance the parents of the child were seemingly ignorant. She had never complained of inconvenience attending it. Her voice is clear and strong; and, strange to say, she can with great ease extend it to *three octaves*. Now I do not remember that any writer has mentioned the *uvula* as connected with the mechanism of the human voice. Mr. Herbert Mayo states, "The range of the human voice seldom exceeds two octaves and a half." I have never seen a case similar to this, but have seen two cases with total absence of the *uvula ;* one in the person of a Hindoo girl at Calcutta, in 1836; and since then in a patient of Mr. Wallace, surgeon, of Bow: in both cases the voice was perfectly natural.—I am, sir,

Your obedient servant,

George Bolster, Surgeon.

ANALYSES and NOTICES of BOOKS.

' L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'Alembert.

On Diseases of the Hip-joint, with Observations on Affections of the Joints in the Puerperal State. By William Coulson, Esq., Surgeon to the Magdalen and City of London Lying-in Hospitals, &c. &c. Second edition. London, 1841.

This is in several respects, we perceive, a different treatise from that fomerly given to the public in the first edition. The author has made considerable changes both in the form and substance of his work, and of those changes, several, we think, are valuable improvements.

In the first place, he has consulted the convenience of his readers by

altering the shape of the volume from 4to. to 8vo. The big editions of the *patres medicinæ,* like the long yarns of our senior relatives, we can readily tolerate; but the like in an *alter ego,* a contemporary, a rival,—for such our indulgence extends not beyond the 8vo. In the next place, he has changed for the better his arrangement. In the former edition, Mr. Coulson placed his observations on the causes and morbid anatomy before those relating to the symptoms, which we agree with the Edin. Med. and Surg. Journal, Jan. 1837, was objectionable in two points of view; first, because he was bound to inform us what the disease was, nosologically speaking, whose causes and anatomy he was about to examine, and this could be done properly no otherwise than by an enumeration of the symptoms, *i. e.,* in effect, by an adequate *definitio morbi;* and, in the second place, because, in a practical work, which Mr. Coulson's evidently is, the symptoms should by all means take the lead, on account of their superior importance to the practitioner: this defect of arrangement he has corrected. Again, instead of crowding together in one chapter, as in the first edition, the various diseases with which Hip-joint Disease may be confounded, Mr. Coulson has in this edition judiciously devoted to each of them a distinct chapter. A chapter devoted to the normal anatomy of the hip-joint in the former edition has been, we perceive, omitted in the present; and, on the other hand, chapters 2, 3, and 4, on nervous affections of the hip-joint, on malignant affections, and on congenital affections of the same, have been, we think, nearly wholly re-written, and, at any rate, greatly enlarged and much enriched with valuable matter; while chapter 5, on Puerperal Affections of the Joints, is an entirely new and very important addition to the work.

The author, we perceive, has withdrawn two plates from his work, and substituted excellent woodcuts: by this change we believe that the expense of the volume rather than the value has been diminished. Altogether the second edition of this work is, as it ought to be, a decided improvement on the first, and is, in truth, an excellent manual of practice, so far as the hip-joint affections are concerned.

The doctrinal features in the present edition that strike us as most characteristic are, first, as to pathology (chapt. ii. sect. 2 and 3), that the hip-joint disease is essentially a disease of the secerning function, and that the tissue first attacked is the synovial membrane of the joint; and, second, as to the ætiology (chapt. ii. sect. 4), that the disease is not a local affection, but merely a local expression, symptom, or effect, of a constitutional taint or cachexy; and, third, with regard to treatment (chapt. ii. sect. 5), that he repudiates wholly the use of moxa, issues, setons, and counter-irritation generally, in strumous subjects of hip-joint disease. In each of those points we are disposed to assent more or less fully to Mr. Coulson's views.

On the whole, we are of opinion that the author has on this occasion fully sustained his reputation as a writer, observer, and practitioner; and we have no hesitation in saying that in its present form his work is, for practical purposes, one of the very best on the subject with which we are acquainted. We especially recommend to the reader's notice his chapter on puerperal affections, in every section of which he will meet with matter of interest and instruction. We regret that we have no space for extracts from this valuable chapter.

MEDICAL GAZETTE.

ILL-TREATMENT OF A WOMAN IN THE ETON UNION.

WHEN things are at their worst, says a popular adage, they must mend; and never could the proverb have been more applicable than to the present administration of the laws for the relief of the poor in England. The " test of destitution," so often lauded and enjoined at head-quarters, turns out to be merely a denial of real relief; and the cold severities delicately hinted at Somerset House, when translated into

vulgar practice, shock the most apathetic looker-on, and force even the economists to confess that some error has been committed. Indefensible misconduct on the part of some understrapper of the new system makes them tremble for its success; and, like Talleyrand, they allow that it was not only a crime but a fault. Such instances have of late been so common, that they cannot be attributed to chance by the most superficial; and it is obvious to every man of penetration, that the wrongs inflicted on the suffering poor of Hendon, Hoo, or Eton, are not the natural growth of these several places, but rank weeds transplanted from London; that although the creatures who are made masters of workhouses do not understand the decencies of oppression, and cannot grind the faces of the poor with any degree of politeness, they perfectly comprehend the spirit of their masters' instructions. Like soldiers to whom a conquering general allows free quarters, their misdeeds are attributable to him, though they often transgress the letter of his permission, and occasionally go beyond what he really intends. Hence, although it is impossible for any one possessed of a spark of manly feeling entirely to subdue his disgust at the petty instruments of tyranny, his anger should chiefly be directed against the more powerful oppressors who first set them in motion: when we read of the ravaging of the Palatinate, under Louis XIV., it is not on the miserable serfs in uniform who fired the villages, but on the minister and general who commanded the deed, that History lavishes her indignation.

Were we to give way to our natural feelings at the working of the New Poor Law, and become registrars of the iniquities committed under its sanction, the heading "ill treatment of a pauper in the —— Union" might be kept standing at our printers'. The circumstances, however, of the case which has given a title to our present article are so very remarkable, that we think it our duty to point them out to those of our readers whom they may have escaped in the immense columns of the daily newspapers.

Elizabeth Wise is an inmate of the Eton Union Workhouse, together with her child, who is not yet three years old. As the child had chilblains, and was otherwise ill, the mother had leave to sleep with her until she should get better. The permission was afterwards withdrawn; but Wise was still allowed to attend to the child's chilblains. Supposing the permission to be in force, she went up to the nursery, on Sunday morning, the 27th of December last, and was unfastening the bandages on her child's feet, when Joseph Howe, the master of the workhouse, came up and desired her to quit the place. According to the master's account she was disobedient; did not leave her little patient with due Bastille readiness, and seems to have reproached several women with the fact of her child having been born in wedlock, and theirs not. In short, she was " refractory." The master accordingly carried her off " like a bird," in the language of one of the witnesses; she being a weak diminutive woman, and he a giant of six feet six. In forcing her down stairs, Wise says she was very much bruised, both on her arms and legs. One of her fingers, too, was hurt against the railings, and bled profusely. So far, indeed, the history does not prepossess us in favour of the Eton Union: we see no exemplification of that perfect system which, while it astounded the impostor, was to afford more thorough relief to genuine indigence. The separation of a mother, too, from so young and ailing a child, forms a strange contrast with the laudations of the new discipline sent forth from

time to time ; and makes us doubt whether even the most grave-faced puffers can pretend to be in earnest. Yet, had matters gone no farther than this, it would have been too painfully familiar to rouse attention ; one does not mind squibs, said Colman, when one has been sitting all night on a barrel of gunpowder ; and we should scarcely have selected the case for comment, had it been merely on a level with New Poor Law harshness.

Elizabeth Wise was now imprisoned in the Black-hole, or Refractory Ward, for twenty-four hours, on bread-and-water diet. Her allowance of the former was five ounces for dinner, according to her statement, or eight, according to the master's. This refractory ward has no fire-place ; there is a little window in it without glass, and the shutter does not shut close, so that the cold air could not be excluded. There were neither blankets, sheets, nor bedding of any sort in the room, and the night was that of the 27th ult. during the hard frost. No wonder that when the prisoner came out the next morning, to use the words of her evidence, " I was so cold, that I had no feeling in any part of my body. I had no animation." But the most singular point of this strange history is yet to come. Wise was refused a chamber-pot. Not, as you might suppose, reader, just to worry and degrade the prisoner, by reducing her to the level of a beast, but for a reason equally humiliating to the order of the Eton Union. It was apprehended, it seems, that she would mutilate herself with the utensil. Was the woman a lunatic, then ? Not a bit of it. Mutilation or suicide was expected simply as the natural result of workhouse discipline. Even when the new system is in its best humour, it is not very amiable; but, " when goodness wears the sterner face of love," and appears in the guise

of a refractory ward without fire or bedding, she thinks it well to be cautious, for even crockery is a deadly weapon in the hands of despair.   A woman with a young child every moment requiring her care, and exciting her sympathies, is most unlikely to commit violence on herself; but the difficulty may be got over in a Union Workhouse.   Separate mother and child—wear her down by every variety of moral and physical hardship—and ask the new friends of the poor for the result. Half an hour after Wise had been released from her den, she was ordered by the master to clean it ; and being still too frozen to do so, she was again locked up in it for seven hours.

When the case came before the Board of Guardians, they resolved that the pauper had been guilty of improper conduct ; but that Mr. Howe " had acted somewhat hastily in the matter, and that he should have provided the refractory room with bedding and proper convenience during the time that Wise was confined there."

The Hon. and Rev. Godolphin Osborne, an *ex officio* Guardian, was not content with this lukewarm resolution, (to his honour be it spoken), but brought the case before the Magistrates sitting in petty session at Eton, on Saturday, January 2d.

The case against the master of the Workhouse was stated by Mr. J. J. Williams, a barrister, who quoted the resolution we have given above, from the Guardian's Minute-Book. Curiously enough, as if it had been destined that this case should afford the utmost possible insight into Poor Law ways, Mr. Barratt, the clerk to the Board, showed great unwillingness to be sworn, and said, " I shall object to prove any copy of any resolution furnished to a gentleman who is a Guardian."

Howe's defence was very lame, and his witnesses did him no service.   It is

by no means clear that Wise spoke to him in the most courtly tone, but it is obvious that her punishment was out of all proportion to her offence; and it is equally certain that the tone in which she addressed him was called forth by the absurd and wicked measure of separating her from the child—though the criminality of this belongs perhaps rather to the Commissioners than to the master of the workhouse.

One of Howe's witnesses, Mr. Hammond, the surgeon of the Union, broke down altogether. "She was a turbulent patient," he said. "She and her husband seemed to know better than I did, and found fault with the pills and salts I ordered. I speak only of her as a patient, and not of disorderly conduct in the house. When I ordered pills they wanted salts, and when I ordered salts they wanted pills." Alas! so do countesses, and eke wives of citizens and notable pin-makers!

The end of the proceedings was, that the defendant was fined ten pounds for an assault, with fifteen shillings and sixpence costs, or in default of payment to be committed to the House of Correction for three months.

Few decent persons will be found to lament the punishment inflicted on Joseph Howe, but many will ask whether before the tribunal of Astrea the instigators of such deeds are not far more culpable than the petty understrappers, whose coarse interpretation of their taskmasters' behests is sometimes censured, as if it were possible to reconcile the laws of humanity and the laws of Somerset-House. But masters of workhouses must recollect that their unpolished violence cannot always be commended by aristocratic Malthusians. Privileges, too, vary with places;

That in the captain's but a choleric word,
Which in the soldier is flat blasphemy.

Mr. Williams was right when he said,

"He was convinced that the bringing forward of this case would be productive of immense good throughout the country."*

Since the above investigation the master of the workhouse has been dismissed by the Poor Law Commissioners;

Sed quis custodiet ipsos
Custodes?

Who will dismiss *them?*

ST. MARYLEBONE INFIRMARY.

Section of one of the Hamstring Tendons.

R. C., aged 21, had suffered from chronic inflammation around the knee-joint for eight or nine years, ending in suppuration, abscess, and considerable thickening. During that period the semiflexed position had been found most comfortable to the patient, and she had been permitted to keep the leg in that position until it became permanently fixed at nearly a right angle with the thigh. By absolute rest and counter-irritation the inflammatory action was ultimately subdued, and all sinuses healed, and the thickening greatly lessened. When perfect quiet was restored, Mr. Phillips ascertained that motion was retained at the joint; flexion could be carried until the heel nearly came in contact with the buttock. A modification of Amesbury's extending apparatus was placed in the ham, for the purpose of endeavouring to make extension. For three months these attempts were persevered in, but without success. At her own request she was discharged, and in a few months she was married. She again applied to Mr. Phillips to ascertain whether any thing could be done for her; he gave her some hopes, and she was again admitted under his care. After a careful examination he determined to make the section of the semi-tendinosus tendon, which alone seemed to offer a decided resistance to extension. The section was made, and on the third day the same extending apparatus which had been formerly used was applied. Extension was made very gradually; sometimes a single revolution, sometimes two, sometimes more, were made, daily, and by the end of six weeks the leg was nearly as straight as the other: motion was perfect, but the muscles had not so adapted themselves to their new situation as to enable her to stand firmly on that leg, but she could rest the whole weight

* Times, January 4, 1841.

of the body on it without inconvenience. She was now discharged, at her own request, and has since presented herself; the muscles are rapidly recovering the tone necessary to enable her to use it as well as the other.

Chronic Eczema.

In the female wards Mr. Phillips has lately had under his care three patients suffering from severe attacks of chronic eczema: the patients were of the age respectively of 38, 52, and 61; the former two presented, at one time, on the hand and arm, the impetiginoid form of the disease. There being no counter-indication, in as far as the digestive organs were concerned, they were all treated by tepid bathing every other night, and a mixture, containing mag. sulph., ʒj.; acidi sulph. dilut. ₥x., three times a day. This plan was persevered in for a month, with a certain though small amount of benefit. At this time five minims of tinct. lyttæ was added to each dose of the medicine in each case. The relief afforded to the younger patient was rapid and decided, so much so, that in six weeks she was discharged cured. In the other cases no very decided amount of good was experienced, although the tinct. lyttæ was carried to 15 minims three times daily. Under these circumstances they took the liq. arsenicalis in doses of five minims three times daily. Its effects, after ten days, were very striking; and by the end of the fifth week, all that remained of the disease was a certain extent of œdema of the lower limbs; which had more severely suffered from the disease, and which was soon dissipated by bandaging.

Incomplete Dislocation of the Humerus.

A lad aged sixteen was thrown from a horse, and dislocated the left humerus; it was reduced in a few hours, at an hospital where he remained five weeks, and was then discharged, A few weeks ago he presented himself at the Infirmary, and was admitted a patient. Upon examination, it was found that the shoulder presented a greater flattening than is usually seen even when the head of the bone is unreduced; that, between the extremity of the acromion, which was sharp, defined, and superficial, and the head of the humerus, there was a distance of nearly two fingers' breadth. The deltoid was paralysed, the other muscles were natural. He could swing the arm backwards and forwards with some force, but he had not power to raise the arm. Mr. Phillips conceived this to be a clear case of incomplete luxation; the head of the bone rested on the inferior margin of the glenoid cavity. The question which excited curiosity was, how it had been produced. Mr. Phillips's opinion was that reduction had been completed, but that sufficient pains had not been taken to

maintain the head of the bone in its proper position; that before the capsule was consolidated, the deltoid being powerless, the weight of the arm was sufficient to bring the head of the bone to the position it occupies at present. He strongly urged the necessity of maintaining the head of the bone in its proper cavity until the ruptured capsule is healed, and that this is not effected at the shoulder joint in less than thirty days. He attributes the occasionally frequent recurrence of dislocation at some joints either to this circumstance, or to malformation.

In this case the course adopted was to keep the head of the bone well supported against the acromion, and to endeavour to restore the deltoid. To accomplish the latter indication, electricity was first employed, in the form of sparks; that failing, a more continuous current of electro-galvanism was directed in the course of the circumflex nerve. It did not succeed, and the red hot iron was used in such a way as to produce very energetic local excitement. A pointed iron was heated to whiteness, and the whole of the integument covering the deltoid in turn came under its action. It was rapidly passed from point to point, being allowed to remain in contact only long enough to produce a red spot, without disorganising the integument. It is a mode which Mr. Phillips occasionally employs with great advantage. It was used a second time in this case without any manifest advantage: recourse was then had to strychnia. The integument was raised by a blister, and removed, and the surface was sprinkled with a mixture of ¾ of a grain of strychnia, with a grain of powdered sugar. This powder was used three times, but the paralysis of the deltoid remained. He became tired of the treatment, and after six weeks he left the Infirmary in much the same condition as when he entered it.

ON THE USE OF
BOILING WATER in the TREATMENT OF CALLOUS FISTULÆ.

By Dr. Ruppius, of Frieburg.

The author was induced to adopt this method of treatment from what he had seen it effect in the hands of Rust of Vienna, and from the observation that the granulations which grow from scalded parts of the skin are peculiarly florid, and prone to unite firmly; a consideration which, we may add, long ago induced French surgeons to adopt the actual cautery for the same means, and is the foundation of the very skilful operations of M. Lallemand for vaginal fistulæ. Two cases are related, one of recto-vaginal fistula

from abscess after a severe labour ; the other, of an incomplete fistula in ano, extending four inches up the side of the rectum. The treatment consists in introducing the pipe of a syringe filled with boiling water down to the further end of the fistula, (which if necessary, must be closed there with a finger of the other hand,) and slowly injecting a part of the contents.   At the first operation only so much of the water should be forced in as is sufficient to stimulate the end of the fistula, so that it may commence healing at its deepest part, and, after the repeated injections, may make gradual progress in healing towards the surface.   In both the cases that are related this procedure was strikingly successful.—*Fricke und Oppenheim's Zeitschrift.   Juli*, 1840 ;_ and *Brit. and For. Med. Rev.*

THE PINE-APPLE.

When the British troops invaded Burma, they found the woods around Rangoon abounding in wild pine-apples, and a variety from the back of the Black Pagoda was in great request for its excellence ; in the Malay Archipelago it acquires an enormous size, and sports into a variety called *the double pine-apple*, each pip of its fruit growing into a branch bearing a new pine-apple.   It was, however, first introduced into Europe from South America, and as it is recorded, by M. Le Cour, of Leyden, about the middle of the seventeenth century : from Holland it was brought to this country in 1690, by the Earl of Portland, according to the Sloanean MSS. in the British Museum.   There is a painting, formerly in the collection of Horace Walpole, in which Charles II. is represented as being presented with the *first* pine-apple, by Rose, his gardener ; but there are some doubts whether that fruit was grown in England, or obtained from Holland.   It may, however, be fairly concluded that pine-apples were exceedingly rare in this country, even at the tables of the nobility, in the beginning of the last century ; for in 1716, Lady Mary Wortley Montagu remarks that pine-apples were on the electoral table at Hanover when she was there that year, on her journey to Constantinople ; and she states that she had never previously seen that species of fruit. *(Letters of Lady M. W. Montagu.)*   Since that period the cultivation of the pine-apple has been prosecuted with perseverance in Britain, but frequently the results have been very disproportionate to the expense incurred. Within the last twenty years, however, success has been more general ; and in many instances a surprising degree of perfection has been attained, much greater indeed in England than in any other country having to contend with an extra-tropical climate ; for instances are on record of pine-apples weighing 13lbs. and 14lbs. avoirdupois ; and from 7lbs. to 8lbs. is by no means an uncommon weight for a single fruit.— *Miss Burnett's Useful Plants.*   Jan. 1841.

[An entertaining compilation, illustrated with handsome plates.]

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XVIII.

*Purulent Ophthalmia continued. Gonor-
rhœal Ophthalmia. Purulent Ophthalmia
of infants. Strumous Ophthalmia.*

WHEN we last met, I spoke of catarrhal
opthalmia, *i. e.* a mild and common form
of inflammation of the conjunctiva, resulting
from atmospheric influences. I described its
characteristic symptoms, and explained the
treatment that has been found most success-
ful for its cure; consisting chiefly in local
stimulating or astringent applications.

I began also to speak of the severer forms
of inflammation affecting the same part, and in-
cluded under the head of *purulent ophthalmia.*
The symptoms and course and consequences
of the two varieties of this complaint, as it
occurs in adults, are so essentially the same,
that one description of its phænomena
is enough. There are certain differences,
however, that require to be noticed, in re-
spect to its exciting causes. I laid before
you the reasons which satisfy me, that what
is called the Egyptian ophthalmia is a con-
tagious disease; and which make it probable
that the complaint is capable of being pro-
pagated from person to person, through the
medium of the air, without the necessity for
any substantial application of the morbid
secretion from a diseased to a sound eye.
These reasons, briefly stated, are as follows:
that the disease was unknown in Europe till
after the war in Egypt; that, arising among
our own and the French troops in that coun-
try, it was conveyed by them to various
places, and extended itself to soldiers who

had intercourse with those troops; that when
once introduced it spreads rapidly wherever
men are crowded together within a small
compass, pay insufficient attention to clean-
liness, and use the same towels and utensils;
that it has been propagated again and again
by the direct application of the morbid secre-
tion; and that its progress is checked by
measures that provide against such accidental
application, and by separating the diseased
from the healthy.

On the other hand, it has been contended
that the disease is nothing more than an ex-
treme degree of catarrhal ophthalmia; that
the peculiar conditions of the atmosphere in
Egypt and other hot countries, where it is
prevalent, are enough to account for it; and
that when troops are disbanded, they do not
give the disease to their friends and families
all over the country, but that, on the contrary,
the dispersion of the sick in this way is the
most effectual mode of stopping the disease.

To these arguments the proper answer is,
that the same difficulties meet us in respect
to some other diseases which are acknow-
ledged by all persons to be strictly con-
tagious.

My own creed upon this matter is, that
the disease may, and often does arise, inde-
pendently of contagion, from the agency of
ordinary causes of inflammation; and that
having so originated, it acquires contagious
properties, which develop themselves only
under circumstances that favour the propa-
gation of most of the contagious complaints.

Gonorrhœal ophthalmia.—I shall next ad-
vert to purulent ophthalmia as it is observed
to occur, in the adult, in connexion with
gonorrhœa. If we look to the mere phæno-
mena presented by the inflamed eye, we find
nothing to distinguish the gonorrhœal from
the Egyptian ophthalmia. Taking the average
of a large number of cases, the gonorrhœal
is the severer form of the two, and runs the
more rapid course. It is said, also, that the
inflammation usually commences on the lids

in the Egyptian variety, while it attacks the whole conjunctiva at once in the gonorrhœal. But comparing individual instances, these mere differences, and slight differences too, in degree and situation, will not help our diagnosis.

But other circumstances may guide us. If a patient presents himself with severe purulent ophthalmia, who has not been exposed to any of the known atmospheric causes of that disease, and at a time when purulent ophthalmia is not prevailing as an epidemic, and if this patient have a clap, we may conclude that we have to deal with a case of *gonorrhœal* ophthalmia: and this conclusion will be further strengthened if the disease affects one eye only. For what, through the lack of any better nomenclature, I am constrained to call *Egyptian* ophthalmia, seldom restricts itself to a single eye. Dr. Vetch says, "there is but one case in a thousand in which one eye only becomes affected." Walther observes that contagious ophthalmia almost always appears in both eyes together, but not in the same degree; and Eble (another German author) states that the contagious ophthalmia has not confined itself to one eye in any instance. These round assertions require, however, some qualification; the nurses, whose cases I quoted in the last lecture, from Sir Patrick Macgregor's paper, suffered each in one eye only. On the other hand, gonorrhœal ophthalmia mostly, but by no means always, *is* limited to one eye. In Mr. Lawrence's instructive book *On the Venereal Diseases of the Eye*, he mentions fourteen cases of gonorrhœal ophthalmia. In nine of these, one eye only was inflamed.

It is always a matter of some interest to make out whether the disease has or has not any connection with gonorrhœa: even though we may gain nothing in respect to the treatment, by the distinction.

Purulent ophthalmia has been said to be connected with gonorrhœa in three several ways: 1st, by direct contact of the gonorrhœal discharge from the urethra with the conjunctiva; 2d, by metastasis of the inflammation from the urethra to the eye, without any such contact of matter; and 3d, independently of either of these ways: *i. e.* purulent ophthalmia has been supposed to occur in connection with clap, just as ulceration of the throat is apt to occur in venereal diseases.

Now the two last of these three modes of origin are more or less questionable; the first is certain.

Very odd speculative opinions are apt to possess themselves of the minds of medical as well as of other philosophers. Some who believe that the disease is communicable by direct contact of gonorrhœal matter to the eye, yet hold that it must come from the

urethra of another person; that the Hudibrastic aphorism is true, " no man of himself doth catch." Dr. Vetch seems to have fallen into this opinion through the very common mistake of drawing positive conclusions from negative experiments. He had known a hospital assistant who, " with more faith than prudence," conveyed the matter of gonorrhœa to his eyes, with impunity. He states also the converse experiment : a soldier in a very advanced stage of Egyptian ophthalmia, attempted to divert the disease from his eyes by applying some of the matter they were discharging to the orifice of his urethra : no effect followed this trial. But in another case the matter taken from the eye of one man, labouring under purulent ophthalmia, was applied to the urethra of another man: and inflammation commenced there in thirty-six hours, and he had a very severe attack of gonorrhœa. Some persons, judging from such cases as this, and from the similarity of the discharge in the two diseases, " have gone the length of concluding (according to Dr. Mackenzie) that gonorrhœa has been *originally* an inoculation of the urethra by the matter derived from the eye in the Egyptian ophthalmia ; whilst others are of opinion that this last disease is nothing else than the effect of an inoculation of the conjunctiva with matter from the urethra in gonorrhœa."

To satisfy you that a person may "catch" the complaint from himself and from others, it is right that I should bring before you one or two well-marked cases.

It is a common persuasion, among the lower classes, that to bathe the eyes in human urine is good for the sight. This piece of practice has cost several persons their vision. A gentleman belonging to the class mentioned to me the other day two cases of purulent ophthalmia so produced, which he had seen among Mr. Guthrie's patients at the Ophthalmic Hospital. In one, a young woman, not so healthy as she ought to have been, used her own water; in the other, an older woman, for what reason it did not appear, preferred her husband's to her own. Mr. Lawrence alludes to several similar cases. He details an instance also, in which partial sloughing of one cornea occurred; the disease having been caused by the patient's wiping his eyes with a towel soiled with the gonorrhœal discharge from his own urethra. But one of the neatest and most conclusive examples of the production of the disease in this way has been furnished by Dr. Mackenzie. A patient was brought to him from the country with his left eye violently inflamed and chemosed, and discharging a large quantity of purulent fluid; the lower lid everted, and the cornea totally opaque. Thirteen days before, this man, who had then a profuse gonorrhœa, but whose eyes were perfectly

well, while stooping down and shaking away the discharge from his penis, had a drop of it flung fairly into his left eye. Violent inflammation immediately set in ; was confined to the eye that was thus inoculated, and produced the results just mentioned : the gonorrhœa going on just as before.

Numerous authentic cases have been recorded of gonorrhœal ophthalmia produced by the application to the eye of gonorrhœal matter from another individual. Mr. Wardrop met with the following example. An old lady went into the dressing room of her son, who had gonorrhœa, and washed her face with a towel which he had recently been making use of. Purulent ophthalmia quickly supervened, and destroyed the eye in a few days. Delpech mentions the instance of a young and healthy woman, who bathed her eyes with goulard water, by means of a sponge which had been used by a young man who had a clap : violent inflammation soon arose, and the sight of one eye was lost. Several cases of purulent ophthalmia have been obobserved in laundresses, who had been employed in washing linen foul with the discharge of gonorrhœa.

Mr. Lawrence seems to be of opinion that purulent ophthalmia is not a very frequent consequence of the application of the urethral discharge to the eye of the same person. "When we consider (he says) how this matter is diffused over the linen of patients, both male and female, how often the fingers must be smeared with it, and how inattentive to cleanliness the lower classes are, we cannot help concluding that the gonorrhœal discharge must be *often* applied to the eyes of the same individual ; yet gonorrhœal ophthalmia is comparatively rare." Dr. Mackenzie, on the other hand, thinks that the application of the matter to the eye is seldom made. "The instinctive closure of the eyelids (he observes) when the finger approaches the eye, making it actually difficult for a person to touch his own conjunctiva, unless with one finger he draws down the lower lid, and intentionally applies another finger to the eye, will serve in some measure to explain the rarity of this kind of inoculation."

It has been noticed that women are much less frequently the subjects of gonorrhœal ophthalmia than men.

Does gonorrhœal ophthalmia ever occur by metastasis ? This question does not admit of a positive answer. Practical men are divided in opinion on the subject. In the majority of cases of gonorrhœal ophthalmia, we are unable to trace any application of the urethral discharge to the eye, either from the same or another individual. Yet it does not follow that no such application took place. The German and Italian writers believe in metastasis. "In all the instances (says Beer) which I have seen, this ophthalmia has

occurred in young, plethoric, robust, and truly athletic men ; and it has always taken place in a very short time, generally in a few hours, after the suppression of gonorrhœal discharge from the urethra." Mr. Lawrence never knew the urethral discharge stop upon the coming on of the ophthalmia ; it has generally diminished, but in some instances has continued as copious as before. He seems to regard the occurrence of the ophthalmia as analogous to those successive attacks of distant parts that are common in gout and rheumatism. Dr. Mackenzie evidently doubts the occurrence of metastasis at all in this disease, and is inclined to refer all the cases in which it has been alleged, to inoculation, or to an accidental concurrence of purulent ophthalmia and gonorrhœa in the same person.

The occurrence of purulent ophthalmia as a part of the gonorrhœal disease, independently of inoculation and of metastasis, seems to me extremely problematical. The eye is well known to suffer, as well as other organs, in the secondary forms of syphilitic diseases, but the conjunctiva is not the part that is attacked. I have never seen nor heard of any satisfactory example of purulent ophthalmia alternating with gonorrhœa, where the possibility of inoculation was excluded. And, upon the whole, my own opinion (you will take it for whatever it may seem worth) is against the existence of this alleged form of purulent ophthalmia. Whether it exists or not is of very little consequence in regard to the main question ; namely, what is the proper mode of *treating* the *purulent ophthalmia of adults?*

Now the two main points to consider, so far as respects the treatment, are—first, blood-letting ; and secondly, the application of strong astringents to the inflamed membrane.

Blood-letting has been carried to a very great extent in this disease, or in *these diseases*, if you choose to consider the Egyptian purulent ophthalmia and the gonorrhœal purulent ophthalmia as two different inflammations. Its effects have not been very decisive or satisfactory ; indeed, we could hardly expect that they would. In the first place the inflammation is so rapidly destructive, that in many of the worst cases, irreparable mischief is done before the patient applies for medical assistance. In forty-eight hours, or a little more, Mr. Lawrence tells us, the affection may have proceeded to such an extent as to be beyond our control. Of course this reason for the want of success is equally applicable to every remedy that has been, or could be, proposed. But independently of this, even when the disease is seen and submitted to treatment in its very beginning, we should have the less confidence in the power of general blood-letting to control it, for these two reasons : that the

part affected is a *mucous membrane;* and that there is *so little constitutional sympathy* with the local inflammation. Free vene- section *tells* most upon inflammation, when it is attended with fever and a hard pulse, *i. e.* with increased action of the heart ; which the abstraction of blood tends to abate. It is also a matter of experience, that general bleeding has more influence over the inflam- mation of serous and fibrous membranes than over that of the mucous tissues. Accordingly, though bleeding has been even lavishly em- ployed in purulent ophthalmia, it has too often disappointed the practitioner. There is one lesson, however, to be learned from co- pious blood-letting in this disease, even when it fails of its object. It clearly demonstrates what may be hoped for, by having recourse to that measure in internal inflammations. " You see a patient (says Mr. Lawrence, who has both had and used freely, very nu- merous opportunities of putting this remedy to the test), " you see a person with his eye bright red, and very painful ; he cannot face the light, and tears gush out, with great suf- fering, if he attempts to do so. You bleed to fainting, and immediately the capillaries are emptied, so that the organ resumes its natural paleness ; the pain is gone, the eye is opened without difficulty, and the full influx of light can be borne without an uneasy sensation. For the time the part has passed from violent inflammation to a nearly natural state. With the restoration of the circulation the inflam- mation will recur after this temporary sus- pension ; but its violence is diminished, and it often gradually abates." Mr. Lawrence is here speaking of acute inflammation af- fecting the textures of the eye generally, and not of purulent ophthalmia in particular ; but I am desirous that, in passing, you should take notice of this direct effect of bleeding to syncope, upon the capillaries of the eye, because it teaches us what the same expe- dient may do for the capillaries of any other *internal* part, which we cannot *see,* when that part is attacked with inflammation. In pu- rulent ophthalmia, however, if you trusted to bleeding *alone,* you would often reduce your patient to a very dangerous state of weakness, and after all fail of yourmark. Dr.Vetchbears strong testimony to the usefulness of blood- letting when freely employed in the early stages of Egyptian ophthalmia; and certainly it ought never to be neglected. In the very onset of the disease, it will aid the local ex- pedients which I shall presently mention ; and if the patient be not seen till the globe of the eye is invisible for the swelling, the propriety of general bleeding will be still farther indicated by the occurrence of throb- bing and circumorbital pain, returning in nocturnal paroxysms ; for this symptom de- notes that the inflammation has descended deeper than the conjunctiva. The bleeding

should be performed in the way I formerly spoke of as being required in serious in- flammation : the patient should be bled from the arm, in the upright position, till fainting is about to ensue, or the pulse begins to falter. You will do more to- wards obtaining safety for your patient's vision in this way, and at less expense of his strength, than by bleeding him many times to a smaller amount. The bleeding *ad deli- quium may* require to be once or twice re- peated, and when the patient begins to rally from his faintness, from twelve to twenty- four leeches may often be applied with ad- vantage ; *round* the eye, and not *upon* the tumid lids, where their bites are apt to add to the existing irritation, and to fester. You had better bleed your patient from the arm, and not from the jugular vein, or the tem- poral artery, for reasons which, as I have fully stated them already, I need not now repeat.

But of late years, more reliance has been placed by many practitioners, upon local stimulants, for checking this horrible malady, than upon general or topical bleeding. Dr. Vetch strongly recommended the insertion of *undiluted liquor plumbi acetatis ;* and Mr. Briggs, in his translation of a work of Scarpa on the eye, advised the introduction of a very minute quantity of the oil of turpentine be- tween the eyelids. But Mr. Guthrie has the merit of having applied, in its full extent, this principle of curing conjunctival inflam- mation, even in its severest forms, by stimu- lant and astringent substances. I told you, when speaking of catarrhal ophthalmia, that Mr. Melin and Dr. Mackenzie treat that complaint by a wash, made by dissolving four grains of lunar caustic in an ounce of distilled water. I might have added other authorities in favour of the same kind of practice. Now Mr. Guthrie treats purulent ophthalmia on the same principle, but with a much larger dose of the nitrate of silver. The greater intensity of the disorder is met by increasing the strength of the remedy. He considers it to be a local disease of a peculiar character ; and, acting upon the aphorism of John Hunter (an aphorism, however, which requires some qualification) that two diseases or actions cannot go on in a part at the same time, he proposes to set up in the inflamed conjunctiva a new action, which shall supersede the original disease, and create another that is more ma- nageable. In this point of view Mr. Guthrie's *ratio medendi* agrees with that of Hahnemann, about which there has been so absurd a noise made of late. I have never had the advantage of seeing Mr. Guthrie's plan tried, but from all that I have heard of it, I believe it to be a valuable dis- covery. *A priori,* we should expect that the caustic application would add to the

existing mischief, and destroy all chance of saving the inflamed eye. But it is not so. Even Mr. Lawrence who was, I have reason to think, formerly very sceptical on this point, appears to be so no longer. In his treatise on the Venereal Diseases of the Eye, he uses this cautious language. "Destructive or injurious consequences have so frequently resulted under the usual management of this disease (he is speaking of gonorrhœal ophthalmia), that I should certainly employ the local astringent, if I met with a case favourable for the trial; i. e. where the affection had not extended beyond the conjunctiva. Blood-letting might be resorted to at the same time; in most cases, however, our aid is not sought until the cornea has become affected, and it is therefore too late for the astringent plan." But he subsequently added a note, to the effect that after the statement I have just quoted was written, he had employed the caustic solution in two cases of conjunctival inflammation with the best result.

Mr. Guthrie's plan, therefore, you ought to be acquainted with. After many trials, he has arrived at the conclusion that the best appliance, in this formidable complaint, is an ointment, made by mixing ten grains of the nitrate of silver, reduced to an impalpable powder, with a drachm of hog's lard. This is what he calls his *ten grain ointment*.

Before applying it to the diseased eye, the discharge must be well cleansed away by a solution of alum; then the ointment having been inserted beneath the lids, they are to be moved freely up and down, so that the whole conjunctiva gets its due share of the remedy; and that it has done so is shewn by its turning white. If the surface does not turn white, the ointment has not been sufficiently applied, and will not answer the purpose. If we wish to be quite sure, he says, we turn out the eyelids, and rub the ointment on them. This application gives pain, which lasts for half an hour, or an hour, or more. "Warm narcotic fomentations may be employed to relieve uneasiness, and opium given to allay pain, and to obtain sleep; while a solution of alum, in the proportion of a drachm to a pint, should be injected from time to time into the eye, to clear it; but should the patient sleep, he must not be disturbed. A mild ointment may be applied to the edges of the lids at night, to prevent their sticking together. The next morning the discharge is again to be removed, and the ointment to be re-applied; for on no account should the action we are desirous of exciting be allowed to cease." Of course Mr. Guthrie means it is not to be suffered to cease prematurely. This with free, but not excessive venesection, is the substance of his peculiar mode of treating purulent ophthalmia; and it appears to have been eminently

prosperous in his hands. I have been informed, by one of yourselves, that purulent ophthalmia has been successfully treated, on a large scale, in Manchester, by applying the nitrate of silver, in substance, to the surface of the conjunctiva; that this gives less pain than the ten grain ointment, though perhaps it may require to be oftener repeated.

I say I have never seen this method of Mr. Guthrie's carried into effect; but after what I have myself witnessed of the intractable and destructive nature of the disease under the treatment ordinarily adopted before his ointment was devised, I will say also that were I so unfortunate as to be attacked with severe purulent ophthalmia, I should desire to have the caustic applied as soon as possible, and to be freely bled at the same time.

There are some minor points in the treatment that require a cursory notice only.

Some persons, and Mr. Guthrie among the rest, recommend the exhibition of *mercury*, so as to affect the gums. Now I believe that mercury is quite useless in this complaint; and if useless, mischievous. The disease is too rapid to be overtaken by the mercury, and if you could obtain the specific influence of that mineral in time, i. e. before any of the destructive effects of the inflammation were accomplished, you would do no good thereby. This is not the kind of inflammation over which mercury exercises any useful control. Mr. Lawrence tells us that he has seen both the ordinary purulent, and gonorrhœal ophthalmia proceeding apparently unchecked, under the full mercurial action.

Practical men are not agreed about the propriety of scarifying the conjunctiva when it is swelled and elevated by chemosis. Mr. Lawrence objects to it, as likely to increase the local irritation; a disadvantage not compensated by the quantity of blood discharged from the divided vessels. Dr. Mackenzie recommends it, stating that the incisions will bleed copiously, and greatly allay the symptoms. Who shall decide in this puzzling discrepancy of opinion? Mr. Guthrie's caustic ointment would, I presume, supersede any other meddling with the inflamed surface. But when the question happens to lie between scarification and no scarification, I should give my vote *for* scarifying; not because I think any useful depletion of the *blood-vessels* could be brought abont by that measure, but because, if properly performed, it would evacuate the serous effusion from the cellular tissue between the conjunctiva and the sclerotic, which effusion constitutes the chemosis, and hastens, if it does not cause, the sloughing of the cornea, by the mechanical pressure that it exerts around it.

Are *blisters* of any use? Hear Dr. Mackenzie. "Counter-irritants are *highly serviceable* in this disease, and ought *always*

to be employed. There is generally a *marked* change in the quantity and appearance of the discharge from the eye, as soon as a counter-discharge is established by blisters on the temples, nape of the neck, or behind the ears." But listen to Mr. Lawrence. " Experience does not warrant us in ascribing much efficacy to *blisters*." Now the truth is, I believe, that during the active stage of the disease, blisters are not of any use ; but that in the more advanced and chronic periods, they are. Indeed, Mr. Lawrence admits that they may be regarded as auxiliary measures, and resorted to after antiphlogistic means.

I agree with the same gentleman in thinking that no reliance is to be placed, in gonorrhœal ophthalmia, upon any attempts to reproduce the urethral discharge ; indeed, in most cases it is not suspended.

Although I have not mentioned purgatives, you will conclude that they form a very proper and necessary part of the treatment during the activity of the complaint.

Purulent ophthalmia of infants.—After what has already been said of purulent ophthalmia in the adult, and of gonorrhœal ophthalmia, it will not be necessary for me to take up very much of your time in speaking of purulent ophthalmia as it occurs in newly-born children.

This is a *very common* disease : it is *very serious* when neglected : it is *very easily managed* when it is seen and treated in time. These are all reasons why you should make yourselves familiar with the complaint, and with the mode of curing it. You may perhaps never have occasion to treat a case of purulent ophthalmia in the adult : you are sure to be consulted about the purulent eye of infants, the *ophthalmia neonatorum.*

The importance of the affection is apt to be overlooked by mothers and nurses ; they say the baby has a cold in the eye, which will go off ; and they wash it perhaps with a little of the mother's milk, or some such insignificant fluid. Meanwhile the eyelids swell, the mischief that is going on beneath them is concealed from sight, and when at last a medical man is consulted, he too often finds that one or both of the eyes has perished : the cornea has sloughed or become opaque, or protrudes, and constitutes what is called staphyloma ; prolapse of the iris has taken place ; or the coats of the organ have shrunk up.

The inflammation usually comes on about three days after the child is born, although it may commence later. It is confined, at first, to that part of the membrane which lines the lids. Their edges are observed to stick together when the infant wakes : there is more intolerance of light, apparently, than is suffered in the analogous disease of adults. The little patients cannot indeed tell us their

sensations by words, but they express them significantly enough by keeping their eyes shut, by contracting their small brows, and by turning their heads away from the light. At length the inflammation extends to the conjunctiva that covers the eyeball, the eyelids swell, sometimes enormously : and an astonishingly copious discharge of pus takes place. By the adhesion of the edges of the lids the puriform matter is sometimes pent up, and distends the lids ; and when they are separated it escapes in a profuse hot gush. The eyelids are sometimes everted during the cries and struggling of the little sufferer, and their mucous surface is then seen to be villous and shaggy, and of as bright a scarlet red as you ever saw the injected mucous membrane of a fœtal stomach. At last those fatal consequences to the eye take place which I have already mentioned. The disease, however, may continue for eight or ten days without any affection of the transparent parts of the eye ; and so long as these remain uninjured, the eye is safe, provided that proper treatment be adopted.

This disease is probably much the most fertile source of blindness with which we are acquainted. It is believed to originate most commonly, if not always, in contagion. We might, perhaps, expect this, from the analogy of the severe inflammation of the same parts in adults. And it is a matter of fact, that in a very large number of cases the mother has been affected, at the time of her confinement, with some kind of vaginal discharge—leucorrhœa, or gonorrhœa ; and the eyes of the children are exposed to these morbid secretions, as they are brought into the world. The circumstance of the disease commencing so regularly on the third day, is greatly in favour of the supposition that it results from inoculation of the eyes by the unhealthy fluids of the mother. The discharge from the infant's eyes has been ascertained to be highly contagious. Dr. Mackenzie mentions a lamentable illustration of this fact, which fell under his observation at the Eye Infirmary, in Glasgow. An infant and its grandfather became his patients the reat the same time ; the latter having been inoculated from the former. Both were so severely affected that the infant had one eye left in a state of total, and the other of partial staphyloma : while in each eye of the old man, the greater part of the cornea remained opaque, and adherent to the iris.

However, the disease certainly occurs in the infants of mothers who seem to be healthy, and who do say that they have any unnatural discharge. It may probably be brought on, sometimes, by bad management on the part of the nurse : by exposure soon after birth to draughts of cold air, or to the injurious influence of a hot and bright fire ; or by the introduction of soap into the eye in the pri-

mary ablutions, or of gin, wherewith the lower classes, in some absurd persuasion of its strengthening virtues, are wont to bathe the unlucky infant's head. The disorder is observed to be most common in damp and cold weather; in low crowded places; and among the children of the poor.

One striking difference between the disease as it exists in adults and in newly born children I have already adverted to; viz. its rapid and often incontrollable progress in the former; and the facility with which it yields to suitable and timely treatment in the latter. If a child is brought to you with purulent ophthalmia, and you are able to separate the lids sufficiently to obtain a glimpse of the cornea, and perceive that it is still brilliant and uninjured, you may confidently tell the anxious mother that, with due care on her part, her child's eye is safe. If the cornea has lost its transparency, it is still within reach of recovery, but the chances are against it: if you cannot get a sight of the cornea at all, you will do wisely to give a doubtful prognosis, or even an *unfavourable* prognosis; for such is the ignorance of the vulgar (and I include both rich and poor under this phrase) that if they are not forewarned of the danger, they are very apt to attribute the blindness that ensues, to your *stuff*, as they call it.

In the severer forms and stages of the complaint, if the lids be very much swelled, and red externally, and especially if you are unable to obtain any satisfactory view of the cornea without using a degree of violence that might be hurtful, it will be right to apply a leech. It should be placed upon the centre of the tumid upper lid; and you should, whenever that is possible, stay by the little patient until the animal drops off, and the bleeding ceases; for sometimes the bleeding is difficult to stop, and must not be trusted to the care of the nurse; and the loss of blood occasioned by the bite of a single leech will often blanch the infant's skin, and make you fear that the depletion, slight as it is in actual amount, has yet been too much. The child's bowels should be emptied by a little castor-oil; and a lotion made by dissolving two grains of the acetate of lead in an ounce of water may be applied to the inflamed organ.

In less severe cases, and I believe in all cases in which you can see the uninjured cornea gleaming through the pus that bathes it, it will be quite sufficient to keep the infant's bowels open with magnesia; to apply a little lard along the edges of the lids, to prevent their sticking together; and to inject carefully into the eye, *beneath* and *between* the lids, a solution of alum; in the ratio of four grains to one ounce of water. Such, Mr. Lawrence tells us, was the treatment in 49 cases out of 50 at the London Ophthalmic Infirmary when he was surgeon to it: no

other means being used than magnesia internally and the solution of alum locally: and out of many hundred instances he scarcely recollected one that suffered in any respect, if the cornea was clear when the infant was first seen. I had, for a considerable period, the advantage of watching Mr. Lawrence's patients under that treatment; and the result of it was so exceedingly and uniformly satisfactory, that I should never think of employing any other. If the eye became at length accustomed to the stimulus of the alum, a solution of the nitrate of silver, (from one to four grains in the ounce of water,) was substituted with advantage. Mr. Guthrie uses, I fancy, his caustic ointment; but I am sure that the simple and less severe plan I have been describing is quite sufficient.

Strumous ophthalmia.—There is just one more disease belonging to the conjunctiva, which I wish to bring before you; and then I shall have done with the morbid affections of this external membrane of the eye. It has received several names: sometimes it is called *pustular* ophthalmia, from the appearance of little pustules upon the surface of the organ. Dr. Mackenzie, who looks upon it as an eruptive disease, affecting the conjunctiva not so much as a *mucous membrane*, but rather as a continuation of the skin, names it *phlyctenular* ophthalmia. It has also acquired the title of *scrofulous* or *strumous ophthalmia*, from its continual occurrence in children of a scrofulous *habit*, and its very frequent association with scrofulous *disease* in other parts. It is a disorder of childhood, and it is so common a form of disorder that, of ten cases of inflammation of the eyes in young persons, nine will be of this kind. I shall call it *strumous* ophthalmia. It is a form of ophthalmia that differs in many striking points from those which we have been considering.

In the first place, it is intimately connected with the scrofulous constitution; the peculiarities of which I formerly explained. Although a disease of children, it is not a disease of infants at the breast. It is most prevalent from the time of weaning to about the age of eight. I mentioned to you, in a previous lecture, the remarkable fact, shewing the strong influence of unsuitable or insufficient nourishment in developing scrofulous disease; that when asked to prescribe for children having bad eyes, you will find, "in nineteen cases out of twenty, that you have to deal with purulent ophthalmia if the child be still at the breast, and with strumous ophthalmia if it has been weaned."

The leading symptoms of this disease are, *slight* redness; great intolerance of light; the formation of little prominences or pustules on the surface of the conjunctiva; and specks which are the result of these. The

complaint sometimes occurs in one eye alone, oftener in both; but then one eye is generally worse than the other. Mere catarrhal ophthalmia is apt to degenerate into this affection in scrofulous children. After seeing two or three cases of strumous ophthalmia, you cannot fail to recognise it whenever you meet with it again.

The redness has this peculiarity, that it is slight and partial. Sometimes it is altogether confined to that part of the membrane which lines the eyelids: generally a few vessels, collected into little bundles, are seen proceeding from some point of the circumference —more commonly from the angles of the eye than from any other part of the circumference—towards the cornea: the vessels are evidently superficial, often prominent. These scattered bundles of vessels (sometimes there is but one) stop when they reach the cornea, or occasionally encroach a little upon it; and where they stop, the small elevations of the membrane may be observed which are called pustules. This is the most common situation of these elevated points, just at the line of junction between the sclerotica and the cornea, or near that line. Sometimes, however, you may see one or two near the centre of the cornea. They are smaller in size when they appear on the cornea, than when they are situated near its edge.

These pimples may be absorbed, and leave behind them a temporary white spot; more frequently they break and form little ulcers. When these ulcers are beyond the cornea they are of less consequence; when they are situated upon it, they become sources of danger in two ways: they may penetrate the cornea, and let out the aqueous humour, and cause prolapsus iridis and various other mischief; or they may leave, after healing, a permanent white opaque speck, (called *leucoma*,) which, according to its size and its exact place, will interfere more or less with the vision.

The intolerance of light is a very prominent symptom of this disease, and sometimes it is really the only symptom that manifests itself. It is curious that this inability to endure a bright light bears no regular or definite proportion to the intensity of the other symptoms. It is not that the eye is painful when protected from the light; but that the access of the ordinary light of the day occasions extreme suffering; the eyelids being spasmodically closed, and the orbicular muscle in such strong, and apparently involuntary action, as effectually to resist all attempts at opening them. Children that are affected with this disease, carry it legibly written in their physiognomy. Although you cannot tell what is the actual condition of the eye without examining it, you *can* tell, as soon as you look at the patient, what is the *nature* of the inflammation under which he is suffering. The child's brow is knit and contracted, while his alae nasi and his upper lip are drawn upwards: those muscles of the face (which happen also to be muscles of expression) are instinctively put in action, which tend to exclude the light without quite shutting out the perception of external objects; producing a peculiar and distinctive grin. In the severer cases the child will skulk all day in dark corners; or if in bed, will lie upon his face, or under the clothes; and while the light is thus kept off, he does not appear to suffer. If brought towards a window, he keeps his head down, and presses his hands or arms over his eyes. When you attempt to open his eye to examine it, a profuse discharge of scalding tears takes place: these pass partly into the nose, and excite fits of sneezing, and partly over the skin, which they sometimes excoriate or inflame; and then, frequently, pustules arise on the skin, and produce a discharge that crusts over the cheek and extends to the forehead and temples. This is called *crusta lactea*, and is very characteristic of the scrofulous habit; it occasionally spreads over the whole body.

You might suppose, from this extreme intolerance of light, that the retina was inflamed, or in danger. But it is not so. The affection of the retina is purely sympathetic, and need not of itself excite any fears about the vision of the eye. Towards dusk, indeed, in the twilight, the child can generally open his eyes, and then is quite as able to see as if he were well. Dr. Mackenzie endeavours to explain the connection of intolerance of light, spasmodic contraction of the lids, and lacrymation, even when there is but little visible redness, by the distribution of the lacrymal nerve; which, after supplying the lacrymal gland, goes to the conjunctiva, and to the orbicularis palpebrarum. We have the same set of symptoms when a bit of dirt gets into the eye, and fixes itself beneath the upper lid. When little or no redness is present, this extreme intolerance of light has been called *photophobia scrofulosa*.

With this strumous affection of the eye there are usually present other evidences also of scrofulous disease. Swelling and redness of the alae nasi and upper lip; enlargement of the absorbent glands about the neck; eruptions upon the head; sore ears; a large and hard belly; disordered bowels; offensive breath; grinding of the teeth; and general debility. And the ophthalmia will alternate sometimes in severity with some of these other local scrofulous complaints; getting better as they get worse, and *vice versâ*.

LECTURES
ON
M O R T I F I C A T I O N,

Delivered at the Medical Theatre of St. George's Hospital.

By Sir Benjamin C. Brodie, Bart.
F.R.S. &c.

Lecture IV.—Dec. 16, 1840.

Hospital Gangrene — Actual Cautery — Mortification from Animal Poisons; from Cold; from sudden loss of Blood; from Inflammation of Arteries.

I think it worth while to point out another case in addition to those alluded to in the last lecture, in which the destruction of parts by caustic may be resorted to with great advantage. I refer to phagedenic and sloughing sores, whether they be those that occur upon the organs of generation in persons who have been exposed to syphilitic affection, or whether they be those that appear on other parts of the body, to which the term *hospital gangrene* is usually applied. The destruction of the parts by a powerful escharotic frequently seems to destroy the poison on which the phagedena and sloughing depends. The best caustic for this purpose is the concentrated nitric acid, applied so as to make a slough of the diseased surface, and extending to the parts just beyond it. The destruction of them to a greater depth than this is unnecessary. This method of treatment was first had recourse to, if I remember right, by Mr. Welbank, who wrote a very interesting paper on the subject.

I have taken this opportunity of speaking of some of the principal cases in surgery to which the destruction of parts by caustic is applicable; but you will find a great number of others in practice in which you may employ them with advantage. I need not, however, occupy your time further on this part of our subject. The observations which I have already offered will be easily applied to other cases; and will, I trust, be found sufficient to initiate you in this department of surgery.

Destruction of parts by heat :—the actual cautery.

The organization of the living body may be destroyed by the application of intense heat. A moderate degree of heat does not at once destroy vitality : it produces a peculiar kind of inflammation, with vesication of the skin ; but a great degree of heat destroys at once the vitality of the part to which it is applied. Of course, the action of heat is altogether chemical. No part will live if its organization be destroyed ; and heat destroys the organization. There is one thing worthy of notice respecting the slough made by a hot iron : it is separated sooner

than the slough made by caustic—that is, the two sloughs being of the same extent, that which is made by a hot iron is separated at an earlier period than that made by caustic. The reason of this is sufficiently evident. If you look at the injured part there is a much greater degree of inflammation round the slough made by the former than there is round that made by the latter.

The destruction of a part by the application of heat to a small extent is attended with no constitutional disturbance ; but if it be to a great extent, the constitution is affected in proportion to the quantity of parts destroyed. This, however, is remarkable—that where on the surface of the body there is an absolute destruction of the skin by intense heat, the constitution often suffers, in the first instance, much less than if a slighter degree of heat had been applied to the same extent of surface. You will have frequent opportunities of verifying this observation, if you watch the comparative effects of burns and scalds in the cases admitted into the hospital. I have been surprised sometimes to find, where a great deal of skin has been completely destroyed, how little the constitution has resented the injury immediately after it had been inflicted ; but it resents it enough afterwards, and when the period arrives at which the slough should be thrown off, then the general system suffers. I remember a lady who had both her arms burned, so that nearly the whole skin of each upper extremity was completely dead ; yet her constitution seemed almost unconscious of the shock. When, however, the time came, at which the slough should have been separated, she began all at once to sink, and died in a day or two.

The actual cautery may be used for surgical purposes on the same principle as caustics ; and there is one occasion on which the former will certainly do what the latter will not effectually accomplish — it will stop hæmorrhage. In some cases of dangerous hæmorrhage from a great quantity of small vessels, or from large vessels, which cannot be secured on account of their being deeply seated, the actual cautery is very serviceable. I have often found it useful on these occasions; but otherwise I have not much had recourse to it. I have indeed employed it on other occasions formerly, but I did not find it do any thing which caustics would not have done as well or better, and it is much more alarming, much more frightful both to the patient and to bystanders. It was the habit of surgeons here fifty or sixty years ago to use the actual cautery to a great extent, and it appears to be one of the many proofs of the advancement of English surgery that we have got rid of this rude piece of farriery.

Mortification from animal poisons.—I

mentioned in a former lecture that I had seen a man who died of extensive sloughing of the cellular membrane, after the sting of a bee. I stated that I attributed this chiefly to his being of a bad constitution, though perhaps something might be attributed to the influence of the animal poison. My reason for making the latter observation was this : there are certain animal poisons which have the effect of producing mortification, especially of the cellular membrane. There is a work of the Abbé Fontana, in which he describes a great number of experiments on the smaller animals, made with the poison of the viper, and the principal local effect that he observed was gangrene of the bitten limb. When I was first assistant-surgeon, a man was brought into this hospital under the following circumstances. A rattle-snake was exhibited as a sight in Piccadilly, and this poor fellow went to see it. He was a carpenter, and having dropped his rule into the rattle-snake's cage, he introduced his hand to take it out, and the snake bit him. He was immediately brought to the hospital, in a state approaching to that of syncope, with violent pain extending up the arm. The next day the whole arm was swollen, and the skin looked purple : there were vesications upon it as if sloughing were going on in the subcutaneous cellular membrane. The man lingered here for nearly three weeks, and then died. At the time of his death there was extensive mortification of the skin of the forearm : and the whole of the cellular membrane, from the bitten finger up to the shoulder, was in a state of slough. From the appearance in the beginning there could be no doubt that the sloughing process of the cellular membrane had begun immediately after the injury was received. The skin itself seemed to have mortified only because it lay over the dead cellular membrane ; and what is curious, the muscles underneath were not at all affected. The poison seems to act, as far as its local operation is concerned, especially on the cellular membrane. Not only was this proved by this particular tissue sloughing so extensively, but it was also proved by this circumstance, that within an hour after the bite extravasations of blood (ecchymoses) might be traced in the cellular membrane as high as the shoulder, from thence downwards on the side of the chest as low as the false ribs, presenting altogether a very singular appearance. The poison, indeed, seemed to operate on the cellular membrane neither in the direction of the nerves, nor in that of the absorbents, nor in that of the blood vessels. In fact, it is difficult to explain the local effects produced by this virulent poison from the anatomical structure of the parts, or on any known physiological principles. I am in possession of the notes of an experiment made by the late Mr. Ewbank

(who died some years ago, having been my colleague in the hospital) with this same rattle-snake. A rabbit bitten in the shoulder became affected by the poison in a few minutes, and died at the end of three-quarters of an hour. Even in this short space of time the cellular membrane, to a great extent, was in a state of slough, although the skin and the muscles were not affected. There are several other animal poisons that seem to operate in the same manner.

I have only one practical observation to make on these cases, namely, that you may prevent the extension of the mischief produced by the animal poison, by the application of a ligature round the limb above the bitten part. It seems to stop the influence of the poison upon the cellular membrane, and at the same time to prevent the poison entering into the circulation and affecting the general system : for in these cases, besides its local operation, the poison has a powerful influence on the constitution. The constitutional symptoms, however, are not to our present purpose, and therefore I shall not describe them.

Mortification from exposure to cold.—As parts may be killed by excessive heat, so they may be killed by excessive cold. You might suppose that cold would produce the death of a part in the following manner : that it would freeze it, and that the fluids being frozen, and to a certain extent expanded in the act of freezing, the organization of the capillary vessels would be destroyed, and death of the part ensue in the same manner as in plants and trees, which are killed by a severe frost. Two or three years ago, when there was some very mild weather, like that of spring, about Christmas, in many places the sap began to circulate in the evergreen trees. But this premature spring was followed by some days of most intense cold. The sap was suddenly frozen in the vessels of the alburnum, and as it froze it expanded and burst the vessels, and killed the trees by destroying their organization. I said that you might suppose at first that death from cold is produced in a similar way in the animal body. I cannot say that such never is the case, but I do not find that that is the way in which it usually happens. When a part is frost-bitten it is not in general killed at once, but after being exposed to a warmer temperature, it inflames, and the inflammation immediately terminates in gangrene. I imagine that the influence of cold upon the animal body is scarcely ever so instantaneous, as at once to freeze the fluid in the vessels ; there is almost always time for these to contract and become emptied of their blood before the parts are frozen. You may see this in your own fingers, when they have been exposed on a cold day, they become quite shrunk and pale, as

if there were no blood in them, and may remain in this state for a very long time. If in a case of frost-bite, you go to the fire to warm the affected part, there is a sudden re-action, inflammation is set up, and mortification follows. In this country we have very little experience of these cases. Every now and then, indeed, a patient is brought into the hospital who has lost a part of his foot, perhaps two or three toes, in this manner, but not until some time after the mischief was done, and we therefore do not see the process by which the death of the part has been produced. There are, however, abundant accounts of death from frost-bite, written by persons who have been in climates colder than ours. I may refer especially to a work by M. Beaupre, a French physician, who followed the Emperor Napoleon in the Russian campaign. By his account it would appear that parts may be under the influence of cold for a great length of time, so as to be completely deprived of sensibility, and yet, with prudent management, may recover perfectly. He states that he has frequently had his foot benumbed while riding on horseback, so that for a long time it has been devoid of sensation, and that he has got off his horse without knowing whether his feet touched the ground or not ; but by rubbing them with snow, and thus very gradually restoring them to a proper temperature, the evil consequences of frost-bite have been prevented.

Mortification from sudden loss of blood. —As the circulation of arterial blood is necessary for the maintenance of life, so whatever for a considerable time prevents a part of the body from being supplied with blood, will produce mortification. A very copious blood-letting, for instance, will under certain circumstances give rise to it. I will mention a remarkable example which fell under my observation some years ago, in a case which I attended with the late Dr. Babington. The patient, a medical officer in the East India Company's service, had gone out to dinner, and drunk an immense quantity of wine, so that he got exceedingly tipsy. This was in the city. He staggered up Holborn as well as he could, and found his way into a chemist's shop. Here he was mad enough to ask the person who stood behind the counter to bleed him, and whether this person was tipsy or not also I do not know, but however that might have been, he certainly did bleed him : and not only that, but these two blockheads agreed that he could not be bled too freely ; and so this drunken man lost, I believe, not less than three pints of blood. He then became exceedingly ill, was carried home in a coach, and the next day both his feet were mortified; the toes and feet up to the instep. We gave him wine and nourishment ; he recovered,

the sloughs separating, the dead bones coming away, and the stumps of the feet healing.

Mortification from inflammation of arteries. — Any thing which obstructs the passage of blood completely through the arteries of a limb will, of course, produce mortification. A single ligature placed on an artery does not do it, because it stops only the main trunk at one point, and there are anastomosing vessels communicating with the artery above and below the ligature, which are sufficient to carry on the circulation. But supposing that instead of one ligature you were to put on half a dozen, at different distances from each other ; in the space of six or seven inches of the artery you would not only render the arterial trunk, but the anastomosing branches also, incapable of carrying on the circulation, and this would produce gangrene. I imagine that such a thing never was done by a surgeon upon the human subject, but something corresponding to it may happen from disease. As long ago as when I was house-surgeon in this hospital, I went to see a poor man at Brompton, under the following circumstances. On a very hot summer's day in August, he was walking in the fields, when he felt a sense of pricking, numbness and weight, as he described it, in both lower extremities. It was with great difficulty that he crawled home. In one of the lower extremities these sensations subsided, but not so in the other. On the following day the whole of one leg, and the thigh as high as the middle, were in a state of mortification. The mortification never extended afterwards, no vesications formed on the foot, it was not swollen, and no part became putrid except just a little in the middle of the thigh where there was a great mass of soft parts. The limb dried, the skin assuming a brownish colour, being at the same time hard and semi-transparent, so that the white tendons could be seen shining through it. It was, in fact, what has been called a case of dry gangrene. The poor fellow went on very well for four or five weeks, without any bad symptoms, during which time the separation of the dead parts in the thigh had made considerable progress. But it seemed to be more than nature could accomplish to complete the work. His powers at last began to fail, and he died at the end of six weeks from the commencement of the attack. I examined the body, and found marks of inflammation every where about the principal artery and vein of the limb. From the bifurcation of the iliac trunk down to the middle of the thigh, the artery was obliterated, being completely filled with coagulated lymph evidently effused from inflammation : closely adhering to the inner surface, but with some

admixture of red coagulum. The vein was filled with lymph, and obliterated in the same manner as the artery. There had been inflammation of the sheath of the vessels, in consequence of which the artery and the vein adhered closely to each other and to the surrounding parts, so that the dissection was somewhat difficult. I suppose that the nature of the case is plain enough. There had been inflammation of the artery and the vein, and the obliteration of the artery was to so great an extent as to cut off the supply of blood, not only through the trunk but through the anastomosing branches. Some years ago I was called with Sir Charles Clarke, and Mr. Bryant, of the Edgeware Road, to see a similar case, which terminated more fortunately. A lady, without any apparent reason, was seized all at once with pain in one groin, and down the anterior and inner part of the thigh, with great tenderness in the course of the femoral artery. When I saw her, which was not till some days afterwards, the whole leg below the middle was in a state of mortification. There was no œdematous swelling of the foot, and no vesication. She had still pain in the course of the femoral artery, which was aggravated by pressure ; and the pulse could not be felt either in the groin or lower down. Considering the resemblance of this case to the one which I have just mentioned, I could entertain no doubt that the disease was similar, and that the mortification of the leg was the consequence of arterial inflammation. After some time the soft parts began to separate, until at last the lower part of the leg and the foot remained attached to the rest of the limb, merely by the tibia and fibula. I sawed through these bones, after which the parts gradually healed, forming a very fair stump. Perhaps you will ask why I proceeded in this manner, instead of amputating the limb at once. The fact is, that I remembered a case published in Saviard's Observations on Surgery (Saviard was a celebrated French surgeon in the early part of the eighteenth century), which was very similar to this which I have just mentioned, and in which he amputated the thigh. In performing the operation he was surprised to find that no blood flowed from the stump, in consequence of the vessels being obliterated. The parts divided in the operation had not a sufficient supply of blood for the healing process. The stump mortified as the leg had done before, and the patient died. It appeared to me, after the evidence afforded by this case, that it was desirable to avoid an operation if possible. At the same time I ought to mention, that in the second volume of the Medical Observations and Enquiries there is an account of a case, apparently of the same kind, in which amputation was successfully performed, the stump healing favourably.

One of the circumstances most deserving of notice in these cases is that the limb mortifies to a certain extent, and that then the mortification stops. This, however, is easily explained. We know that the obliteration of an artery must prevent the supply of blood to certain parts, but no further. Another peculiarity is, that the parts become dry, hard, horny, which condition of them has given rise to the name of dry gangrene. This is also easily explained. If mortification be the result of inflammation or of venous obstruction, there is always an effusion of serum before the parts completely die, in the form of vesication of the skin, and œdema of the cellular membrane ; and then, when the parts die, being infiltrated with serum, they readily become putrid. But here the supply of blood is cut off; the blood is prevented from entering the limb, so that there can be neither vesication nor effusion of serum into the cellular membrane ; and the dead parts dry readily from the absence of moisture. M. Dupuytren has described the gangrene that occurs in old age as the result of arterial inflammation, but I am quite satisfied that he is mistaken on this point. Gangrene from arterial inflammation is a comparatively rare disease, and may occur at any period of life ; whereas, the gangrene of old age arises, as repeated dissections have enabled me to determine, entirely from other causes. I shall offer some observations on this kind of gangrene in the next lecture.

ON

PHLEBITIS OF THE CEREBRAL SINUSES,

AS A RESULT OF PURULENT OTORRHŒA.

BY JAMES BRUCE, M.D., Liverpool,

Formerly House Surgeon to the Glasgow Royal Infirmary.

THE following case is the first in which I observed inflammation of the lateral sinus in connection with purulent otorrhœa ; but it occurred unfortunately at a period when my attention was not particularly directed to this department of pathology.

CASE II.—Thomas Watson, æt. 27, seaman, was admitted into the Glasgow Fever Hospital on the 13th of August, 1835, as a case of continued fever. He had been subject to a purulent discharge from the right ear from a very early period of life. The discharge had ceased about a week before he entered the hospital, and its suppression was followed by rigors, headache, and the

general symptoms of pyrexia. He experienced, shortly after, a severe pain in the right mastoid process, and an abscess speedily formed in that situation; it afterwards burst, and gave exit to a quantity of fœtid sanious matter. On admission pulse was 80, strong and intermitting; tongue brown and dry; appetite impaired. Complained of violent pain in occipital region. On the 16th pulse 96, strong. Pain of occiput relieved. Very drowsy, but when spoken to he answers questions correctly. 17th, had retention of urine, but to-day it is voided involuntarily. On the 19th pulse rose to 104; the skin and conjunctivæ were of a yellow tinge, but this disappeared on the following day. He continued much in the same condition, pulse varying from 120 to 68, till the 28th, when the headache became more intense. His head was leeched, and a blister was applied to the occiput. Next day pulse was 116, feeble; skin cold and livid. Appeared to be in a state of stupor bordering on coma. Died next day.

Inspection.—Vessels of brain unusually congested. Each lateral ventricle contained about two ounces of sero-purulent fluid. The right ventricle was lined with a thin coating of coagulable lymph in the form of a membrane, and of a greenish yellow colour. Right lateral sinus, from its junction with the longitudinal sinus to its exit from the cranium, was filled with purulent matter, and lined with a false membrane of uniform thickness; the groove in the bone in which it is lodged being rough and porous. On making an incision into the neck, behind the angle of the jaw, on right side, a quantity of puriform fluid escaped, evidently from the cut extremity of the internal jugular vein. No affection of the thoracic viscera. Liver and spleen softer than natural. Mesenteric glands enlarged.

The case just related sufficiently illustrates the connection which exists between chronic otorrhœa and disease of the lateral sinus, but it is unfortunately defective in several important points relating to the pathology of phlebitis. The internal ear was not examined, and the state of the sinus at the torcular Herophili, as well as that of the jugular vein at its termination, was not ascertained; so that we have no means of determining whether, in this instance, the pus communicated

directly with the current of the circulation, or was separated from the blood by an obstructing coagulum.

When the foregoing cases came under my observation I was disposed to believe that they belonged to a class which had not been previously alluded to by pathological writers. This impression has since been removed by a careful examination of the works of the principal writers on diseases of the brain; but I am more than ever strengthened in the conviction that too little attention has hitherto been paid to this singular affection of the sinuses of the dura mater. In most of the cases on record the inflammation of the sinuses appears to have been idiopathic, or to have been the result of a previously existing disease of the meninges, or of the brain itself. Abercrombie was perhaps the first to point out the connection of this lesion with a primary affection of the ear, as we find a case of this description in one of his papers on Diseases of the Brain, published in 1818[*]. In the Révue Medicale for 1825, there is an elaborate article on Phlebitis, by M. Ribes[†], of Montpellier, in which he relates a singular case of inflammation of the superior longitudinal sinus, evidently of a chronic nature, complicated with malignant disease of the brain; and this case is afterwards referred to by Dance[‡] in his researches on phlebitis, as the only example of the disease on record[§]. In the following year a short paper by M. Gendrin[||], entitled "sur la Phlébite Encéphalique," appeared in the Révue Médicale; it contained an analysis of the cases related by Abercrombie and Ribes, and the history of a case of phlebitis of the middle cerebral vein, in conjunction with ramollissement of the brain, where the patient, a lady, had died hemiplegic about a fortnight after accouchement. In the same year Dr. Hooper published his work on the "Morbid Anatomy of the Brain," which contained a coloured plate representing both lateral sinuses laid open, filled with pus, and lined with a false mem-

brane. A communication existed be-tween the left lateral sinus and a carious opening in the temporal bone; and the author, who neglected to give a history of the case, expresses his belief that the perforation of the bone was effected by the purulent matter, which has always a tendency to form an outlet for itself. In 1829 a memoir on the "Diseases of the Sinuses of the Dura Mater *" was read before the Académie Royale de Médecine of Paris, by M. Tonnelé, in which the author states that two dif-ferent kinds of concretions may be formed in the sinuses during life: one of these, apparently identical with the fibrinous polypi found in the right cavities of the heart, sometimes contains central deposits of puriform matter; whilst the other species bears a close analogy to the false membranes found in other parts of the body, and may exist either with, or without, suppura-tion. He relates several cases of the latter form of the affection, in none of which does there appear to have been any complication with disease of the ear. In one case, where the right lateral sinus was full of pus and lined with false membrane, the affection appeared to result from an extensive ulcer on the occiput; whilst in another, where the patient, a child, died comatose on the sudden disappearance of an exanthe-matous eruption from the scalp, a su-perficial ramollissement of the brain was found in conjunction with a suppurative phlebitis of the superior longitudinal si-nus and veins of the pia mater. The cases, however, are briefly reported, and the post-mortem appearances imperfectly described. Since that period, various examples of disease of the sinuses have been recorded by different writers; in all of them the structural lesions were not precisely the same, but they were all evidently traceable to the same pathological condition of the vessels. In an old woman who had been epileptic for two years, Prichard † found the calibre of the left lateral sinus occupied by a deposition of lymph, which had become organized. A graphic delinea-tion of another form of this affection is to be found in the great work of Cru-veilhier ‡. The disease occurred in a child, and was accompanied by rigidity

of the limbs and dilated pupils. The superior longitudinal sinus was filled with a strongly adherent bloody clot, in the centre of which there existed a quantity of semi-concrete puriform matter. The torcular Herophili, and posterior half of both lateral sinuses, were in the same condition, and most of the cerebral veins contained small cylindrical masses of bloody coagulum and caseous pus.

I have now adverted, in a very cursory manner, to the principal facts in our possession relating to phlebitis of the cerebral sinuses, as it occurs in an idio-pathic form, or as the result of some primary lesion of the brain, or its membranes. Before proceeding to analyse the small number of cases of that disease that have been observed in connection with long continued dis-charge from the ear, I shall state the particulars of another interesting exam-ple of this complication, which occurred in the Northern Hospital of this town in April last.

Case III.—A man who had been long subject to purulent otorrhœa was ad-mitted into the hospital under the care of Dr. Carson, jun., with symptoms of cerebral affection. He complained of severe headache, and lay almost con-stantly in a state of lethargic stupor, from which he could be roused, even till the last, to answer any question put to him. Some days before death he had rigors, followed by symptoms of acute pleuritis, for which he had a small bleeding employed; it could not be carried farther, on account of his increas-ing weakness. The case was casually alluded to in conversation, by one of my friends lately connected with the hospital, and he mentioned that the temporal bone had been found carious, and that he had removed it from the cranium, along with a portion of the dura mater. My attention having been previously directed to this disease, I suggested the propriety of examining the sinuses of the dura mater corre-sponding to the temporal bone; and on calling at the hospital next day, I was gratified to find that my conjectures had been fully verified, and that a lesion of the sinus had been discovered, analogous to that already described in a former part of this paper. The superior surface of the petrous portion of the right tempo-ral bone was of a greenish-black colour, and was perforated at one point by the

* Archives Gén. t. xix. p. 455, 610, 613.
† Prichard on Diseases of the Nervous System, p. 176.
‡ Cruveilhier, Anatomie Path. liv. 3, pl. iv.

caries, while at another point, a thin diaphanous lamella remained undestroyed. A carious opening also existed at the upper edge of the fossa, containing the lateral sinus; and the wall of the sinus at the point of contact was slightly eroded, and of a greenish colour. The dura mater covering the diseased bone was much thickened, and coated with a layer of lymph. The lateral sinus was filled with puriform fluid, and coated internally with a false membrane of recent formation; the calibre of the sinus was greatly contracted, and at the torcular, its cavity was completely obliterated by the quantity of false membrane and lymph deposited in that situation. The inferior petrosal sinus was similarly affected, and coagula were 2 and in some of the larger veins. It is impossible to say how far the inflammatory products extended downwards into the jugular vein; but in sawing out the temporal bone a quantity of purulent matter escaped from the incisions in the neck, and was supposed to have emanated from a deep-seated abscess in that region. The patient's relatives would not allow the examination of the thoracic and abdominal viscera: but it is almost certain that the pleuræ had become sympathetically inflamed after the formation of secondary abscesses in the lungs, and that the same lesions would have been found as in the case first related.

I have already adverted to Hooper's case of disease of the lateral sinus, in connection with purulent otorrhœa and caries of the temporal bone. After the most careful research, I have only discovered four examples of this complication recorded by other writers, and as the symptoms of the disease are obscure I shall now endeavour to give a very brief analysis of each of these cases.

I.—Dr. Abercrombie*.—A young lady, aged 15, who had long been subject to purulent otorrhœa, was affected with rigors, headache, and pain in the ear, with quick pulse and foul tongue. In a week afterwards an abscess formed in the mastoid region, and a quantity of fœtid pus was evacuated by puncture, with some relief to the headache. Pulse varied from 148 to 84 in the course of the day. Was then seized with pain in

left side of chest, for which she was bled, with partial relief: she felt better next day, but pulse was very rapid, and strength sinking, and she died quite sensible on the 14th day.

Inspection—Right temporal bone in many places rough and dark coloured, with matter betwixt it and dura mater. Right lateral sinus much thickened, and filled with a deposition similar to that which occurs in the cavity of an aneurism. Left pleural cavity contained fully a pound of purulent fluid.

II.—Dr. Abercrombie.—A young lady, aged 16, liable to purulent discharge from the ears, complained of severe headache. Eyes heavy: an oppressed look; pulse 120. She had afterwards rigors and pain in the occiput. Pulse varied from 120 to 84, and subsequently from 120 to 140, in the course of the day. There was occasional delirium and coma, but she was sensible when roused, and answered questions distinctly, until a few minutes before death.

Inspection.—Left lateral sinus full of pus and caseous matter; its coats were thickened, and its inner surface was dark coloured, irregular, and fungous; at one part the cavity was nearly obliterated. A portion of bone was carious in the course of the left lateral sinus, and the auditory canals were extensively diseased.

III.—Dr. Bright*.—A baker, who had lost a portion of his palate from syphilis, was seized with severe pain in right ear, and some bloody matter was discharged from it with relief. The left ear afterwards became worse than the right, and for seventeen nights before entering Guy's Hospital he was in a state of frenzy from pain in the head. Was tranquil during the day, but noisy and restless during the night. His answers were frequently incoherent. He was able to help himself out of bed, and two days before his death sat by the fireside.

Inspection—Sloughing abscess behind left ear. Ventricles of brain slightly distended with serosity. The lateral and petrosal sinuses were filled with dark ill-conditioned pus, which ran up to the sella turcica, filling both the cavernous sinuses and the circular sinus. The jugular vein was found full of unhealthy green pus, till it joined the

* Abercrombie on Diseases of the Brain. pp. 35—43.

* Bright, Medical Reports, vol ii. p. 66.

subclavian; and its coats were thick, opaque, and green, with a deposit of fibrinous matter. A mass of lint, sodden with fœtid pus, was found in the upper and back part of pharynx. Several abscesses in both lungs, containing dark green fœtid pus. Effusion of lymph in pleuræ and pericardium; right costal pleura gangrenous.

Dr. Bright remarks that the disease of the ear probably owed its origin to the irritation caused by the corrupt mass of lint in the pharynx.

IV.—Dr. Stokes*.—A boy, of strumous habit,and long subject to otorrhœa, was attacked, after exposure to cold, with severe pain behind one of his eyes. When he came to the Meath Hospital he was screaming with agony, but had neither delirium nor convulsion. A distinct tumor formed in the upper portion of the neck, about an inch and a half behind mastoid process, and was at first supposed to arise from periostitis of the base of the skull; but on making an incision, no matter could be discovered. Ear continued to discharge fœtid pus. Patient died delirious.

Inspection.—Brain and membranes natural. In the left lateral sinus was a quantity of extremely fœtid matter, of an almost cheesy consistence, and mixed with blood, and a communication was discovered between it and the internal ear, the bones of which were carious, and its cavity filled with the same kind of pus.

This case is adduced by Dr. Stokes as a curious example of œdema of the external parts, depending on deep-seated disease. These are the only complete cases of phlebitis of the cerebral sinuses following disease of the ear with which I am acquainted. Another example of this affection was observed by Dr. Stark, of Edinburgh, and is briefly alluded to by Dr. Craigie†, in his recent work on the Practice of Medicine : the temporal bone was carious,and the lateral sinus, from the torcular downwards, through the right jugular vein, as far as the subclavian, was thickened and filled with lymph, purulent matter, and clots of blood. The brain was also diseased.

In reviewing the details of the preceding cases, it can hardly be doubted that inflammation of the sinuses of the dura mater may exist in a chronic form, without occasioning other disorders of the vital functions than might be accounted for by co-existing disease of the brain or its membranes. In the patient, mentioned by Ribes, who had been for years subject to epilepsy and temporary fits of insanity, the lateral sinus contained false membrane, but no pus, and one of the meningeal veins was greatly enlarged and varicose: a similar condition of the middle cerebral vein was also observed in the case related by Gendrin. In general, however, it is probable that the pus secreted in the sinuses is transported directly into the current of the circulation, contaminating the vital fluid, and giving rise to those lesions of distant organs so frequently found in connection with a primary phlebitis. Although it is to be regretted that in most of the cases already cited the line of demarcation between the diseased and healthy portions of the jugular vein was not carefully examined, there is no want of facts to demonstrate that in many cases of suppurative phlebitis there is no obstacle to the direct intermixture of the pus with the circulating fluid. I have seen the brachial veins filled with pus, and terminating abruptly in the axillary ; the only appearance at the point of union being a leaden grey discoloration of the lining membrane of the diseased vein. If it were necessary to adduce other facts of the same nature, I need only refer to the careful dissections by my friend Mr. Douglas *, of Glasgow, recorded in his excellent dissertation on the Pathology of Secondary Abscesses. I have insisted more particularly on this point, in consequence of the views lately promulgated by M. Tessier†, of Paris, in which he maintains that the first phenomenon observed in every case of phlebitis is the obliteration of the vein by a coagulum ; and that a suppurative is limited by an adhesive phlebitis in every stage of the disease. In the first case described in this paper, we have witnessed an apparent confirmation of the opinions of M. Tessier : we have seen the obliteration of the lateral sinus by lymph and false membrane at the torcular Herophili, while at the other

† L'Expérience, Journal de Méd. Nos. 35, 41, 45, 59, Paris, 1838.

extremity of that vessel the cavity is blocked up by an adherent bloody coagulum. Here, then, we have a circumscribed phlebitis, in which the pus contained in the inflamed vein cannot possibly communicate with the current of the circulation. How then are we to account for the formation of the secondary abscesses in the lungs, and the purulent effusion into the pleural cavities? Are we to believe in the existence of an undiscovered phlebitis in some other organ? or to admit with Andral, Tessier, and others, that these lesions are to be ascribed to a pathological alteration of the circulating fluid, independent of any primary inflammation of the venous system? The rejection of the former hypothesis does not necessarily imply the adoption of the latter. There is certainly more than mere coincidence in the relation between phlebitis and the formation of secondary abscesses; and it is not sufficient for M. Tessier to have shewn that discrepancies exist between the theories of Dance and Cruveilhier as to the period at which the pus enters the circulation; but he must prove, what is contrary to observation, that the obstructing clot is found in the vein in every case of suppurative phlebitis.

When we reflect that the sinuses cease to be traversed by blood during the inflammation of their parietes, we are naturally led to inquire in what manner is the venous blood returned from the brain? This problem is ingeniously solved by Cruveilhier *. He shews that the cerebral veins, although distinct at their termination in the sinuses, anastomose freely with each other at their origins, and, being destitute of valves, they may be substituted one for another; so that, in order to intercept the venous circulation of the brain, we must have complete obliteration of all the sinuses. He succeeded in rendering the superior longitudinal sinus impervious in a dog; but the animal experienced no bad effect from the obstruction. This free communication existing between the cerebral veins may, perhaps, account for the absence of hæmorrhage and serous effusion in most of the recorded cases of inflammation of the sinuses of the dura mater; and it is a subject worthy of inquiry, whether the symptomatic œdema ob-

served in some examples of disease of the lateral sinus, and in many cases of ramollissement and abscess of the brain, is not in some degree connected with obstruction of the ophthalmic and other veins

In conclusion, I have very few remarks to make on the treatment of chronic purulent otorrhœa. Issues and blisters at the nape of the neck, and frictions with tartar emetic ointment over the mastoid process, have been recommended; but in the more advanced stages of the disease all means generally prove unavailing. Perforation of the mastoid process was formerly resorted to in the chronic form of this affection, but owing, perhaps, to the unfavourable issue of this operation in three cases in which it was performed by Itard, it has now fallen into discredit. The operation, however, is not so extremely dangerous as is generally supposed. M. Dezeimeris * has recently examined the principal cases on record, and states as the result of his researches that the operation has been performed on nine individuals, and in some of these it was done on both sides; so that we have altogether fourteen cases of perforation. One patient died; in two cases the operation did not succeed; in two there was only a mitigation of the symptoms, and in nine the operation was completely successful.

SOME REMARKS
on
S T R A B I S M U S,

INCLUDING AN ANALYSIS OF TWO HUNDRED CASES.

To the Editor of the Medical Gazette.

SIR,

IF you consider the inclosed remarks upon a subject already so hacknied, worthy of perusal, their insertion in your periodical will oblige me.

I am, sir,
Your obedient servant,
C. RADCLYFFE HALL.

Manchester, Jan. 4, 1841.

Having made notes of upwards of two hundred cases of strabismus, upon which I have operated during the last three months, I venture to hope that

---

the following observations may not prove altogether uninteresting.

Of two hundred cases, the left eye was exclusively affected in one hundred and ten persons; the right eye in seventy-one; both eyes together in nineteen. In one hundred and three instances, the strabismus was single convergent of the left eye; in sixty-five, single convergent of the right eye; in seven, single divergent of the left eye; in six, single divergent of the right eye; in nineteen, double convergent.

Age of the patients.—From two to three years, one; from three to four years, three; from four to eight years, eleven; from eight to fifteen years, forty-eight; from fifteen to twenty years, forty-four; from twenty to thirty years, fifty-eight; from thirty to forty years, twenty-six; from forty to fifty years, five; from fifty to sixty years, three; sixty-two years, one.

Duration of the strabismus.—From one to three years, in seven cases; from three to six years, in eleven; from six to ten years, in twenty: from ten to fifteen years, in forty-one; from fifteen to twenty years, in forty-nine; from twenty to thirty years, in thirty-two; from thirty to forty years, in twelve; from forty to fifty years, in six; from fifty to sixty years, in one; sixty-two years, in one. In the remaining twenty cases, the duration could not be ascertained.

Causes.—Under this head, I am obliged to enumerate the circumstances assigned and believed to be the causes of strabismus by the patients themselves, or their parents, without being able to vouch for the correctness of the testimony, except where physical conditions yet remained to substantiate the opinions given.

1. Convulsions during infancy, in nine cases; falls on the head, in seven; severe concussion of the brain, in one; difficult dentition, in three; hooping cough, in two; intestinal worms, in three; epilepsy, in two; a severe thrashing, in one; excessive fright, in one.

2. Ophthalmia which had left no opacities, in fourteen; opacity of the cornea, in five; opacity said to have existed formerly, in one; wound of the cornea, by a stocking needle, in two; by a fork, in one; by a thorn, in two; blow on the eye, in five; burn of the eye from a piece of metal flying into it,

in one; a habit of looking at the sun, in two; crush from a cart-wheel going over the orbit, in two; amaurosis, in two; imperfect cataract, in three; exposure during infancy to the light and heat of a blazing fire, in three.

3. Imitation of a squinting person, in thirty-nine; watching the motion of a shuttle, in one; voluntarily trying to squint, in one; a habit of looking at a scar on the eye-brow, in one; at a scar on the nose, in two; at a scar on the cheek, in two; at a small encysted tumor at the inner canthus, in one; at a small nævus in the same situation, in one; at a mole on the nose, in one; a habit of sucking the thumb, and looking stedfastly at it, at the same time, in one; holding the head sideways whilst knitting, in three.

4. Measles, in four; small-pox, in six.

5. Severe burns of the abdomen, in two.

In four instances, I was assured that the squint was congenital. In the remaining cases of the two hundred, no causes were assigned.

Under the first set of the above, are included cases in all of which, probably, the strabismus occurred consecutively to some affection of the brain. From the anatomical relations of the vessels and nerves within the cranium, Mr. Lucas has well remarked, we may account for many of those cases of strabismus which follow determinations of blood to the brain. The nervus abducens is more especially in close contiguity to several important blood-vessels. During the long-continued paroxysms of hooping-cough, and in the convulsive struggles of epilepsy, the cerebral circulation must be obstructed, and we cannot feel surprise that, as one of the effects of congestion, strabismus should occasionally result. It may also happen in these cases, that the retina of the affected eye has itself suffered from the disordered circulation, and thus a difference of visual power in the two organs has arisen. Compression of the sixth nerve in any part of its course, or at its origin, as in apoplexy, hæmorrhage from fracture of the skull, &c., so long as it affects no part of the third nerve, will, of course, by inducing paralysis, occasion convergent strabismus. In cases of cerebral hæmorrhage, there is often a temporary squint, which disappears as soon as the origin of the nerve supplying the antagonist muscles

has become affected by the effusion. A few years ago, I saw an interesting exemplification of this. Samuel Beech, a butler, had been subject to attacks of what is generally miscalled determination of blood to the head. On one of these occasions, I accompanied my father to see him. He had had several threatening symptoms of apoplexy, but could converse, though with some hesitation. After losing twenty ounces of blood, he fainted : on his recovery from this, he was found to have lost all power of distinct utterance ; his mouth was slightly drawn towards the right side, his tongue when protruded was directed towards the left, and both eyes possessed the proper visual axes, although the left eye had previously been affected with convergent strabismus for fifty years. As he gradually recovered command over the facial and lingual muscles, the squint returned, so that in about six weeks, the defect, together with complete power of speech, was re-established. In this case, there was probably some slight effusion producing palsy of the third motor nerve, portio dura, and lingual nerve of the left side. The squint arising from partial paralysis of the rectus externus oculi, or else from an hypertrophied state of the rectus internus, would no longer exist when a palsied condition of the antagonistic muscles destroyed their over-balanced power. In proportion as the cause of this last paralysis was removed, the adducting muscles regained their former superiority.

When strabismus depends on irritation of some distant part, as where it is caused by constipation, worms in the intestinal canal, irritation of the fifth pair of nerves in dentition, or, as it is stated, by severe burns of the abdomen, —the whole nervous system becomes morbidly sensible, and more or less diseased action is often set up in the brain, as proved by the occasional occurrence of effusion in such cases, if neglected. We can do little more than surmise whether the over-action of the *ad*ducting muscle arises in the first instance from spasmodic contraction, or from impaired contractile power of the *ab*ductor. But, it is certain that, in the majority of cases, after some years have elapsed, the overpowered muscle is only weaker than its antagonist, not completely paralysed, though the degree of deficiency varies very consider-

ably. The habit of squinting once formed, interstitial changes of the muscles engaged result, the over-acting one being not unfrequently hypertrophied, whilst it is rather assumed than demonstrated that the other is in an opposite condition.

Causes residing in the eye itself must act in different ways in the production of strabismus. When a mechanical impediment obstructs the passage of light through the pupil, except in a certain position of the eyeball, any variety of squint may result from the instinctive effort of the individual to accommodate his eye to the rays of light : *e. g.* dense opacities of the cornea, capsular cataract where a portion has been removed, detachment of the ciliary border of the iris with obliteration of the natural pupil from injury, a partially depressed opaque lens half blocking up the pupil, &c. When the strabismus is occasioned by ophthalmic inflammations, it may arise from the cornea of the affected eye being directed upwards and inwards so as to exclude the light as much as possible, and at the same time, as Dr. Mackenzie observes, to lessen friction from motion of the eyelids. I have seen four cases of double convergent strabismus, where the patient attributed the defect to having had sore eyes for a considerable time during childhood ; the disease, from general marks of scrofula, having been, I presume, strumous ophthalmia. In many instances of strabismus, the central part of the cornea has appeared slightly nebulous ; here the obliquity must certainly be ascribed to other effects of inflammation than the slight haziness it has left. When one eye is inflamed for a length of time, its retina becomes morbibly sensitive, partly from sympathy with the tissues more especially the seat of disease, and partly from the prolonged exclusion of light, so that, when once more exposed, the natural stimulus proves too powerful, and the eye is habitually inverted ; just as, when the power of the retina is suddenly impaired, as by looking at the sun, the other eye being closed, by amaurosis of one eye occurring rapidly, or by one of the eyes of an infant being exposed to a bright fire, it is turned out of the proper axis, to prevent the impression made upon it from confusing that conveyed to the sensorium by the more perfect organ. I have not seen a case of diver-

gent strabismus from any of these causes.

Blows on the eye may lead to strabismus either by the inflammation they occasion, or by injury to the retina from the mere concussion of the eyeball. Muscles habitually called into action gradually obtain an increase of power at the expense of their antagonists. The tendency to copy abnormal muscular actions, so strong in children, is manifest in chorea, epilepsy, and hysteria, and we can scarcely hesitate to admit imitation as an occasional cause of squint. In one family, where the mother squinted, each of her five children presented a similar defect; in another, where the father, who was much from home, was the subject of strabismus, not one of his seven children acquired it. In many instances, several children in the same family have had squints, which, if we credit the testimony of the parents, the younger 'learnt' from the elder child. I was unable to ascertain any other cause than the one assigned in every case enumerated as occasioned by imitation.

I have not seen an instance of divergent strabismus produced by the habit of directing the eye towards some personal mark in the immediate vicinity.

In measles and small-pox, the conjunctiva participates more or less, and strabismus may occur from one eye having suffered a higher degree of inflammation than the other; or, in variola, from a pustule having left a corneal opacity. But without any dense opacity of the cornea, there is occasionally, after small-pox, a more or less opaque condition of the capsule of the lens; or, without this, considerable impairment of vision; so that, in some cases, it is probable that inflammation implicates the deeper-seated structures, and by injuring vision of one eye more than of the other, may give rise to strabismus. In three instances, where the eyes appeared perfectly healthy in structure, the squint was attributed to a habit of constantly looking at a deep pit left on the side of the tip of the nose.

In every case but two, the power of vision of the squinting eye was more or less impaired. Occasionally the patient has asserted that he could see equally well with both eyes, but on closing one and the other by turns, and requesting

him to read small print, the focal distance of the two was found to differ.

The degree to which the eye could be everted in convergent strabismus, on closure of the other, varied from very slight, to apparently complete abduction.

Operation and its results.—I have seen no reason to change the mode of operating I have previously described.* The time occupied is so short, the operation almost free from pain, and its effects so little to be feared, that at the desire of the patient I have not hesitated to perform it in some cases where the probability was against ultimate success. A slight opacity of the cornea is not a decided contra-indication to the operation. Jane Jones, æt. 36, had convergent strabismus of the left eye, with slight opacity on the upper part of the cornea. The operation was performed on Oct. 3d ult. Dec. 28th her eyes are perfectly straight, their movements accord, and the previously impaired vision of the left eye has become much improved.

Unless forewarned, patients are often alarmed by the double vision which usually occurs after the operation. It generally lasts from one to three weeks, but in one instance two months elapsed before this troublesome symptom finally disappeared. In another case, the patient was so much annoyed, that in order to pursue her avocations she was obliged to tie a bandage over one eye; and thus prolonged the evil. In this case the operation had been performed

* MEDICAL GAZETTE, for November 13th, 1840.
In the Lancet for January 2d, 1841, Mr. Clay informs us that though he succeeded beyond his hope in banishing the necessity of the hook, by the new speculum which he invented, he has since performed the operation with only scalpel and forceps, which he has no doubt " will outlive all the schemes proposed." In his own words, " Thus doing away with Dieffenbach's and a variety of other hooks, my own speculum, and even the probe, as unnecessary. * * * How infinitely simple this plan is to any one proposed, and how much less liable to mischief than even that of the celebrated Guerin." I confess the plan I have always adopted of using one pair of scissors and a common forceps only, without hooks or specula of any kind, appears to myself and others, not infinitely less simple, whilst any surgeon who has witnessed both, will acknowledge that it is far safer, quicker, more bloodless and less painful, than any operation for strabismus with the scalpel. With the knife, there is more danger of letting out the humors of the eye than would be supposed from the description of the various modes of operating, and if I had myself been in the habit of using sharppointed instruments, whether scissars, bistoury, or scalpel, I believe, in a few instances, the eyeball would inevitably have been punctured.

on both eyes at one time, the convergent strabismus being double. The confusion of vision after the division of both internal recti at the same time, is greater than when one eye only is operated on at once; it has occurred to such an extent in some instances as to cause slight vertigo. The simple expedient of covering one eye relieves for the moment, and, sooner or later, the retinæ become habituated to their new relative axes, and the inconvenience disappears. When one eye only has been subjected to operation, though objects in general at first appear double, when viewed in one particular direction they appear single. The direction is that in which the rays impinge on what *was* the visual axis of the strabismic eye, and on the true visual axis of the originally sound eye, at the same time.

The improvement of vision of the previously squinting eye is usually very decided. Thomas Kaye, æt. 14, previous to the operation for convergent strabismus of the left eye, was unable to read common print at the usual distance when the straight eye was closed. The day but one following, he could read the same book distinctly with either eye, and two months having now elapsed, he says vision is equally perfect in both eyes. When there has been no other structural affection of the eye itself except the existence of small corneal opacities, in every instance vision has rapidly improved after the restoration of the eye to its proper direction. In the only cases in which I have operated for strabismus, where large and dense opacities existed, the pupil of the affected eye has been totally obliterated from adhesion of the iris to the cornea. It may be doubted whether anything was added to the personal charms, by thus rendering more prominent an eye which bore such evident sequelæ of disease; but, in deference to the wishes of the patient, the trial was made.

In one case only has erysipelas followed the operation. The woman had been subject to erysipelas of the face. Slight puffiness, with redness, and a tingling sensation of the right cheek, appeared on the day following division of the rectus internus of the right eye. It remained stationary for about a week, disappearing without vesication, and having had no further treatment than cold applications and aperients, the patient meanwhile following her usual employment.

The progress of healing in the conjunctiva depends on the kind of wound, the constitution of the patient, and the care taken to avoid exposure of the eye to cold subsequently to the operation. When the patient has been perfectly still during the operation, and not, by a sudden jerk of the head when the bit of conjunctiva was snipped off, caused a slight tear of that membrane, possessed of a good constitution, and been sufficiently careful, in some cases the wound has healed in a week without any granulations, though the redness has rarely quite disappeared before the fifteenth or twentieth day.

In the majority of patients, the day following the operation the conjunctiva around the incision is red and swollen, but not hot or painful; there may be slight ecchymosis beneath the conjunctiva above, below, or external to the cornea, and the eye waters if kept exposed. At the end of the first week a small prominent granulating body occupies the site of the incision, the conjunctiva immediately contiguous alone retaining its increased vascularity, and there is no unnatural sensibility of the eye. After the third or fourth week a small oval button of granulations, adherent by a slight pedicle, is found to have replaced the granulating eminence. Snipping through the pedicle is not attended with the slightest pain, provided the patient does not close the eyelids upon the scissars, and in a few days more all redness has disappeared, and a scarcely perceptible fine vertical seam is the only trace of the operation. Such is the most common course, but occasionally the subconjunctival ecchymosis lasts for five or six weeks; causing however no other inconvenience than what arises from its appearance. If the button of granulations is not removed, it keeps up redness of the inner portion of conjunctiva for an indefinite length of time. The granulations show a tendency to form a second time, when they are advantageously repressed by the nitrate of silver, or they may be allowed to form a second button, which, when once more removed, very rarely re-appears. In about five instances, however, I have had to remove granulations three times, before they ceased to return. The use of sulphate of copper or lunar

caustic, with the intention of preventing luxuriant granulations entirely, has not proved satisfactory. When the patient has been exposed to cold winds, or got wet immediately after the operation, the granulations have been redder, slightly bedewed with pus, and the button longer in being formed. If the constitution is of the well-marked lymphatic temperament, with flabby tumid eyelids, the granulations are usually larger, paler, altogether more sluggish, and remain longer than in other cases; and there is sometimes ecchymosis of the lids, producing the appearance of a black eye. In one woman of this class, though not the least difficulty attended the operation, the upper eyelid became distended so rapidly as to cause the patient to remark almost immediately that it felt stiff and swelled. The next day the swelling had in a great measure subsided, and in a fortnight all traces disappeared.

I have never seen, in my own cases, any more serious affections of the eye from the performance of the operation than what I have above described; never the slightest inflammation of the cornea, sclerotica, iris, or of the general cellular tissue of the orbit. The greater number of patients have been working people, who have had the operation performed during their dinner-hour, and resumed their occupation in the afternoon. No lotion has been applied, but the eye has been shaded for a couple of days, as I found it inconvenient to adopt, what I believe is the better plan, the use of gold-beaters' skin to keep the lids motionless.

In a young child the tendon is very delicate, and easily cut through when fairly over the blade of the scissars, but in older patients the tendon is sometimes so enlarged as to offer considerable resistance to the instrument, and unless the scissars are well made, it is not divided at one cut. If the tendon is of its natural size, and the eye can be fully everted when the other is closed, on division of the rectus internus, the cornea is not suddenly abducted to the outer canthus, but rarely passes more outwardly than the central axis. When the eye, on the contrary, is extremely inverted, and can scarcely be abducted beyond the central point, the tendon is generally found to be hypertrophied, and on its division the eye is almost jerked outwardly for the instant, but

returns immediately to the centre. In the proportion of about one case in six, fibrous adhesions have required division after cutting through the tendon. In one case only did the eye remain inverted to the original extent, after careful division of all the adhesions I could find. As he could fully evert the eye, and as it was straight when the other was closed, I directed him to bandage the sound eye until the divided muscle had re-united, but have not seen the case since the operation.

In some instances the inversion has been merely lessened immediately after the operation, but by a voluntary effort the cornea could be completely everted, and in the course of time, varying from two days to three weeks, the eye has become perfectly straight. I have never found the internal rectus hypertrophied in these cases. On the other hand, the cornea has sometimes been everted, but, in every instance I have seen, has gradually attained the proper central axis. The longest interval which elapsed was six weeks. In the first case, the overstrained rectus externus was at first unable to antagonise to the full extent the remaining adducting forces, but regained its power by degrees : in the second, the rectus externus acting too energetically, retained the eye in a state of semi-abduction, either until, having no opposing force, its power gradually declined, or until the renewed attachment of the internal rectus enabled that muscle once more to counteract the undue influence of its opponent.

The following is the method by which I have decided whether strabismus affected one or both eyes. If a patient with convergent strabismus is directed to look straight forwards at an object about three yards distant, if one eye has the true visual axis, being perfectly straight as long as the attention is directed to the same object, and capable of being freely moved to the full extent in every direction, whilst the other eye is inverted, the strabismus is single. If, however, both corneæ are inverted under the above circumstances, although the inversion of one eye may be so much slighter than that of the other as generally to have escaped observation, the strabismus is double. In this case, when one eye is closed, the other is perfectly straight, but when both are open, and the object of vision *not so near as to require convergence of unaf-*

fected eyes, the inversion, however une-
qually, affects both. I have met with
two instances in which the power of
vision was said to be equal in the two
eyes, and either eye squinted according
as one or the other received the most
direct impression of the object looked
at. If the right eye was covered, and
the left directed to some object, on
opening the right eye it was inverted,
and remained so as long as attention
was directed to the same object, the
left cornea being in the exact centre.
The left eye being shut, and the object
viewed with the right, on opening the
left eye it was found to be inverted,
whilst the right remained straight.
Each eye, when the other was closed,
could be freely moved in every direc-
tion, and when at rest its cornea oc-
cupied the proper central situation.
Either eye converged, one or other
being always, both together never, in-
verted. Having no rule for choice in
these cases, in one I divided the inter-
nal rectus of the right, in the other
that of the left eye, and with equally per-
fect success.

In three cases of double convergent
squint, I operated on both eyes at the
same sitting; in sixteen cases an in-
terval of about three weeks intervened.
Both cases have done equally well,
but as the greater number desired to
follow their occupation without inter-
ruption, it was generally more conve-
nient to operate on one eye only at
once.

In twenty-nine instances, the inver-
sion, though completely removed for
the time, has returned after the opera-
tion. In these cases I have performed
the operation introduced by Mr. Elliot,
of Carlisle, of dividing the internal
rectus of the perfectly straight eye, and
in every instance with complete success.
The first case of this kind which par-
ticularly attracted my attention was the
following:—

Mary Crawford, æt. 20 ; extreme con-
vergent strabismus of the left eye, of
which the power of vision is very much
inferior to that of the perfectly straight
right eye.

Oct. 20th.—On division of the inter-
nal rectus of the left eye, the corneæ of
both were in the exact centres.

Nov. 15th.—The left cornea is now
nearly as much inverted as ever, but
can be more completely everted when
the right eye is closed. The tendon of

the internal rectus of the left eye again
divided, and all adhesions cut through,
cornea once more in the centre, com-
plete power of abduction, and only as
much of inversion as is usual after a
successful operation.

Nov. 28th. — Right eye perfectly
straight as heretofore, but left as much
inverted as before the last operation.
When the right eye is closed, the left
has its proper central axis. The ten-
don of the inner rectus of the right eye
was divided ; it was much enlarged :
the left eye instantly became straight.

Dec. 26th. — Both eyes perfectly
straight, and vision of the left much
improved.

In this case strabismus affected the
eye of which the muscle appeared na-
tural in size, and that only ; whilst the
eye of which the rectus internus was
hypertrophied was perfectly straight.

Ann Bridge, ætat. 21.—Double con-
vergent strabismus ; right eye much less
inverted than the left, and the strongest
in respect of vision.

Nov. 1st.—Internal rectus of left eye
divided. Eye can be completely ab-
ducted, and appears straight. The
muscle natural in size.

Nov. 25th. — Left eye perfectly
straight, but inversion of the right eye
much increased. The tendon of the
internal rectus of the right eye was very
much enlarged. On its division, the
eye was forcibly jerked outwards, and
rendered more prominent. Its cornea
remained rather everted for about a
fortnight.

Dec. 15th.—Both eyes are perfectly
straight, though the right, the one last
operated upon, retains its slightly
greater prominence.

This is one of three cases of double
strabismus, where the eye, of which the
rectus internus was altered in size, was
least inverted, until after division of the
corresponding muscle of the opposite
eye, when its inversion became much
increased. Any explanation of this
rather singular fact must be in a great
measure hypothetical. I may hazard
the following :—To take the case of
Mary Crawford. Right eye straight,
with hypertrophied rectus internus ;
left eye inverted, with inner rectus of
the natural size. Contraction of the
rectus *externus* naturally excites a con-
sentaneous action of the rectus *internus*
of the other eye. Hence, when the outer
rectus of the right eye overacted, so to

speak, in order, by antagonising the hypertrophied internal rectus, to maintain the cornea of that eye in the proper visual axis, it excited the adducens of the left eye to overpower the non-hypertrophied rectus externus, and thus gave rise to convergent squint of the left eye only.

John Jones, ætat. 24. —Right eye has been amaurotic since childhood. Extreme convergent strabismus of right eye, of which the internal rectus was found to be greatly hypertrophied. Eyes have remained perfectly straight since the operation on the squinting eye. Thus, hypertrophy of the rectus internus, though it generally produces convergent strabismus of the same eye, yet in some cases the other eye is the only one affected with squint. In the latter case an operation on the squinting eye alone is of no service, the inversion returning as soon as re-union of the muscle to the eyeball has taken place, and the enlarged internal rectus of the straight eye must be divided.

In most of the cases of single strabismus in which the squint has returned, though perfectly remedied for the first few days after the operation, there has been no apparent deviation from the natural condition of the internal rectus of either eye; but the visual power of the affected eye was invariably much less than that of the straight eye. When the inversion was originally extreme, the squint has always been somewhat less after its reappearance than before the operation. Division of the muscle of the straight eye has perfectly succeeded in each of the twenty-nine cases. In eleven the cornea was slightly everted for a few days, but it invariably resumed the proper situation. I have never practised division of both internal recti at one operation, in single convergent strabismus, as Mr Elliott has done ; because, as already stated, in one instance only has division of all the internal adhesions of the squinting eye proved insufficient to materially lessen the inversion for the time. So far from considering that " the curious proposition of operating on a sound eye to remedy the evil of its fellow is too absurd to notice," * I humbly conceive that great merit is due to Mr. Elliott for having been the first to direct attention to an interesting and eminently practical fact.

It has not been proved, that simple division of one of the recti, where all the structures of both eyes are perfectly healthy, would cause permanent obliquity of the injured eye. I believe the squint from this cause would be only temporary, and that in proportion as the cut end of the muscle became firmly united to the sclerotic, would the eye regain its proper axis ; but this is mere supposition.

Mary Lyons, ætat. 27, applied on November 2d, with convergent strabismus of the right eye, the cornea of the left eye being exactly in the centre. Vision of the left eye better than that of the right. By operating on the right both eyes were rendered perfectly straight.

Dec. 20th.—Right eye has remained straight, but the left is inverted, though not to the same extent as the other eye was formerly. Vision is now the best in the right eye. The internal rectus of the left eye being divided, both eyes again became straight. The muscles of both eyes appeared alike of the natural size.

This is one of several instances of single convergent strabismus, in which an operation on the strabismal eye has merely substituted one squint for another ; the previously straight eye gradually becoming inverted after the operation on the squinting one, though I have never seen it equal in extent the primary inversion. Some writers are of opinion that in all these cases both internal recti were originally affected, but that the eye least inverted escaped notice from the defect of the other being more extreme. When, prior to any operation, one eye always retains the proper visual axis in looking at an object placed at a little distance in the front, whilst the other remains inverted, and immediately after the operation both eyes are perfectly straight, there appears to be no just ground for doubting that the strabismus was single, whatever might be the condition of the muscles, and that any subsequent undue convergence of the originally straight eye must be owing to some change produced by the operation.

In single convergent strabismus, the brain has been so long accustomed to take cognizance of impressions made on the central point of one retina only, that when the previously oblique organ is by the operation retained in the proper axis, and consequently receives

* Mr Clay, in the Lancet for Jan. 2, p. 497.

direct instead of oblique impressions of objects, in proportion as its power of vision becomes gradually more acute, the other, previously straight eye, may become more inverted, and thereby incapacitated for seeing distinctly. This, however, can only obtain where there was no physical cause for diminished vision in the primarily strabismal eye, beyond the obliquity, and where indeed the difference in the visual power of the eyes is not extreme. The reason why hypertrophy of the internal rectus produces in one case single strabismus of the same, and in another of the opposite eye only, and why, after an operation for single strabismus, the defect sometimes returns in the same, at others attacks the primarily straight eye, depends, I conceive, entirely upon the degree of vision exercised by the individual organ. When the left eye has been inverted, and the right eye perfectly straight, and after operating on both eyes the rectus internus of the right eye has been found hypertrophied, and that to a considerable extent, the power of vision of the left eye has been much impaired, and has not improved after the first operation to the degree usually observed. When single convergent strabismus re-appears after the operation in the same eye, the power of vision is always much deficient; whereas, if the other eye becomes strabismic, and the one primarily affected remains straight, the diminished visual power is transmitted along with the inversion.

The rationale of Mr. Elliot's operation appears to me to be this:—When the brain has been long accustomed to receive impressions of oblique rays from the centre of one retina, and direct ones from that of the other, as in single convergent strabismus, there is a tendency to maintain such a position of the eye-balls as shall preserve this relation, since any alteration in the impressions conveyed produces more or less confusion of perception until the sensorium has become habituated to the change. If, by re-union to the globe, the internal rectus regain its power of producing inversion *before* the brain has become accustomed to receive impressions made directly upon the centres of both retinæ without confusion of vision, the squint is reproduced. By dividing the inner rectus of the straight eye, it is temporarily prevented from receiving direct rays

from many objects, and the other eye consequently accommodates itself to correct vision, and by the time that the eye last operated on has perfectly recovered, so as to be capable of free motion in every direction, the power of vision of the first is so much improved that the two can act consentaneously. By covering the unaffected eye from the moment of the operation, and using the other exclusively for a week or two, the same result may in some cases be obtained, provided the muscles of the so-considered sound eye be natural in size. By this plan, however, there is certainly some risk of inducing inversion of the previously straight eye, since as the vision of the other improved by exercise, that of the closed eye would slightly deteriorate from want of use, and as soon as the re-adhesion of the divided muscle enabled it to act upon the globe, the cornea of the closed eye would be inverted, just as is that of the straight eye when covered, in single convergent strabismus. Mr. Elliot's operation effectually prevents this.

In seven cases of single convergent strabismus, the cornea was directed diagonally upwards and inwards. Division of the internal rectus and of a few adhesions posterior to its insertion, in four patients, rectified the inversion immediately; in three, not until several days had elapsed.

In two instances only (out of thirteen) has division of the rectus externus failed to remedy divergent strabismus. But in six of the eleven successful cases the cornea has only by degrees attained its proper situation. I have not tried the effect of dividing the rectus externus of the straight eye, in the two cases of failure.

From the more intimate adhesion of the conjunctiva to the sclerotica near the outer canthus, I have never seen any ecchymosis, or granulations, after the operation for divergent strabismus; but the wound has usually been completely healed in a few days, and in a fortnight all traces of vascularity have disappeared.

It was a question whether the contraction of the cicatrix left by the operation for convergent strabismus might re-induce inversion. I have never seen more of a cicatrix than a slight linear seam, except where, from the sudden motion of the patient, the portion

of conjunctiva snipped off for the ad-
mission of the probe-pointed lower
blade of the scissars has been larger
than needful, when a slightly puck-
ered appearance has remained, not
sufficient to attract observation, and of
course utterly inadequate to produce
any injurious effect on the eyeball.

The following are some of the objec-
tions urged by those who are rather
sceptical as to the utility of the opera-
tion :—

1. The squint returns in the same
eye, or,

2. Attacks the previously straight eye.

3. The previously squinting eye re-
mains too much everted.

4. The existence of a mass of sub-
stance in the inner canthus forming an
enlarged second caruncle, and produc-
ing an appearance almost as disagree-
able as the original defect.

5. If both eyes are straight, the one
that has been subjected to operation
remains unduly prominent, giving a
peculiar and unpleasant expression to
the countenance.

6. Amongst non-professionals, there
is often considerable fear lest vision
should suffer from the operation.

I believe the objections 3, 4, and 6,
to be entirely groundless. Reasoning
from the cases I have seen, in single
convergent strabismus of only moderate
degree, and not depending on any phy-
sical defect in the eyes themselves,
division of the rectus internus of the
squinting eye may be confidently ex-
pected to produce a perfect cure. In
the majority of such cases, at the ex-
piration of a few weeks there have
been no signs by which a non-profes-
sional person would detect that the eye
had ever been inverted. In a few in-
stances, however, the eye has continued
to appear slightly fuller, though to a
less extent than immediately after the
operation. When the inversion is ex-
treme, the patient should be informed
that the eye may perhaps be rather
everted for a week or two after the
operation, or that the strabismus may
return in the same, or else affect the
other eye. In either of the latter cases,
division of the inner rectus of the pri-
marily straight eye will permanently
remove the defect. When both eyes
have been operated on, they generally
appear equally full, but where the in-
ternal rectus of one eye was much larger
than that of the other, the first eye

is the most prominent, for in every case,
in proportion to the hypertrophy of the
muscle divided, has the eyeball pro-
jected.

In double convergent strabismus, an
operation on the eye most inverted will
sometimes gradually correct the undue
convergence of the other ; more fre-
quently, both recti interni must be
divided.

The following case, though more cor-
rectly one of luscitas than of strabismus,
may not perhaps be devoid of interest.

Nov. 9th.—Robert Haworth, Salford,
æt. 53. Forty-five years since was
severely crushed by a flag falling on
his head. Left eye is so much inverted
that only the outer portion of the iris
can be distinctly seen, two-thirds of the
cornea being buried in the inner can-
thus. Has not the slightest power to
evert the eye, either when the other is
open or closed. He can discern nothing
when the straight eye is closed. As the
sight of the right eye is failing, he is
desirous of having some attempt made
to improve the position of the inverted
one. At his request, notwithstanding
the assurance that it was most probable
that no benefit would result from an
operation, I made the attempt.

Having snipped off a small portion of
the conjunctiva below and external to
the cornea, I passed a bent steel probe
backwards beneath the eye-ball for
about three-fourths of an inch, and
directing its point inwards drew to-
wards me, and cut through the interven-
ing structures from within outwards
with a sharp-pointed bistoury. Being
now able to pass the probe along the
inner side of the eyeball, I divided all
the adhesions there in a similar way.
The eye was still as much inverted as
ever. The probe was then re-intro-
duced into the incision on the inner
side and passed horizontally backwards
to a considerable depth, its point being
directed above the eyeball towards the
outer canthus ; the mass of intervening
substance was rendered tense and cut
through. The whole of the cornea
could now be seen. Two days subse-
quently, the cornea was nearly but not
quite in the centre. With care, the
wound, extending through three-fourths
of the conjunctiva surrounding the
globe, healed without any unfavourable
symptom. At the present date, his con-
dition is,—cornea nearly in the centre,

eyeball fixed, pupil larger than that of the opposite eye, iris very sluggish ; obscure vision of that eye, improved by the use of spectacles.

It may be questioned whether restoring to its proper axis an eye, of which the vision is irremediably impaired, will not, by confusing the sensorium, injure rather than benefit sight, provided the other eye possesses perfect vision. In the above instance, however, the visual power of the straight eye having previously begun to fail, the man affirms that he sees better than before the operation, and certainly his personal appearance is rather improved.

NEW SURGICAL INSTRUMENT.

To the Editor of the Medical Gazette.
Sir,

Should you deem the following description of a new surgical instrument worthy of insertion in your valuable journal, I shall feel obliged.—I am, sir,

Your obedient servant,
JOHN CROXTON FOULKES.

7, Great Homer Street, Liverpool,
Dec. 24th, 1840.

The difficulties we have to contend with in the treatment of diseases of the urinary organs, particularly those which present themselves in the retention of urine from spasmodic or permanent stricture, must be familiar to every practical surgeon. The increase of spasm from the use of different sized instruments often compels the practitioner, without being able to afford his patient the desired relief, reluctantly to defer any further attempt until the irritation caused by the frequent introduction of the instruments is somewhat relieved. With the view of obviating some of these difficulties, I was induced some time ago to give an order to Messrs. Reay and Robinson, of this town, to make me an instrument on a new principle, which I beg to offer to the profession as possessing many advantages over any other I have seen. Having tested its utility in several instances I can with confidence recommend its use in many cases which will naturally suggest themselves when the principle of the instrument is understood. Without further observation, I will endeavour to explain it by referring to the annexed plates. The catheters are all

made of flexible gum, consisting of an outer or larger size, No. 12, see fig. 1, A, 9¼ inches long ; a middle one, No. 7, 13 inches long, fig. 1, B ; and a small one, No. 2, 16½ inches long ; fig. 1, C B, passing through A, and A through B : the two larger cases, A and B, are tipped with silver, and the smaller or inner, C, rounded as a common catheter, with an aperture at the side for the escape of urine ; the whole, when put together, forming a sufficiently round point to protect the urethra from injury : D, the stilette ; E, the end of B, as when pushed forward through A ; and F the end of C, as when pushed forward through B.

FIG. 1.   FIG. 2.
To be introduced in the same manner as an ordinary catheter, see fig. 2,

until it arrives at the stricture, and if we find that the outer case, A, will not pass, then the middle one, B, is to be tried; and if the operator does not succeed in getting that through, the smaller one, C, is to be passed on into the bladder.

The advantages this instrument possesses in many cases over the ordinary catheter or bougie, are easily perceptible: the larger case expands the urinary canal, and dilates the orifice of the stricture, so that an instrument introduced through it will find its way more readily, with less pain to the patient and irritation to the urethra than are caused by the instruments now in use; as we are with these obliged to withdraw one for the introduction of another. The danger of forming false passages, the coiling of bougies, and the attacks of sympathetic fever, are greatly diminished, or altogether avoided, by the use of the instrument which I have invented.

SUSPENSORY APPARATUS.

To the Editor of the Medical Gazette.

Sir,

Having experienced great advantages from the use of an apparatus of which a diagram is annexed, in the treatment of fractures of the leg, 1 am anxious to offer a brief description of it to the profession. The principle of treatment by suspension adopted, has not the attraction of novelty for a recommendation, as several notices of it have appeared in your pages from the pen of your able correspondent Mr. Grantham. The only merit, therefore, which the subject of the present communication can justly claim, is the more convenient adaptation of the principle to ordinary practice, a merit (trifling as it may be) the promulgation of which probably may be useful in inducing others at least to give trial to a method of treatment preferable, in my estimation, to every other, which one of the largest casualty hospitals in the kingdom has afforded me an opportunity of putting into practice. It is, however, far from my intention to present to your readers an account of the success of the great number of cases which have been treated with the apparatus. It will be sufficient for my purpose to say, that the very important desideratum of uniting comfort and convenience of the patient to security of the limb against displacement, are attained. This is accomplished by the great readiness with which the fractured limb follows the various motions of the body, and on that account the principle of suspension is well adapted for the treatment of those individuals who have but a very imperfect understanding of the word "quietude." The treatment of fractures of the leg is always best performed in bed; nor, upon slight grounds, should the sanction of the surgeon be
given for the patient's removal from that situation, at least during the early stages of the process of union. Yet the apparatus admits easily of such removal, and with proper precaution is capable of fulfilling the intention of the surgeon, if secured on a chair in front of the patient when seated, thus allowing the urgent calls of business to be better attended to than if he were in the recumbent posture.

The apparatus is very simple in its

character, consisting merely of a leg-rest, for which a long thigh splint, or a narrow board may in its absence, be used as an imperfect substitute, two splints, and a cradle. The first, or leg-rest, may be made either of wood or sheet-iron, the upper surface of which is hollow, and roughly shaped to the form of the back of the leg. An oval hole is made at its lower extremity for the reception of the heel, and at the upper extremity it is sloped off to adapt it to the very trifling angle formed between the thigh and leg when the latter is suspended. The rest is of sufficient length to reach from the foot to about five inches above the knee-joint on the posterior surface of the thigh, and so fitted to the ham as to afford support to the extremities both of the tibia and femur, and to remove all strain from the ligaments by which they are united. At the lower extremity is attached a foot-piece ten inches in length, and at a right angle with the rest, but capable of being inclined to either side should the position of the foot, which it is intended to support, so require. The rest is rounded on its under surface, and by being divided in the middle into two parts, which overlap each other, is capable of adaptation to the various lengths of the legs of different individuals, and of being securely fastened by a thumb-screw placed underneath, when it has been properly adjusted. The maximum length to which it can be adjusted is about twenty-six inches, the minimum length about twenty-one inches. Its breadth from side to side, at the upper extremity, is five inches, and at the lower extremity four inches.

The two splints and the cradle, being similar to those in ordinary use, need not any description. The latter, however, should be made of iron rod three-eighths of an inch in thickness. The dimensions of the cradles in use at the London Hospital are sufficiently ample for the purpose of suspension, and admit of being covered by the bed linen. They measure in length about fifteen inches; in height from the bed, fourteen inches; and in the width of the opening, fourteen inches.

In applying the apparatus to its proper use, the leg-rest and splints being sufficiently padded, the fractured limb is adjusted on the former, and secured by the latter, placed one on each side, and fastened by tapes carried around the whole in the usual way. This being satisfactorily accomplished, the rest, &c. is suspended by means of two other tapes, passed under it and over the middle bar of the cradle, now put in a convenient position over the limb. One of these tapes should be placed near to the ankle-joint, and the other a little below the knee, and both so arranged as to slide easily on the bar above and the leg-rest beneath. In suspending the apparatus care should be taken that it be not elevated too much, since two inconveniences arise therefrom, the one of which results from the too great elevation becoming irksome to the patient; the other from the suspending tapes becoming too short to admit of the apparatus swinging sufficiently easy to follow the motions of the body. The only elevation necessary for the attainment of the required objects, is that which will enable the rest to swing without coming in contact with the surface of the bed. But this contact sometimes is caused by the sinking of the cradle on a soft bed—an occurrence, however, which is easily obviated by placing a thin board under it of a size somewhat larger than is sufficient to cover the area on which the cradle rests.

The apparatus is convenient from the facility with which it admits of the removal of one or both of the side splints, and on that account it is as useful in the treatment of compound as of simple fractures, since change of dressings can be easily effected. The circumstance of the elevation admits too of better drainage to discharge, so that the frequent renewal of dressings becomes unnecessary. It also admits of examination without disturbance of the line of direction of the fractured bone, an advantage of no mean importance which it possesses over the method of treatment by starched bandages, &c. &c. I must conclude by saying, that when once properly adjusted I have not, in any case of the many treated by suspension, witnessed the displacement of the fractured bone, even in instances where previous displacement had been of continual occurrence during treatment by a fixed apparatus. I have not any hesitation, therefore, in affirming that the suspending apparatus, as above described, has afforded me more satisfaction in the treatment of fractures of the leg than any apparatus I have hitherto seen,

and I have, in consequence, thought it a duty (however trivial the subject may appear to some) to offer it, through the medium of your pages, to the profession at large.—I am, sir,

Your obedient servant,

J. LUKE.

39, Broad Street Buildings,
January 1841.

DISSECTION OF CASE AFTER THE OPERATION FOR STRABISMUS.

To the Editor of the Medical Gazette.

SIR,

ENCLOSED you will find a case which may, to many of your readers, be of some interest, especially as it is, as far as I know, the first which there has been an opportunity of examining after the operation for strabismus. You will perhaps be so kind as to publish the case in your journal, should you deem it to be sufficient interest.

I am, sir,

Your obedient servant,

PRESCOTT G. HEWETT,

Curator to the Museum of St. George's Hospital.

Jan. 12, 1841.

George Clarke, æt 30, was admitted into St. George's Hospital, under the care of Mr. Babington, on November 11, 1840, for an ulcer of the leg. He was also affected with strabismus of the left eye, which was drawn outwards, the deviation being very considerable.

On the 1st December, Mr. Babington divided the left external rectus. Rather more inflammation than usual followed, but this subsided in a few days without any particular treatment. At the time of the operation the success appeared to be complete, but after the subsidence of the subsequent inflammation, it was evident that the defect, though much diminished, was not entirely removed, the axes of the two eyes being not absolutely in the same direction. The difference, however, was very slight, and it gradually lessened, so as to be scarcely perceptible, when the patient was attacked with inflammation of the lungs, supervening on tubercles, and died on Jan. 1st, 1841.

The eye and its appendages were removed, and carefully dissected. It was found that the external rectus had been completely divided, just at the part where it was beginning to be tendinous; that the muscle itself had re-tracted to the distance of about three-quarters of an inch from its natural attachment, but that it still remained connected with the globe by a strong band of cellular tissue. This band was about three lines in width, and about six lines in length, and was attached to the ball of the eye about two lines behind the original insertion of the muscle, and such was its strength that it allowed of being pretty forcibly pulled upon without giving way.

There can be no doubt that this band consisted of the loose cellular membrane, which naturally connects the muscle with the globe, stretched into this elongated form by the retraction of the muscle, and afterwards condensed by inflammation.

The preparation is in the Museum of the Hospital, and I shall have great pleasure in showing it to any member of the profession who may wish to see it.

ON THE

AGENCY OF SOUND IN THE HUMAN EAR.*

To the Editor of the Medical Gazette.

SIR,

I AM again to offer my best acknowledgments for your indulgence in admitting my several papers into your able periodical. I hope that my present essay may also be favoured with a place in it, although delayed so much longer than I had contemplated.

I had entertained expectations that as you considered my observations on the stethoscope and the human ear merited reception, and many of the Scotch clergy had previously acknowledged that I had pointed out practical errors which occasioned confusion in their churches, those able professional gentlemen whose illustrations of sound in the stethoscope led me to this branch of acoustics, would have assisted my efforts, and pointed out where I was in error; for errors I must have committed in tracing this mazy path, more especially from the way in which it has been begun and carried on.

I have animadverted on the opinions and experiments of some very distinguished men, in no case from any selfish intentions, but solely with an earnest desire to arrive at truth, nor have I ever

* For a former paper on this subject, by the same gentleman, see Vol. II. for 1840, p. 424.

entertained an inclination to do anything for effect, or to wander from my own simple ideas ; endeavouring to explain these comprehensively in simple and unaffected language.

The first impression on my mind in relation to the economy of speech in apartments was to consider the influence of surrounding solids, and so satisfied was I of the evil effects of glass, that the original paper I penned on this subject was on sound and light ; yet on a reference to those who are considered the best authorities, I found that their theories rested almost entirely on the mere form of an apartment, and even where theory adverted to reflecting bodies more generally, this did not influence practice, nor call forth their attention to the necessity of adjusting sonorous solids.

Next, on viewing the auricle, or that part of the human ear which is presented to the eye, I could not imagine how it was calculated to collect any fluid to a definite point, nor could I think of any mechanical arrangement in nature or art resembling it, that is intended to collect any fluid to one point.

It occurred to me that it resembled a sugar refiner's filter, which is intended to collect as much fluid as possible on a limited extent of area, allowing the fluid to pass through the cloth of which it is composed.

If I am correct in the single circumstance of the prevailing sonorous influence of glass in apartments, the current theories which profess to treat of the economy of speech in apartments are defective, and if nothing can be found of analogous form and properties to the external part of the human ear, which collects fluid to a given point, or is capable of conducting the original intellectual sounds to the ear, these latter facts are alone sufficient to prove that the popular theories on the agency of sound in this organ are also defective.

I am, sir,

Your obedient servant.

W. SHAND.

1, Somerset Place, Glasgow,
    24th Dec., 1840.

On this subject my ideas were more limited and superficial when I commenced it, and many novel circumstances occurred as I progressed, yet I am not aware that in the original principles laid down, so far as they extend,

there are any material errors, although many minute modifications have necessarily been introduced. It has also been requisite frequently to repeat certain leading facts in order to impress them on the mind, as material to a knowledge of the multifarious divergencies that must arise, wherever a change, however trifling in matter or form, occasions alteration in sound.

Previous to entering upon the labyrinth or internal division of the ear, where the sense of hearing is supposed to commence in the acoustic nerve, which is immersed in a limpid fluid, through which sound must pass to reach the nerve, it may be proper to make some further remarks on external bodies. As it is in conformity to their positions and the sonorous influence of the atoms of any mass of matter, the density of these atoms, their relative distance from each other, and their uniformity, that sound is ruled;—as the ground must act a material part, let us consider its influence, and by what means the distinct character of what may be termed intellectual sounds, as speech, may be preserved by it.

The external surface of the ground is invariably rough,* and its component parts unequal, by which means sounds of moderate intensity are in a certain degree broken and divided, similarly to what is experienced in light when the rays are reflected or refracted by any rough transparent body, and the degree of sound in this case that is reflected or transmitted is less than where this is effected by any body composed of more uniform atoms and smooth surface.

If, then, thin solids vibrate much, and produce much sound, and bodies of more density or thickness produce comparatively little, the upper stratum of the ground, without powerful percussion by a solid in contact with it, must give out little sound. The human voice is also given out horizontally, and not directly towards the earth, and a yet more effectual cause for its not reflecting with much effect, so as to occasion derangement in sounds, is, that sound acts more powerfully in a vertical than in any other direction.

This is perceptible in apartments,

---

* The difference of effects on rough and smooth surfaces may be exemplified in various ways, and that a rough surface may be genial to speech, is experienced in Dr. Reid's class-room in Edinburgh.

where more vibration and sound is pro-
duced in ceilings than in the walls of a
room, and it is peculiarly obvious in
arched or curved bodies placed over a
speaker's head, as these invariably pro-
duce prolonged sounds and confusion
in speech throughout an apartment ;
but if a horizontal arch be placed at the
same distance in front of a speaker, the
same degree of derangement is not
occasioned.*

If these various circumstances be
considered collectively, it will be ap-
parent by what means intelligent sounds
are preserved when operating on the
ground, notwithstanding that so much
derangement is occasioned by surround-
ing solids in apartments, where the sur-
face exposed is of more limited extent.

Let it then be considered what is the
difference of effect when the ground is
in a comparatively dry state, and when
saturated with moisture.

After a fall of rain sound is heard
louder, more clear and distinct, and
passes further, than when the ground is
dry.† This difference is most percep-
tible in tropical countries, and sounds
are most intense and clear when the
ground has been much heated by the
sun's rays, and on porous land saturated
with moisture, near to the temperature
of the human body, as in the locality
of the Cober, where it seems to be in
that state of expansion best calculated
to give intensity and preserve distinct
sounds. All this argues the more con-
sistent and potent effects of solids and
aqueous fluids over those of the atmos-
phere, and that their action and power
of conduction is more rapid is generally
admitted.

In order more effectually to illustrate
this part of my subject, it may be proper
to recur to and make a few additional
remarks on the phenomenon alluded
to in my essay, in the MEDICAL GAZETTE
of the 9th February, 1839. In the
house in Spanishtown where I noted
the extraordinary concussions produced
by the Port Royal gun through the
Rio Cober,‡ at the distance of eleven

miles from the place where it is fired,
while no remarkable effects are occa-
sioned by field ordnance discharged
close to, and on the opposite side of the
town, beyond what is common in other
situations. The most apparent influence
is in the glass windows in inner walls,
covered by venetians on the side next
to the river, and in the opposite direc-
tion, and when these are closed so as
to prevent any material influence from
the atmospheric undulation on the
glass, this does not prevent the action
or noise in the windows ; evincing that
the most effectual vibrating action is by
the ground towards the river, where it
is most porous, and capable of retaining
water in its interstices ; and it is most
powerfully sonorous when the ground
is fully saturated with moisture, and at
a high temperature.

There is no sensible difference in the
state of the atmosphere over the town
and towards the river, nor am I aware
of any difference in the atmosphere in
any situation that could give rise to this
palpable and immense difference in
action and sound in the two directions.

These circumstances appear to me to
illustrate several facts previously ad-
vanced, and demonstrative of the com-
bined influence of solids and aqueous
fluids in conducting sounds with inten-
sity and distinct efficacy beyond what
is experienced in dry solids in contact
with air, which is practically evinced in
many cases, and in none more than in
apartments where uniformity of arrange-
ment of sonorous solids is not thought
of or attempted, and the consequence is
universal confusion in degree according
to the extent and sonorous properties
of the materials therein. In regard to
the physical properties of the human
ear, I cannot in fact imagine any me-
chanism throughout art or nature in
any manner resembling it, where sounds
are more certainly changed from their
primitive character than must be the
case in the central cavities of this organ;
nor is there any instance so decidedly

---

* In Dr. Peddie's Independent Church, in Old
Edinburgh, there is a concatenation of large hori-
zontal arches opposite to the pulpit, without much
confusion being occasioned, but one of these
arches of thin deal over the pulpit would occasion
perturbation in every part of the church.

† This is consistent with what is experienced in
the trachea and mechanism of speech, which can-
not produce music or speech if not lubricated by
(saliva) moisture.

‡ In this as in other cases where much sound

is produced, we must not view the matter ab-
stractedly in the string or stratum of water, any
more than we would determine the power of the
tuning-fork unconnected with other sonorous
solids. The porous banks of the Cober, especially
when saturated with rain, vibrate powerfully, and
in many places diffuse sound loudly, and to a
great distance, and here, as elsewhere, we must
consider what has the most predominant influence.

In fact, I might in a variety of ways expatiate
on causes and effects in this locality, illu. tr.tive
of many points, but from this I must desist, as
likely to perplex the reader.

demonstrative as the labyrinth of the human ear itself, that the media it contains are by the hands of the Creator adjusted for the conduction and preservation of sound, while there are in no instance to be found solids of similar texture and diversity of form in juxtaposition with air, that are capable of preserving, and which must not deteriorate, intelligent sounds. In all cases the motion of solids in connection with water is more in accordance as to time than solids moving in air; and it must be held in recollection that sound is ever regulated by the action in matter.

It is an important consideration, which, like many other facts, I overlooked in its proper place, that the atmosphere, which is the proper medium of transit between the solids which produce or reflect sound, and between these and the organ of hearing, as it passes in all directions, its sonorous pulsations operate on all the surfaces of all the solids within its reach, and that sound is produced in the ratio of the surfaces of the solids on which it may operate. But the properties and influence of sonorous solids are very different; and these, in a certain degree, operate in an inverse ratio to the atmosphere, which may be said to consist of a multiplicity of imperceptible elastic balls, which, when set in agitation, act more like particles that are thrown from the surface of a brewer's or distiller's vat in a state of fermentation. Every atmospheric atom in agitation is an elastic ball, acting upon and recoiling from the surface of solids, on the same principle as a boy's hand-ball when thrown against a wall; but not so the solid, the component parts of which act more powerfully upon each other, but, as already explained, to a more limited distance, and return to their original places. For these reasons less surface of the solids requires to be in contact, and the remaining parts of the solids must have freedom of action, both in the mass of matter and the atoms or crystals of which they may be composed. If these principles be correct, and one solid requires only to operate on a limited surface of another sonorous solid to produce vibration and sound throughout both, while the sonorous pulsations of the atmosphere impinging on a solid increases sound in the ratio of the extent of surface exposed to these, how is it to be reconciled that vibration is not produced by the fibro-cartilaginous pinna, while the tremulous atoms in the atmosphere enter by so small an orifice, covered by a solid also of sonorous materials, in the most natural direction in which sound approaches the ear?

In this mazy path I have travelled through all the elements that seem to me to be productive of sound. In this and my last essay certain elementary principles are more plainly and simply defined than previously, and to which it may be proper to advert briefly.

These show in what manner sound operates in different solids, as well as in the musical string; also, how it is produced in general in solids only: that the atmosphere is the proper medium of transmission from one solid to another solid, and from these to the organ of hearing; but, in order to conduct it in the human ear, that the Creator has employed the joint agency of solids with the denser fluids, as shown by causes and effects, not only in external bodies, but in the organs of speech; and that being the effects of mechanical action, those properties which govern it in these must also do so in the organ of hearing; which is confirmed by many facts. That on similar principles it is, in the stethoscope and in apartments, predominantly ruled by sonorous solids which are the primary, and the atmosphere, the minor agent, and yielding principle. The fact that sonorous solids produce most sound when a limited portion of their surfaces is in contact, but that the atmosphere produces sound on solids in the ratio of the extent of solid surfaces on which it operates, and by means of its component parts passing in all directions, seems to me to illustrate clearly certain points most important as connected with the different principles of solids and fluids, and necessary in order to understand by what means the influence of reflecting solids are produced, and why these are prejudicial or otherwise.

I may repeat that in sound, as in heat, precedence must be given to those elements which produce and conduct most freely and abundantly; and we are no more to consider air as the primary element in the production, than we are to believe that it alone produces flame or heat, because it is necessary to the existence of both.

Previous to concluding this paper, I

shall give another practical instance of the principles on which sound operates by the atmosphere on solids, by means of its diffusion in various directions, and in the ratio of their extent of surface, in order to demonstrate the predominant effects of sonorous solids in apartments for speech or music, and also in the organ of hearing. To illustrate my subject it is not necessary to resort to the Villa Simonetta, or any foreign source, but to bodies within reach of my ear and understanding.

Some days ago, when walking from the city of Glasgow to my residence in the neighbourhood, music was playing on my left hand in the Zoological Gardens. On the same side, and very near to me, was a brick wall with trees behind it, which impeded and prevented the pulsations of the atmosphere produced by the music from acting directly on my ears; but the music was heard very loud from my right hand, on which, at a little distance, stood a range of buildings, (Newton Place). The first impression on the mind was that the music originated behind these buildings; but on reaching the end of the wall on my left I was sensible that it came from that direction, and yet the sound was still louder from the right, being reflected upon the ear by the walls and windows in front of the buildings. Had I passed into the next range of buildings, a straight line with, but apart, from these (Somerset Place), new and at least as powerful reflections must have been experienced, because the latter are nearer to the Gardens, and more directly exposed to sound from that source.

That reflected sounds were more powerfully impressed on the ear, and more sensibly communicated to the nerve of hearing, in this case than original sounds, is obviously no delusion, and the analogical reasoning I would apply is this:—The brick-wall and trees divide and damp sound in the direct and natural course in which the mechanical action in the atmosphere would in their absence conduct the musical sounds to the ear, but by no means do they so effectually impede these as the tragus carries the sonorous pulsations from in front over the minute orifice in the external ear, nor do the trees behind the wall divide these so much as does the hair at the extremity

of the tragus ; nor can any of the obstructing external bodies be considered so completely non-sonorous as the cerumen which lines the very minute and peculiarly acute angular opening in the ear, the area of which is so limited when contrasted with that of the pinna or auricle.

As regards the influence of the reflecting surfaces of the buildings in this case, it is clearly demonstrated, that similar bodies must produce similar effects in apartments, and that in all these cases we must reason according to the operations of nature, and the principles which I have endeavoured to define.

ON OPACITY OF THE CORNEA,

PRODUCED BY SULPHURIC ACID.

By R. DUNDAS THOMSON, M.D.

Physician to the Blenheim Dispensary*.

[*For the Medical Gazette.*]

THE author was induced to take up the consideration of this subject in consequence of having seen a patient, along with Dr. Maddock, of Judd Street, upon whom a quantity of oil of vitriol had been thrown by an evil-disposed woman in a fit of passion. The case formed the subject of a criminal trial at the Old Bailey, and from the evidence the culprit was sentenced to transportation. The parts injured were the right cheek and cornea. The whole of the conjunctiva was soon after the injury extensively excited to a state of inflammation; but the most irritable parts were the linings of the eyelids, which gave rise to great uneasiness and pain. The acid, according to the statement of the unfortunate sufferer, was only in contact with the cornea for two minutes, when he had an opportunity of washing it off with water; yet permanent opacity was produced. The appearance of the patient two days after the reception of the injury was as follows:— The right cheek on its upper half was red, and painful to the touch, and when the cooling lotion was removed, a smarting sensation pervaded the injured parts; the edges of the eyelids were very irritable and red; and the lining mem-

brane of these appendages was exceedingly vascular. The patient complained of some foreign body being " in the eye." The cornea in its central portion was dull, white, and opaque, and was not sensible to the rays of light, although much uneasiness was excited when the light was made to fall upon the whole eye. The lids of the left eye were also exceedingly irritable, perhaps as much from sympathy as from injury. Some traces of the action of acid could apparently be detected on their exterior. The general health was not considerably impaired, but appeared to suffer in some degree from the nervous irritability occasioned by the circumstances under which the patient was placed.

Finding no attempt, in any work on the Eye, to account for the remarkable transparency of the cornea produced by oil of vitriol* the author made a series of experiments for the purpose of elucidating, if possible, this important subject. He found that when oil of vitriol was brought in contact with the cornea of the sheep, permanent opacity of that structure was produced in from one and a half to two minutes; and that the depth to which the action extended depended upon the quantity of acid, and the time during which it remained in contact. When a drop was allowed to remain in contact with the cornea for two minutes, and when the latter was washed, it was found that the influence was superficial, and that an opaque layer might be scraped off with the point of a sharp lancet or scalpel, leaving beneath an entire and transparent surface. A chemical examination proved that the opaque portion was the result of an union between the basis of the constituents of the cornea and the sulphuric acid. The author therefore, suggested that the composition of this substance was analogous to that of some false membrane, such as is produced in croup, where a chemical compound formed with the albumen or some of its modifications existing in the secretion from the mucous membrane, and a chemical agent, generally an acid, preternaturally thrown out with the secretion. These

researches were important in a practical point of view: they showed that the removal of a superficial layer, which consisted of the combination of sulphuric acid and the albumen, or variety of that substance, constituting the cornea, would leave a transparent membrane beneath. The practicability of such a method of overcoming opacity of the cornea was a subject for further physiological experiment.

Since this paper was read, the January number of that valuable journal, the British and Foreign Medical Review, has appeared. At page 64 the following note occurs :—" As this is passing through the press we observe that in a communication made to the British Association, at Glasgow, the epidermic part of the conjunctiva corneæ, which is rendered opaque and peels off, is erroneously supposed to be a false membrane: the author, Dr. R. D. Thomson, does not seem to be aware of the difference in the chemical composition of the epidermic layer and the proper substance of the cornea: and consequently that the reagents which render opaque the former have not the same effect on the latter."

The reviewer here asserts, but produces no proof, that there is an essential difference in the chemical composition of the conjunctiva and that of the cornea. His remark, however, is not borne out by the results of the author, nor by those of any authority with which he is acquainted. It is certain from the experiments of the author that sulphuric acid renders the cornea opaque as well as the conjunctiva. The experiment is so easily made, that any one may satisfy himself of the accuracy of Dr. Thomson's statement. It also affords a convenient mode of exhibiting the layers of the cornea, as by rendering each layer successively opaque and removing it, an entire and transparent surface beneath is brought into view.

The author did not intend to assert positively that the new compound formed on the surface of the cornea was a false membrane. He merely suggested that its composition was analogous; and that by its removal, a fresh surface, apparently healthy, was left exposed.

---

* By oil of vitriol is understood the sulphuric acid of commerce, consisting of one atom dry sulphuric acid and one atom water.

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à alonger ce que le lecteur se
    tue à abréger."—D'ALEMBERT.

Lectures on the Morbid Anatomy of the
    Serous and Mucous Membranes. By
    THOMAS HODGKIN, M.D., &c. Vol.
    II. Part I. 1840.

No one acquainted with Dr. Hodgkin's
former works could fail to derive plea-
sure from the announcement of the
publication of another portion of his
book on Morbid Anatomy, since it
affords an assurance both that the health
of this most ardent pathologist is happily
restored, and that his unexpected re-
moval from Guy's Hospital (whose
museum owes so large a portion of its
value to his labours, and on whose
school he conferred so much honour,)
has not diminished his devotion to an
ill-remunerating science.

The present volume, though brought
out under the disadvantageous circum-
stances of not being able to refer to the
preparations from which it was chiefly
composed, maintains the character of
its predecessor. Its title of *Morbid
Anatomy*, indeed, but ill represents the
nature of its contents, which in many
parts include much of diagnosis and of
practical medicine. It might, there-
fore, have been justly called *Pathology.*
Under the head of the Morbid Anatomy
of the lower end of the Ileum, for ex-
ample, the greater part of the doctrine
of fevers is examined; and under that
of Pulmonary Mucous Membrane the
whole of Phthisis and Tuberculous
Diseases generally is considered. Nor
do the contents of the work show that
the specific part of its title has set close
boundaries to its contents; had it been
so we should scarcely have found the
whole of Pneumonia, or of Phthisis, or
of Pulmonary Apoplexy, treated of.
However, the materials thus by force
brought in are too good for us to quarrel
with digressions that, in other cases,
would have been intolerable, or would
have needed long apologies; they rather
lead to the wish that the author had
not limited himself to the diseases of
two classes of membranes only, but
(omitting all but morbid anatomy) had
determined to treat of the whole of that
subject, and had filled up a wide gap
which still exists in medical literature.

In a work of this kind it is difficult
to point out all the novelties, and the
more so as being written in the form
of lectures, into which, for complete-
ness' sake, much that is old and well
known must be admitted, the new
things, however numerous, lie widely
scattered, and are but briefly noticed.
Amongst the best remarks are some of
those on Pneumonia. In treating (in
the first volume) of the inflammation
of the serous membranes, Dr. Hodgkin
particularly insisted on the necessity of
distinguishing two modes of inflamma-
tion; the one plastic, in which the
more solid part of the product consists
of fibrine, and is susceptible of organi-
zation, and is therefore entitled to the
title of *Vital;* the other, in which the
product of the inflammation continues
to retain a more or less fluid form, the
minute particles of which it is mainly
composed being held in suspension in
a serous or viscid fluid portion. In this
latter product no organization takes
place, and it may therefore be styled
non-plastic, inorganizable, or puriform.
Now the same differences of modes of
inflammation occur (the author be-
lieves) in the lungs also; the first form,
the plastic (or adhesive) inflammation,
is met with in all cases of *franche*
pneumonia, and is especially well
illustrated in the lobular pneumonia of
children; and this form also produces
the genuine red hepatization; the non-
plastic form gives rise to the grey or
light-coloured consolidation of the
lung, which is not produced, as is
generally taught, at a later stage of the
red induration, but which (the author
is persuaded) is of a light colour from
the very commencement. The reasons
given for this opinion seem to us nearly
sufficient, viz., that many cases in which
this form of change is found have been
of too short duration to admit of the
probability that a transition from red
to grey has taken place, and that there
is an essential difference in the form
of portions of lung affected by these
two modes of disease; in the plastic
form the bulk of the lung is but little
altered; in the non-plastic, its texture
seems remarkably distended, so that
the pleura appears smooth and tense,
and the lobules of large size. So much
softening of the lung accompanies the
non-plastic form of inflammation, that
the affected tissue often breaks up into
a dirty half-fluid matter, and gives the
appearance as if a cavity had existed

much like that produced by the soften-
ing of tuberculous matter; and in this
way, by the discharge of the fluid, and
the contraction of the cavity, the
patient may recover; but in general
this disease terminates fatally.

The remarks which are made on
tuberculous disease are of considerable
value: among them the author alludes
to the frequent occurrence of a peculiar
condition in which a rounded portion
of lung, varying in size from that of
a pea to that of a walnut, or even a
small orange, is infiltrated with a greyish
translucent effusion, (an early stage of
tuberculous matter) by which it is
rendered completely solid. Almost
at the circumference of the mass, there
are generally a multitude of small
opaque whitish points, like those seen
in the centre of miliary tubercles,
passing into a state of crudity, and
very thickly set together. When these,
and the smaller number of similar
opaque points that occur in the centre
of the mass, enlarge and become more
numerous, and unite, a rounded mass of
opaque tuberculous matter is formed;
and, ultimately, when they soften, a
tuberculous cavity of the same size.
Sometimes, though much more rarely,
the opaque points forming the margin
advance so slowly, that they are com-
pletely softened before the central part
has even acquired a general opacity;
and it consequently becomes detached,
as a solid slough. The author justly
regards this form of tubercle (of which
we can, from our own observation,
confirm his accurate description) as
peculiarly illustrative of the changes
which tuberculous matter undergoes.
The appearances here presented prove
that the deposit of a translucent ma-
terial precedes the formation of the
opaque substance more generally
known as tubercle—a truth often
doubted; and that this opaque matter
is not a new deposit after the removal
of the translucent substance (as Andral
supposed it must be in the few cases
in which he admitted that the clear
substance ever existed), but the result
of a real change in the constitution and
characters of the latter material—a
change which need not be very great
to produce all the alteration that is
visible, namely, a loss of transparency
and an assumption of opacity.

We should have been glad to multiply
our extracts from this work, but we
should not know where to cease. We
prefer, therefore, to commend it all to
our readers; it will well repay them to
peruse it: if they will do so attentively
they will join with us in feeling anxious
for the appearance of what still remains
to complete the work.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."
CICERO.

DOMESTIC HYGIENE.

MORE than three years have now
elapsed since we called the attention of
our readers to the important topic of
public hygiene.* The domestic care of
health is at least of equal interest: and
we willingly turn to the discussion of
some practical points.

That part of hygiene which consists
in the judicious administration of the
sick-room, in removing all which is
adverse to the well-being of the patient,
and assisting the efforts of the practi-
tioner for his recovery, deserves the
fullest consideration; and we are glad
to find that it has just been discussed
by a physician of long experience†.

Besides the hygiene of the sick-room,
Dr. A. T. Thomson discusses a topic
which does not appear on his title-page
—the domestic practice of physic. The
former is one which all allow to be of
unmixed utility, and of absolute neces-
sity; concerning the latter, a greater
difference of opinion prevails.

That bipolarity, or combination of
opposite tendencies, which some philo-
sophers profess to see in all human
schemes of action, and in the whole
frame-work of society, is no where more
conspicuous than in the subject of the
practice of physic by the laity. It

* MEDICAL GAZETTE, June 10 and 17, 1837.
† The Domestic Management of the Sick-room
necessary, in aid of medical treatment, for the
cure of diseases. By Anthony Todd Thomson,
M.D., &c., London, 1841.

would obviously be best if so difficult an art as physic, demanding so much study and reading, as well as a tact sharpened by long experience, and the nice balancing of probabilities, could be practised by those alone who made it the business of their lives. Yet the *re; angusti domi,* so often preventing the remuneration of practitioners, added to other causes, render this difficult; and medicine has been practised in all ages by persons of all ranks, from kings and prelates down to nurses and cottagers. Ought we to try, then, by argument and ridicule, to lessen the populous tribe of lay practitioners ; or should we endeavour to give the irresistible torrent a more favourable direction, and teach amateurs to practise less destructively ?

It might be argued, in favour of the extinction of lay practice, that it is more likely to do harm than good: that its alleged limitation to slight cases is evidently false, as the diagnosis between trivial and serious illness often demands the skilful physician ; that most of the persons who plead poverty as their excuse can pay for regular advice ; and that it is the duty of the State to pay for those who cannot. As for the still more dangerous pretext of treating serious disease till the arrival of the physician, it might be answered that if this succeeds once in a hundred times, in the other ninety-nine the amateur will mistake the disease, or the treatment, or both. Lastly, it might be urged that an anxious mother prescribing for her own child—a common case—is in the worst condition for that cool deliberative judgment, without which medicine is a most dangerous lottery. To this the fautors of medical liberty reply—that medicine, in the language of Celsus, *nusquam non est;* that it is not the privilege of a few highly civilized nations, but the common inheritance of mankind; that as in every country instinct teaches the

sufferer to ask relief, so philanthropy prompts some one to afford it; that the aid thus cheerfully proffered is morally, if not physically, efficacious, by removing from the patient's mind the painful thought that he is deserted by his fellow-men ; and that the vulnerary herbs of the feudal ages, and the distilled waters of the last century, were often useful from the confidence which they inspired. They allege, too, that although lay diagnosis is certainly not perfect, it suffices in the majority of cases; and that colds, coughs, and sore-throats, are laically treated with the foot-bath and diluents with marvellous success. They object equally to the half-crowns wrung from demi-paupers, just able to pay—or to owe; and to the attendance extorted from Union practitioners, exasperated by scanty salaries, and the studied insults of the Poor Law people. Finally, they remind their opponents that difficult as it would be to put down any branch of lay practice, it would be utterly impossible to stop the domestic treatment—the most dangerous of all, in their estimation. Much may be said on both sides of the question. Nay, a third party might advocate a *mezzo termino* in the shape of Dr. Gooch's proposition of employing female practitioners of medicine, on which we formerly commented. Meantime, both of the two chief parties pursue their way ; regular advice is daily brought within the reach of additional multitudes ; and the appearance of well-written books, addressed to the laity, shows that the other theory also continues to be practically worked out.

We wish that some qualified person would give us a medical account of tea. There is no lack of commercial facts and botanic doubts about this interesting leaf; but where is the man who can teach us much concerning its hygienic or therapeutic value ? Is it a good, or only a lesser evil than strong drinks ?

Dr. A. T. Thomson thinks that tea, coffee, and weak cocoa, are well adapted for breakfast; but excludes them all if the breakfaster is dyspeptic: we would join in banishing the two last, but incline to retain the first. But then it must be in reasonable quantities; as an imperial pint of warm water requires some strength of stomach to encounter. The evening tea he supposes to be useful, because " the food taken at dinner, being in a few hours converted into chyme, requires a certain degree of dilution to enable the soluble matter to be carried into the blood." Does it really require this dilution? and, if so, is tea the best diluent ? A curious fact about tea is, that it is precisely those classes who use the most dubious leaves who declare that they could not live without them, and say that their tea is the most refreshing meal they have. Will any astringent leaf serve the turn? or, is it the warm water which soothes their stomachs ?

Dr. Thomson does not think that gout is produced by the wine drunk at good dinners, particularly the champagne, but by the quality and quantity of the food. On this point we once before touched. That French wines have no strong tendency to produce the gout may be seen in France, especially in the wine districts; but, in this country, the drinkers of Champagne and Burgundy are chiefly rich men, and gout has in all ages been the disease of the opulent.*

The account of the requisites in a sick room is very good, and shows the practised physician. It should be perused by those young doctors whose eye has not yet become sufficiently critical, and does not seize at a glance the salient merits and deficiencies of such a chamber. Almost or quite every thing is noticed. The size and aspect of the apartment; the necessity of a chimney; the tables required,—one small for the patient's bedside, the other large, with its drawer ready to furnish broad tape for bleeding, old soft linen, a sponge, a bone spatula for spreading ointment, and a number of other little matters. Then there should be a sofa, or else a reclining chair; a chest of drawers holding a host of towels; a washing-stand with additional basins; the lamp called a night-nurse, &c. &c. If there is a mirror so placed that the patient when in bed can see himself in it, it must be removed. French beds, without curtains, are best, and, if the room is large enough, it is a good plan to have two, for the convenience of change. We recollect that Franklin recommends this as a great luxury. Ventilation is, of course, of primary importance. Dr. James Gregory, when he failed in persuading the poor to let air into their rooms, used to poke his cane through the panes. (No bad example of the *argumentum baculinum.*) But so hydra-headed is error, that when he returned, he often found the holes pasted over with paper.

If the air of the patient's apartment is too dry, the vapour of warm water is to be diffused through it. But granting that we have all this, and more, that we have the air of the room at 60°, a minim measure, and the irresistible spoon for giving medicine to children*, something still is wanting to give life to this inert machinery. We want a nurse.

Dr. Thomson justly says that it is difficult to procure a good nurse; but to get one with all the qualities which he enumerates, would savour of the impossible. She should be between the ages of twenty-five and fifty-five; strong, yet not coarse, heavy, and masculine; her strength is to be combined with activity, and though a moderate

---

* Martial consoles a slave by telling him, that if he has the lash, his master has the gout in feet and hands :—

" Tortorem metuis ? Podagrâ chiragrâque
    secatur,
Et mallet potius verbera mille pati."

degree of corpulence is not always an objection, obesity is. She is to be healthy, and, in particular, not asthmatic, nor suffering from habitual cough ; not gouty, rheumatic, labouring under any spasmodic affection, palpitation, or periodical headache. Nor is she to have piles, nor any skin disease, nor any hypochondriacal or hysterical tendency. In short, she is to be a decidedly healthy woman. Her temper is to be of the very best kind ; and though she need not be beautiful, " a certain degree of good-looks is a recommendation." Many other qualifications is she to have ; among them that of having no antipathies, *e. g.* to spiders ; but we refrain from enumerating the long list.

There is a story in the books that a lady wishing to have a faultless governess wrote a long letter to Colonel Bandoleer, her brother, detailing all the perfections of this ideal teacher ; she received a reply of two lines only, stating that the Colonel had long been in search of such a person, but that when he found her, he intended to make her, not his sister's governess, but his own wife. Was she ever found ? The books are silent. Is there such a nurse living as Dr. Thomson describes? We do not know ; but we do not blame him for being so *exigeant*, as it is necessary to paint perfection, to teach inquirers to find excellence.

Dr. Thomson's directions concerning diet are judicious, and he has given receipts for beverages and dishes well suited to the sick and the convalescent. Some good *tisanes* might be added from the French Codex.

We cannot at all agree with him in what he says at the head of his list of domestic medicines—namely, that they " may be administered without risk at the discretion of the invalid or his friends," when we find among

them, antimonial wine, Dover's powder, and laudanum. The doses are given under the heads of the several remedies, but surely the original license was injudicious. We are glad that in this list he has omitted calomel, with which lay practitioners make wild work.

PREVALENCE OF SMALL-POX.

A CIRCULAR letter has been addressed by the Poor Law Commissioners to the Boards of Guardians of the Unions, in certain districts of the metropolis where small-pox is at present prevailing very extensively. They state, on the authority of Dr. Gregory, that the Small-pox Hospital is more than usually crowded, so that it may be necessary to provide accommodation in the Union houses for the reception of such cases. It appears that a large proportion of the cases of small-pox have occurred in persons not protected by the cowpox, and the Commissioners strongly urge the propriety of taking further steps for inducing the public to avail themselves of the benefit of vaccination. They even think, moreover, " that if extra exertions of the vaccinators should require further remuneration, the Guardians would be perfectly justified in giving it."

The following is the return of cases admitted into the Small-pox Hospital during the year 1840 :—

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Jan. 12, 1841.

Sir B. C. BRODIE, Bart., President, in the Chair.

On Defective Closure of the Tricuspid Foramen as a frequent cause of Dropsy. By PEYTON BLAKISTON, M.D., one of the Physicians to the General Dispensary, Birmingham.

VARIOUS appearances found in the heart of patients affected with dropsy referred to that

organ have been generally considered as the real causes of the obstruction preceding the serous infiltration. Dr. Blakiston adduces instances from Boiullaud and Dr. Hope, and from his own observations, in which the aortic and mitral aperture had been very greatly narrowed, probably for a length of time, without producing dropsy till the near approach of death. The increase or diminution of the substance of the walls of the heart, and of the capacity of its cavities, he finds also to have occurred without dropsical symptoms. Agreeing with Dr. Hope in the frequent coincidence of hypertrophy and dilatation of the heart with dropsy, but considering that in such cases, when the proportion between all the cavities is preserved, no cause of obstruction can be recognised, he asks, is it not probable that some obstacle to the circulation, hitherto unobserved, is somehow connected with, if not dependent upon, the dilatation and hypertrophy ? The dropsical effusion being, at least in most cases, more immediately dependent upon impediment to the venous circulation, points attention to the right side of the heart ; and the dilatation of its cavities generally dilates also the right auri-ventral foramen. The author compares the statement of Hunter, Dr. Adams, and Mr. King, with his own observations respecting the degree to which the tricuspid valves close the foramen in the normal structure, and after some remarks on the dimensions of the heart's cavities, and of the valves, infers that not only in permanent dilatation of the cavities, but also from shortening of the chordæ tendineæ, and from morbid adhesion of the valves to the walls of the heart, the closure of the tricuspid valves must be so imperfect as to allow regurgitation into the right auricle. As, however, the opinions of authors respecting the sufficiency of evidence in support of regurgitation in such cases are various, Dr. Blakiston proceeds to discuss this question, and inquires whether the pulsation of the jugular veins, nearly synchronous with the systole of the heart, can be admitted to be, according to Dr. Hope's opinion, independent of regurgitation. It is not unfrequently absent, Dr. Blakiston states, in hypertrophy of the right ventricle. He argues, however, that the *force* of pulsation is not the measure of the degree of regurgitation, but of the impulse from the right ventricle. If both ventricles be hypertrophied, the pulsation or shock will be great ; if both be attenuated, the pulsation will be weak : while the obstruction to the circulation arising from the relative proportion between the power of the two ventricles is the same in each case, " both the venous current and that of the regurgitation fluid being derived from ventricular constriction." Of all the morbid appearances found in the heart in cases of cardiac dropsy, the deficient closure of the

right auri-ventral aperture by the tricuspid valve, arising from different causes, is the only one which appears to be constantly present. The opinion of the author therefore is, that this defect is a frequent and direct cause of cardiac dropsy. " 1 would not be understood," says Dr. Blakiston, " as claiming that this deduction should be received as an established truth, but as bringing it forward, with the cases and facts on which it is based, in order that its accuracy may be tested by others." In conclusion, those numerous cases upon which Dr. Blakiston states his own opinions were formed, are perspicuously and concisely narrated, and the symptoms during life and the appearances after death, illustrating the subject of the paper, are placed in relief, so as to admit of easy comparison. Among them is detailed a case communicated to the author by Mr. Hodgson, of Birmingham, and a brief classified statement of morbid appearances in thirty-four cases of disease of the heart recorded by Bouillaud.

At the conclusion of the paper, Dr. Budd asked if the author believed that the dilatation of the tricuspid orifice was essential to the occurrence of dropsy. On being answered in the negative, he said that the phenomena alluded to by Dr. Blakiston seemed to him to be only illustrations of the general fact, that in all cases of obstruction at any part of the heart, all the parts seated behind it in the course of the circulation suffered dilatation, whether their valves were diseased or sufficient to close their respective orifices or not. The same fact was to be observed in many cases of stricture of the urethra, in which dilatation took place in the bladder, ureters, and kidneys, successively, although the valvular structure between the ureters and bladder remained uninjured.

Dr. Blakiston did not deny the influence of disease of one part of the heart in producing changes in another ; the object of his paper, and of the cases it contained, (but which were not read,) was to show that there were many examples in which dropsy had occurred when the only apparent disease of the heart was the dilatation spoken of, while, on the other hand, there were many more of disease and obstruction of other orifices, or their valves, without dropsy having taken place ; and thus to render it probable that in many cases this dilatation of the tricuspid orifice was the essential cause of the obstruction of the circulation, by the regurgitation of blood which it permitted in the systole of the right ventricle, and hence of the general dropsy.

Dr. Copland said that the opinion of dilatation of the tricuspid orifice being a cause of dropsy, was not novel, but had been generally admitted, not only by M. Bouillaud, but by most of the modern writers on

diseases of the heart. He had in his mind the cases of two medical men, in both of whom this was the only or the most remarkable change, and in both of whom the dropsy was general and excessive. As to the obstruction of the circulation producing dropsy, it was manifestly unimportant whether this was the effect of an actual and fixed mechanical cause, or of the regurgitation of blood through a constantly open orifice ; in either case the ultimate result must be the same.

Dr. Mayo said that he thought the mode of testing the efficiency of the tricuspid valves described in the paper, and which consisted in the injection of water into the right ventricle, through the pulmonary artery, was not capable of affording any positive result. It was said that the water commonly passed between the valves ; and this was what might have been expected. The efficiency of these valves depended on the action of the columnæ carneæ to which they are attached, and this, depending as it does on nervous influence, was lost with life. The tricuspid and mitral were not like the arterial valves, a kind of flood-gates, capable of being forced down by the force of any fluid directed against them, but were guided in all their movements by the contractions of the muscles belonging to them ; and when these had ceased to act, it was impossible that the valves should exercise the same influence as before.

Dr. Marshall Hall thought that the attention was too exclusively directed to dropsy as a consequence of disease of the heart. Other effects, not less important, often resulted from it. He had lately had under his care, a case in which, in consequence of disease of the heart, with obstruction on the left side, bronchitis had come on, with this remarkable character, that it was entirely without cough, though clearly discoverable by other signs. After a time hemoptysis ensued, and the patient expectorated considerable quantities of blood. Then the liver was found enlarging, and it attained a very considerable size, and then hemorrhage (not from hemorrhoids) occurred repeatedly from the intestines. On examination after death, pulmonary apoplexy was found ; the enlargement of the liver was chiefly the result of congestion of the hepatic veins ; there was excessive congestion of the veins of the intestines, and from these the hemorrhage had taken place. In cases of this kind the succession of events was plainly traceable, and in the midst of such a complication of symptoms the dropsy was of comparatively small importance. Here the first effect of the obstruction of the left side of the heart was congestion of the lungs, producing bronchitis, with effusion of fluid into the air tubes, and then, as it increased, pulmonary apoplexy ; then followed obstruction at the right side of the heart, and on this the lividity of the

face and upper part of the body, and the congestion of the liver, producing its enlargement. Next, the obstacle to the passage of blood through the liver was communicated to the blood of the portal veins, and from this resulted the great congestion of the intestines, the hemorrhage from the intestines, and the ascites. He had cases very similar in many respects to this, which were still under his care ; and all tending to show that there were many other consequences of diseased heart which required notice as much as that which had in this paper exclusively occupied attention—namely, the dropsy.

On Dislocations, especially the Hip-joint, accompanied by elongation of the capsule and ligaments. By EDWARD STANLEY, F.R.S. Surgeon to St. Bartholomew's Hospital.

The object of the paper is to direct the attention of the society to the subject of dislocations of the larger joints, and especially of the hip, occurring under other circumstances than as the direct consequence of external violence, or of the destructive processes of inflammation.

The histories of six cases of dislocation of the hip-joint are related. In the first case both hip-joints were dislocated in the same individual, as a consequence of disease in the spinal cord producing spasms, with impairment of motion and sensation in the lower limbs. In the second case, dislocation of the hip-joint occurred as a consequence of an attack of hemiplegia. In the third and fifth cases, rheumatic affections of the hip-joint were followed by its complete dislocation. In the fourth case, the dislocation of the hip-joint was consequent on pain in the thigh treated as sciatica. In the sixth case, the dislocation of the hip-joint occurred in the sixth week from a fall. In the second case, the opportunity had been obtained of dissecting the dislocated joint, when the following peculiarities in it were discovered. The capsule and the ligamentum teres were entire, but elongated to the extent of allowing the head of the femur to pass beyond the limits of the acetabulum.

Mr. Stanley observed that the phenomena presented in these several cases were wholly different from those which are attendant on either dislocations of the hip-joint from external violence, or the ordinary dislocations of the joint from disease, and that he considered the dislocations in these cases could be explained only by the elongation of the capsule and ligamentum teres. In corroboration of this view of the subject, Mr. Stanley adverted to the effects of inflammation of a mild character in fibrous tissue, such as composes the ligaments and capsules of joints ; that this inflammation, whether from rheumatism, external injury, or other cause, may be followed by a simple yielding, ex-

tension, or elongation of the affected tissue ; that such a change in the ligaments of the knee-joint is frequently observed, permitting a displacement of the articular surfaces to the extent that it might be inferred from the view of the outside of the joint that there had been a complete destruction of its ligaments.

Mr. Coulson said that he should think the first and second cases detailed were of a kind similar to one that he had seen, in which a man was capable of dislocating both his thighs on to the ilia, and at will replacing them. In those cases which were described as dislocations consequent on rheumatism or sciatica, he should have little doubt that the pain was the consequence of the ulceration of the tissues of the joint, as in the usual cases of scrofulous disease of the hip. He had never had an opportunity of observing elongation of the ligamentum teres, or the capsule of the hip; in the cases of dislocation he had seen, they were usually both ulcerated.

Mr. Bransby Cooper said it was a thing altogether inexplicable and new to him, that there should be any disease capable of elongating a tissue such as the fibrous tissue of the capsule of the hip, which was by nature expressly intended for the fixing of the former, and which was, in the healthy state, altogether incapable of yielding. He had never seen such a case as elongation of these structures, and but for the dissection which had been made he should have doubted the possibility of such an occurrence as a relaxation of a fibrous tissue consequent on paralysis, such that a dislocation should take place without (as far as he could see) any muscular power sufficient for the dislocation of the bone ; for the limbs, in the two first cases, were said to be paralytic.

Dr. Copland related a case of what might be termed spontaneous dislocation of the hip, and which exactly corresponded with some of those related by Mr. Stanley. It occurred in an elderly woman, who had had pains in the limb, apparently rheumatic, and in whom, unexpectedly, and without any evident cause, gradual shortening and inversion of the limb occurred. Mr. Copland Hutchison subsequently examined the limb with him, and there was no doubt whatever that dislocation of the femur on the dorsum of the ilium had taken place.

Mr. Solly said the case alluded to by Mr. Coulson was well known to him. It was that of a watchmaker, in Shoreditch, who possessed the power of voluntarily dislocating and replacing his thighs. The man had told him that he was quite unconscious how he had learned to do it, but such was now the laxity of the tissues, that it was effected without any difficulty whatever. Mr. Solly would suggest that in the first two cases

detailed in the paper, the sensibility of the fibrous tissues being lost in the general paralysis of sensation, dislocation might have taken place by the spasmodic action of the muscles, without the patient having felt it.

Mr. Stanley said that he also was acquainted with a case in which the hips could be dislocated at will ; it was that of a lad of 18, whom you could see as you stood behind him, throwing first one and then the other high-bone out the acetabulum, and then again replacing them, and raising himself to his usual stature. The main questions discussed in the paper might be reduced to two. First, whether elongation of ligamentous tissue sufficient to permit dislocation could take place; and this he thought was certainly established, not only by the drawing and the preparation that was exhibited, but from the well-known fact of the lengthening of the arm by its dropping down in cases of paralysis of the muscles of the shoulder, and from that which was constantly observable in long-standing cases of disease of the synovial membrane of the knee-joint, in which both the crucial and lateral ligaments became so elongated as to permit dislocation of the tibia backwards and outwards beneath the condyles of the femur, although the tissue of the elongated ligaments did not appear materially altered. In the second place, the question might be whether such elongation had occurred in all the cases related, and this he thought was also established. The cases were certainly distinct from all those of ordinary dislocations from accident; and they were equally distinct from dislocations such as commonly occur from disease of the head of the femur, and other tissues of the joint ; the preparation exhibited, and another which he had hoped to be able to present, from which the drawing was taken, showed that in these the elongation really existed, and there was so much similarity in all the cases, that it appeared reasonable to assume the same cause in all.

Dr. Copland said that he could not understand why Mr. Cooper should have any doubt respecting the capability of ligamentous tissues to be elongated : he believed that Sir Astley Cooper had particularly described a state in which they become singularly relaxed.

Mr. Arnott said some of the cases related in the paper had an important bearing on others in which surgeons were very likely to fall into disgrace, on the suspicion of having overlooked a dislocation, which, in reality, had not occurred till a considerable period after the accident. He had been lately consulted in a case of this kind : a man had a fall, and the surgeon who examined him, finding no change in the position of the parts about the hips, treated it as a bruise. The man remained for some time rather lame ;

but it was not till a very considerable period had elapsed that the limb was found to be shortened and inverted. On examination, it was now certain that the femur was dislocated unto the dorsum of the ilium ; and on the evidence of the surgeon who had first attended the case, and on whom some obloquy had been cast, though perfect reliance might be placed on his opinion, it was equally certain that the dislocation had not existed from the time of the accident. Attempts were made at reduction, and the limb was twice or more drawn down to its full length, and even to something beyond the length of the other ; but it was found impossible to replace the head of the femur in the cotyloid cavity.

The President said that it had fallen to his lot to see many cases of what were called spontaneous dislocations of the hip. These he believed had been of two kinds ; in the one he considered that inflammation of the synovial membrane had taken place, producing increased secretion, distending the capsule, and gradually pushing the head of the femur outwards, so that the trochanter became more and more prominent, till at last the head passing beyond the brim of the acetabulum, the muscles drew it up to the dorsum of the ilium. Some cases of this kind were related in his work on Diseases of the Joints, but whether in these elongation of the ligamentum teres and capsule had taken place, he could not say, not having had an opportunity of dissecting any. In other cases the dislocation followed disease of the hip, commencing either in the articular cartilages or in the head of the femur. These cases were commonly accompanied by suppuration in the joint, with distension of the capsule, and often ulceration of it. In some of these the head of the bone passed through an ulcerated aperture in the capsule ; in others part of the capsule remaining entire it was drawn up with the bone ; in others again the whole capsule seemed destroyed, so that its tissue could no longer be distinguished from that of the surrounding parts. As to relaxation of the ligamentous tissues, he thought this was far from uncommon ; he had somewhere recorded such a state as occurring in hysterical women, who could often produce at will subluxations of many of the joints of their limbs, and had a peculiar rlaxity of all the ligaments. He had lately seen a lady in whom this laxity existed remarkably in the lower jaw, so that it was apt to be dislocated in the common movements of the mouth ; and he believed this state was much connected with the general condition of the health, for after this lady's strength had been improved by a course of steel medicines, the looseness of her jaw was remarkably decreased. The same relaxation of ligaments existed

in some other nervous affections : only that morning he had seen a child who had suffered from what might be called infantine paralysis from some disease of the brain : the joints of the leg were all loose, and the astragalus could be easily drawn so far forward that no doubt it might be completely dislocated by a very slight accident. As to the cases in which dislocation followed a considerable time after receiving an injury to the hip, he had seen some of these, and had always supposed them to be the result of slow disease of the joint, by which the femur was either pushed out of its socket by an accumulation of synovial secretion, or by which the ligamentum teres and other parts were slowly destroyed by ulceration. He remembered well having a young man under his care who had been sent up from the country, where he had suffered some time from the effects of a blow on the hip. He was not much relieved by the treatment, and one morning, to his great mortification, the hip was found to be dislocated.

Mr. Bransby Cooper said the states of elongation of the ligaments alluded to did not bear on the cases in question. Those occurring in the knee-joint were hardly to be regarded as elongations ; for in dislocations of the tibia backwards, neither the crucial nor the lateral ligaments would be likely to be put on the stretch. Besides, in these cases of disease of long standing, all the tissues were so altered that ligaments at length scarcely deserved the name, and could not be expected any longer to perform the functions of ligaments. He knew also very well that there were states in which dislocations could be produced with great facility after they had once occurred ; four or five such cases had been lately in Guy's Hospital. But there was no proof that in these there was elongation of the capsule or ligamentum teres, tissues which he would again urge were especially adapted and formed to resist physical extension. He must repeat, that it was to him a new and perfectly inexplicable fact, that in a state of paralysis such a disease of a fibrous tissue should take place as should produce its elongation and enlargement ; and that in a person lying paralytic, and therefore necessarily in the recumbent posture, dislocation should take place when there seemed no muscular power by which it could be produced.

At the conclusion of this discussion, of which we have been able to insert only a very brief and imperfect sketch, and which was carried on with unusual vivacity for more than half an hour beyond the usual time, the President announced that Dr. Franz had brought to the Society an instrument for the cure of short-sightedness, which he would be happy to explain to the members of the Society. This

apparatus, of which the main intention is to provide a means for gradually increasing the distance at which a book is read, by gradually raising a support for the head to a greater distance from a small reading-desk, excited considerable attention. It was, we believe, invented by Dr. Berthold, of Gottingen, and was named by him the Myopodiorthoticon. (A minute account of it is inserted at page 866 of the last volume of the MEDICAL GAZETTE.)

Before the reading of the paper was commenced, Mr. Bransby Cooper begged to be permitted to assure the President of the gratification the Society felt in seeing him again amongst them after his recent serious accident; an assurance which was warmly confirmed, and for which Sir B. Brodie briefly returned thanks.

REPORTS OF CASES,

By H. M. HUGHES, M.D.

Assistant Physician to Guy's Hospital, and
Physician to the Surrey Dispensary.

(For the Medical Gazette.)

Cynanche tonsillaris. — Women, it has appeared to me, are more subject to this affection than men. Among the patients who have presented themselves at the Dispensary, as well as among those visited at their own residences, this increased liability of females to inflammation of the tonsils has been evident. The number of those in which the complaint was so severe as to render them incapable of leaving home was only seven, and of these six were females. The treatment in all was simple; consisting merely of the administration of emetics and saline aperients, the inhalation of the vapour of warm water, and the application of leeches and blisters, while the disease was acute, and the use of astringent, acid, and capsicum gargles, and the exhibition of bitter infusions and occasional purgatives, when it has assumed the chronic form. Two of the cases terminated by suppuration, and the remainder by resolution, but none presented any features worthy of especial notice.

Erysipelas of the face. — Of the three cases which came under my notice as patients of the dispensary during the year, two were of a trifling nature, and were cured in a few days by a brisk mercurial purgative, saline medicines, and simple emollient applications. The other occurred in a woman, aged 68, who had formerly been in a superior station in life, and had always been of very temperate habits. When she was first seen the disease, originally induced by a draught of cold air, had already existed three days, and covered the vertex, and one side of the face. The rash was of a dusky crimson hue; the pulse was feeble, but not much excited;

the tongue coated and moist; and the bowels rather confined, Regarding her age, the feebleness of her pulse, and the unusual absence of constitutional excitement, together with the dark colour of the rash, I thought it prudent, after a purgative of rhubarb and calomel, at once to commence with tonics and stimulants. I therefore prescribed decoct. cinchon. ℥iss.; ammon. sesquicarb.gr.iv. to be taken every eight hours, and ordered the affected parts of the face to be freely punctured with the point of a lancet, and to be afterwards fomented. The following day the erysipelas had extended, but the turgesence and tension of the parts punctured was much reduced, her bowels had been freely acted on by the powders, and as she was in no respect worse from the exhibition of the tonic, it was ordered to be continued every six hours, and the punctures of the face to be repeated. The same medicine and the daily punctures were prescribed to the fourth and fifth day, when the rash, after extending over the whole face, and to both ears, gradually subsided, and the patient without a bad symptom of any kind was speedily restored to her former health and strength. I have noticed this case simply for the purpose of mentioning the admirable effects I have seen result in similar instances from frequently repeated acupuncturation of the parts about the head and face affected with erysipelas, originally practised, I believe, by Dr. Sutton, and highly recommended by Dr. Bright. The minute vessels of the part are thereby unloaded, the turgesence of the surface reduced, and the pain relieved, without decreasing in any appreciable degree the power of the patient. I have ordered it and seen it ordered in many cases. In several it has appeared to arrest the progress of the disease, in most it has afforded very decided relief, and in none am I aware, though some of the patients have ultimately died of the complaint, that its effects have been injurious, or otherwise than advantageous. The patients generally represent the pain caused by the operation to be severe, but it is of short duration, and the ease that is afforded by it more than compensates for the brief previous suffering. No marks, or such only as are perceptible upon close and attentive examination, are left by the punctures.

Colica pictonum. — In consequence of an extensive white-lead manufactory existing within the district, a considerable number of patients, suffering more or less severely from the poisonous effects of that mineral, have applied for advice at the dispensary. Seven only, however, during the year were confined at home with colic. Of these six were employed in the white-lead works, and the seventh was engaged in melting the "dross" and refuse lead of plumbers. Most of them had previously suffered more than once from

the same complaint, and one of them had been affected for several weeks with partial paralysis of the hands.

Upon the proximate cause of lead colic, scarcely any thing of a definite character appears to have been ascertained, as in the comparatively few fatal cases that have been examined, no single morbid condition, or assemblage of morbid conditions, has been so frequently noticed as to be considered characteristic of the disease or in any degree satisfactorily to account for all its accompanying phenomena. In the most recent work * upon the subject, it is regarded as a neuralgia of the sympathetic nerve, and the opinion is in some degree supported by the " arthralgic" affections which frequently accompany it, but far from being its invariable, or even general attendants. But as it has been observed by the reviewer of that work, " neither the character of the pain, the symptoms existing simultaneously with it, the subsequent degeneration into paralysis, nor the modes of treatment most commonly found effective in its cure, afford any countenance to the idea that the disease is a neuralgia." It may be, I think, with truth asserted, on the contrary, that the established sedative action of lead, when administered as a medicine, its decided influence in causing paralysis of the voluntary muscles of the parts to which it has been in frequent or long continued contact, as well as an attentive consideration of the symptoms accompanying the complaint, and of the medicines which are most effectually employed for its removal, all tend to confirm the opinion that colica pictonum essentially depends upon paralysis of a portion of the intestinal tube and that the spasm (if it really exists) results from the contractile efforts of the intestine above the part paralysed to overcome the obstruction there existing. Pains approaching in character those of colica pictonum, accompany obstructed intestine from other causes, and like them are generally removed by a free action of the bowels. Nor is it difficult to conceive that paralysis may affect one portion of the canal while spasmodic contraction exists in another, if it be believed probable that the lead may be taken into the stomach together with the food, and from particles floating in the air—that like magnesia and sulphur it may accumulate in the colour, and that it may there act simply as a sedative upon the nerves of the part to which it is applied. The prophylactic influence of cleanliness, of care to avoid eating and drinking in an atmosphere impregnated with the mineral, and of occasional doses of castor oil, or other aperients, tends to confirm the probability, or at least the possibility, of this origin of

the complaint. In a paper published in the 1st vol. of the MEDICAL GAZETTE of 1835, I mentioned several facts collected from authors who have written upon the diseases produced by lead, and many which had occurred under my own observation, which then appeared to myself almost to prove that this mineral sometimes induces paralysis of the limbs by contact with the extremities of the nerves supplying the muscles paralysed. Since that time I have noticed many circumstances which have tended to confirm the truth of the opinions there advanced. If those opinions are tenable in reference to the external surface of the body, it would, I conceive, be difficult to show that they are not equally applicable to its internal surface also.

The treatment adopted in the seven cases of colica pictonum referred to above, and indeed in almost all of those who have applied to me for advice, was simple and uniform. To quiet the stomach, to allay the pain, and to induce a free action of the bowels, were the indications which directed it. In almost every instance, indeed with only one exception, which will be hereafter mentioned, it was sufficient in relieving the symptoms in a very few hours, and in completely curing the complaint in a very few days. Ten or twelve grains of calomel, with one or one and half of opium, were directed to be taken directly, and if rejected to be repeated in three or four hours, and the abdomen was ordered to be assiduously fomented with hot decoction of poppies. Four hours after the pill had been retained, a common aperient draught of ʒij. of *warmed* infusion of senna, and ʒiss. of epsom salts were ordered to be taken every four or six hours till the bowels were freely moved. If the desired effect was not produced in twenty four hours, the action of the medicine was assisted by a turpentine enema. The severe pain has almost always been removed when the bowels have been freely moved, but a dull heavy pain at the scrobiculus cordis has not unfrequently remained for two or three days, and a tendency to constipation has existed for a longer period. Under such circumstances five grains of blue pill, with half a grain of opium at bedtime, and the use of less powerful aperients have generally sufficed in a short time to restore the patient to his accustomed health. Though I believe that in severe and obstinate cases venesection expedites the cure, and very materially assists the operation of other remedies ; I have yet never thought its employment necessary in uncomplicated examples of lead colic. A very large majority of M. Tanquerel's cases were attended with constipation, but diarrhœa is stated to have existed in a few throughout the entire course of the disease. I have never seen an example of lead colic with diarrhœa as an accompaniment.

In only one of the patients was there any paralytic affection of the hands, and in one only was there any cerebral disturbance of importance. The case of the latter was briefly as follows:—

Cornelius Lyons, aged 34, a rather slight man, of light complexion, came under my care as a patient of the dispensary, March 7th, 1816. He was employed in a white-lead factory, and on one previous occasion had suffered from colic. His pain was exceedingly severe, occurring in paroxysms of several minutes duration, and a heavy aching of the abdomen existed during the intervals. He had occasional vomiting ; the abdomen was flat and supple : the tongue slightly coated and moist ; the gums edged with a dark blue line, and the bowels constipated ; he complained of no pain in his head or limbs.

R Hydrarg. Chlorid. gr. x. ; Opii, gr. j. ; st. sumend. Haustus Cathart. ℥ij. (tepid) post hor. iv. ; deinde 6ta quaque hor. ad sedes. Fotus Papaver. callid. abdomini applicand.

For three days I heard nothing of him, and supposed therefore that he had been relieved, but on the 10th I was requested to see him again. I then found that his pain was still severe, that vomiting was still frequent, and that his bowels had not been opened. I also heard that he had that morning had an epileptic fit, and I myself saw one of a well marked character which occurred during the visit, and lasted for about ten minutes. I was now for the first time informed that he had previously been in a hospital for a month in consequence of a severe pain of the head, for which he had been cupped and blistered with relief, but that he had never before that morning suffered from fits. After his recovery from the epileptic paroxysm he did not complain of pain of the head, and his pulse was natural as to frequency, feeble, and small. He was ordered

Sp. Terebinth. Ol. Ricini, aa. ℥j. ; Decoct. Avenæ. ℥xiv.; M.ft. enema statim injiciend. Rep. Mist. et Fotus. R. Hydrarg. Chlorid. gr. j. ; Opii gr. ¼ ; M. ft. pil. singul. cum dosib. mistur. sumend ; Empl. Cantharidis nuchæ applicend.

11th.—Bowels only slightly moved ; but he experienced very great relief after the exhibition of the enema, and the sickness and pain were considerably alleviated ; pulse still feeble ; did not complain of pain or heaviness of the head.

R. Haust. Cathart. ℥iv. ; Decoct. Avenæ. ℥xvj. ; M. ft. enema statim. injiciend ; R. Ol. Ricini, ℥ij. : Tr. Opii. ♏x. M. capt. dimid. st. et rept. in hor, ; vj. nisi alvus soluta fuerit.

12th. — The bowels had been freely opened ; the sickness had ceased, and the pain of the abdomen had almost entirely disappeared. He complained of headache, and the pulse was only 60 in the minute, full and strong.

V. S. ad ℥viij. Rep. Enema vesperè ; R. Hydrarg. Chlorid. gr. j. ; Ext. Hyosciam. gr. iij. ; Ext. Coloc. C. gr. vj. ; fiant pil. ij. ter die sumend.

After this time I called at his house, but found him away from home, and when he came to the dispensary on the 17th, I heard that he had returned to his occupation. He had no ptyalism, his bowels were freely moved twice or thrice daily, and he had no pain.

Rep. Pil. om. nocte. R. Magnes. Sulph. ℥j. ; Tr. Hyosciam. ♏xv. Inf. Gentian. C. ℥iss. M.ft. haust. ter die sumend.

28th.—Discharged free from complaint.

This patient has not since suffered from colica pictonum, but is at present under my care as an out-patient at Guy's Hospital for paralysis of the wrists and hands.

CASE OF ACUTE HYDROCEPHALUS CURED.

BY DR. BIERBAUM, OF DORSTEN.

A BOY, whose head was disproportionately large, had from his birth frequently suffered from indigestion, and the greatest variety of children's diseases, which very much checked the development of his body. In April 1837, when he had completed his second year, after being chilled in the feet, and taking indigestible food, he was attacked with a gastro-rheumatic fever, and hardly had he got over this, when in consequence of taking cold again, one of the most destructive of children's diseases came on. The patient could not bear his playthings ; became very peevish ; complained of violent headache ; could not hold up his head, but let it fall from one side to the other, and when lying down, plunged it deep into the pillow. The temperature of the head was burning hot, while the extremities felt cold ; the carotids pulsated strongly ; the face was of a corpse-like paleness ; the eyes red and intolerant of light ; the nose and the external auditory meatus quite dry ; the tongue clean and red ; thirst great ; appetite gone ; bowels costive, urine scanty ; the pulse frequent and hard. To this were added vomiting, terror, coma vigil, the greatest indifference, seizing the head with the hands, grinding of the teeth, respiration hardly audible or visible, and interrupted by sighs, and repeated exclamations that he was burning or falling. It was equally obvious that the disease was inflammation of the brain, and that the child was in great danger. Several leeches were applied to the mastoid process, a blister was

put on the back of the neck, mercurial oint-
ment was rubbed on the submaxillary glands,
and two grains and a half of calomel * were
administered daily. On the seventh day of
the treatment, the submaxillary glands were
considerably swollen, the angle of the mouth
was sore, and its cavity reddened, but there
was no remarkable mercurial odour, and no
commencement of salivation. On this day,
15 grains of calomel having now been taken,
and two drachms of mercurial ointment
rubbed on, a happy change took place, and
gave great probability of a favourable termi-
nation. In the evening, the left cavity of
the nose again secreted mucus, and after-
wards the right cavity ; the eyes (of which
the left had been affected with œdema of the
upper lid) again poured out tears when the
child cried ; and each external auditory
meatus, but the left one more than the
right, likewise began to secrete mucus. The
return of these natural secretions, which de-
serve the greatest consideration, afforded the
surest sign of the decrease of the morbid
processes above mentioned. In order to aid
these critical endeavours of nature, and give
the last blow to the disease, Dr. Bierbaum
used six more grains of calomel, and another
drachm of mercurial ointment ; so that in
all, twenty-one grains of calomel, and three
drachms of mercurial ointment had been
employed. It was now time to discontinue
the treatment, as was shown by the mercurial
fever which came on, and which disappeared
again in a few days. In this manner the
child fortunately escaped its threatened fate ;
it recovered rapidly, and still enjoys the most
perfect health.—*Med. Zeit. v. V. f. H. in
Pr.:* and *Schmidt's Jahrbücher,* Sept. 1840.

APOPLEXY, WITH HEMIPLEGIA,

IN CONSEQUENCE OF FRIGHT.

By Dr. Ritter.

The only peculiarity of this case is its cause.
A robust and rather plethoric woman, thirty-
eight years old, was in perfect health, and
speaking to a neighbour, when her servant-
girl frightened her by brandishing a bright
spiral wire over her head, so as to make it
look as if a snake were falling on her. In
her fright the woman suddenly fell down in
in an apoplectic fit, and remained for some
time nearly unconscious. When examined
she complained of a noise and beating in the
left side of the head, deafness of the left ear,
and of blindness and loss of taste on the
same side. She could not move any part of
the left side of the body, and in every respect
resembled a patient suffering from hemiplegia
in consequence of sanguineous apoplexy. By

active antiphlogistic treatment, and various
other measures, she was gradually restored
from this state in about three months.

LECTURES
ON THE
PRINCIPLES AND PRACTICE OF
PHYSIC.

Delivered at King's College, London,

By DR. WATSON.

LECTURE XIX.

Strumous Ophthalmia continued. Recapitulation. Treatment of Strumous Ophthalmia. General remarks on Conjunctival Inflammations. Iritis: its symptoms and treatment. Causes of Iritis.

WHEN we separated yesterday, I was about to describe the treatment which has been found by experience to be the best for relieving strumous or phlyctenular ophthalmia. Before I take up the subject where it was then dropped, let me briefly remind you of the character and principal symptoms of the disorder. It is a form of inflammation of the conjunctiva, to which *scrofulous* children, from the time they are weaned, to about the age of eight, are extremely liable. It *may* occur considerably later. Sometimes it is the first and only token of the existence of the scrofulous diathesis; generally it is observed in children who bear other marks of the strumous *habit*, and are afflicted with other forms of strumous *disease*.

Its symptoms are—first, slight vascularity; the redness being partial, and resulting from one or more fasciculi of superficial vessels, that advance from the circumference of the visible part of the eye towards the cornea, where they usually stop: sometimes however they pass a little beyond its edge: at the extremities of these fasciculi, upon or near the line of separation between the cornea and the sclerotica, small prominences appear, which are sometimes absorbed, and sometimes break and form ulcers. Less frequently the phlyctenæ are situated towards the central

part of the cornea. Secondly, with this partial vascularity and these pimples, and sometimes even without them, there is *extreme* intolerance of light. The pain produced by exposing the eye to the influence of light imparts a characteristic expression to the countenance of the suffering child. Tears flow over the cheek, and inflame it often, and give rise to the eruptive appearance termed *crusta lactea*; or, from its sometimes covering the cheek like a mask, *porrigo larvalis*.

I may add to this summary of what was stated in the last lecture, that sometimes the vessels which pass along the conjunctiva and over the cornea, instead of leading to pustules, extend laterally; so that several bundles of vessels unite by their mutual ramifications; and that part of the conjunctiva which covers the cornea becomes thick, as if it were darned, and more or less opaque. Indeed, the greater portion or the whole of the cornea covering may thus be rendered patchy and vascular. The appearance presented by the eye under these circumstances is called *pannus*.

Treatment of strumous ophthalmia.— You will readily believe, from what has been said of this complaint, that it is an obstinate and troublesome one. Even when removed, it is very apt to recur again. The scrofulous *habit* on which it depends we cannot get rid of; and whenever the exciting causes of scrofulous *diseases* come into action, this form of scrofula is very prone to declare itself, at the period of life which I have already mentioned.

More good is to be done by general treatment, applied to the system at large, in this form of ophthalmia, than in those we were occupied with before; and this is one strong point of difference between them.

In the first place we must endeavour to correct that unnatural condition of the whole system, and especially of the digestive organs, which is commonly so striking a con-

674 DR. WATSON ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

comitant of the local disease. It will be proper to clear out the bowels in the outset, and occasionally, by a mercurial purge; and to regulate them at other times by laxatives, such as rhubarb, or the confectio sennæ, or castor oil. The recovery will be greatly promoted also by those measures which are found to benefit the general health in such constitutions; warm clothing, frequent ablution of the body, nourishing though plain food, the respiration of a pure atmosphere, *change* of air, and regular exercise.

In addition to these measures, tonic medicines should be administered; the preparations of iron, for example, or the dilute mineral acids : but the best remedy of this kind is, undoubtedly, the sulphate of quina. This may be given to a child in grain doses, three times a day, dissolved in water, with a drop of the dilute sulphuric acid, and some syrup of orange peel. Dr. Mackenzie, in particular, has put this medicine fairly to the test, having employed it in a very large number of cases with the happiest results. In most of his patients he declares that it acted *like a charm*, " abating, commonly in a few days, the excessive intolerance of light and profuse epiphora; promoting the absorption of phlyctenulæ, and hastening the cicatrization of ulcers of the cornea." And Mr. Lawrence adds his testimony to the same effect; and his experience in this disease, like Dr. Mackenzie's, has been large enough to make it highly valuable.

A few words will suffice to explain the kind of local treatment that has been found useful. You may feel tempted to apply leeches round the eye. This is seldom requisite, except when there is more redness and pain than common, and the tongue becomes white, and the skin hot. Certainly you must not take the intolerance of light as a fit indication for the use of leeches. Abstraction of blood rather aggravates that symptom, apparently by increasing the irritability of the retina. Warm fomentations are generally very comfortable to the patient's feelings.

When the general disorder of the system has been somewhat rectified, local stimulants and astringents are of great service. The vinum opii, and the solution of lunar caustic, are the best. These are often tedious cases, and therefore it is necessary that you should be aware of one great objection to the long-continued employment of the nitrate of silver wash, which objection has been pointed out by Dr. Mackenzie. It is apt (but only when frequently repeated for a long time together), to stain the conjunctiva of an indelible olive colour. For this reason the vinum opii is to be preferred in slow cases, and in cases where frequent relapses happen. The good effects of either of those preparations are very striking; they diminish the

irritability of the eye, and promote the healing of the ulcers. The red precipitate ointment, and the citrine ointment of the Pharmacopœia diluted, are also found beneficial.

Counter-irritation is another local measure, which is of undoubted utility in this complaint. A great change for the better in the state of the organ often occurs, almost suddenly, upon the rising of a blister placed behind the ear, or at the back of the neck. And issues in the arms are not only serviceable in promoting the cure, but have a marked effect in many children, in preventing relapses. Mr. Welbank, in his notes to Frick's *Treatise on Diseases of the Eye*, says that he has seen chronic strumous ophthalmia, of seven years' duration, quickly and effectually relieved by an issue in the arm. " Having once (says he) in the case of a boy in Christ's Hospital, directed the healing of an issue which had been made above twelve months, I found the immediate consequence to be a relapse of strumous inflammation and ulceration of the cornea, resisting every measure but the renewal of the issue."

He suggests also (what parents are sometimes more willing to assent to) the advantage of making counter-irritation by piercing the lobe of the ear, and inserting a ring or silk; and " a very convenient form of vesication will be found in the application of a strong thread, smeared with the *emplastrum cantharidis*, and firmly tied behind the ear at the angle of its reflection."

When ulceration is going on in the cornea, and threatening to penetrate it, the progress of the ulcer may be checked by touching the surface once in two or three days with a pencil of lunar caustic which has been scraped to a fine point.

When the more urgent symptoms have abated, and the discharge of hot and irritating tears has ceased, the crusta lactea may very easily be got rid of. The crusts are to be removed by a light poultice, or by warm water; and then the part must be bathed from time to time with a lotion made by mixing the oxide of zinc with water; a drachm to four ounces is the proportion I am in the habit of prescribing. If rose water be used instead of common pump water, the prescription will be thought the more *elegant*. This lotion will speedily dry up the discharge, and in a short time no trace of the ugly looking crust will remain. Parents are highly delighted and very thankful when you thus accomplish the removal of a large disfiguring and disgusting scab, which they naturally enough felt apprehensive might leave behind it a corresponding scar. But it is quite superficial.

I have now done with the exterior membrane of the fore part of the eye—with its

mucous membrane. In examining some of its diseases, we have had the opportunity of noticing several things which illustrate the pathology of the mucous tissues generally, and which exemplify the influence of other circumstances also, as well as of peculiarities of tissue, upon the morbid processes to which these membranes are obnoxious.

We have seen that the mucous surface of the eye readily enough takes on inflammation, under vicissitudes of external temperature, and from the agency of other atmospheric conditions ; that the inflammation is apt to spread, often rapidly, over the whole surface of the membrane ; and that, in some cases, it may be strictly limited for a long time together, or entirely, to the mucous tissue in which it began ; but that when intense, or under special circumstances, it may dip through and extend to the subjacent textures : that, on the other hand, the inflammation sometimes occupies separate specks only of the membrane, and then is more likely to penetrate to the deeper seated tunics ; that although the membrane is folded upon itself, so that different portions of it are mutually in apposition and contact, these opposing surfaces do not become adherent to each other under inflammation : on the contrary, that they readily pour forth pus. This tendency to the formation of pus I formerly shewed you to be commonly observable, whenever the air finds free access to the inflamed part. The pus thus poured out possesses the remarkable property of exciting the same kind of inflammation when placed in contact with any healthy mucous membrane of the same or of another individual ; whether it be the conjunctiva of the eye, or the internal lining of the urethra. That the pus, in short, acts locally, upon certain parts at least, as a poison. And we perceive, in this fact, how a disorder that originates in common and accidental causes may become capable of propagating itself indefinitely—may become, in one word, *contagious*. We have seen also that the most intense inflammation may occur in this membrane, without exciting much or any constitutional disturbance ; an illustration of the fact that the inflammation of mucous membranes is not so prone to light up fever, is not in general attended with so much pyrexia, as inflammation of some other tissues, and especially of the serous and fibrous tissues ; and in proportion as this constitutional sympathy with the local disease is small or absent, so the influence of general bleeding upon the inflamed part is slight or ineffectual. The effect of a new and strong local irritation, in altering or superseding the original inflammation in some cases, has been illustrated in the treatment of purulent ophthalmia as it occurs in the adult subject. The influence of age in modifying the phæ-

nomena, and in qualifying the plan of treatment, has been made perceptible in the differences noticed in these respects, between purulent ophthalmia in infants, and in grown-up persons. We have witnessed, too, the remarkable characters impressed upon inflammation of the very same part, by the presence of the scrofulous diathesis. We shall hereafter meet with numerous examples of chronic inflammation, and the deposition of tubercular matter, and the formation of ulcers in consequence of the elimination of that matter, in other mucous membranes. Whether the phlyctenæ, or pustules, which appear upon the surface of the eye in strumous ophthalmia result from a similar separation of tubercular matter from the blood-vessels, near the extremities of which these prominences are placed, has not been clearly ascertained. One other lesson we have learned from this review of conjunctival inflammation, viz. that general bleeding, carried so far as to produce syncope, will sometimes completely empty the capillaries of an inflamed part of the red blood wherewith they were, just before, so turgid.

Iritis.—I shall next request your attention to a part of the organ which is strictly internal—the iris ; that thin curtain with a circular aperture nearly in its centre, which hangs between the cornea and the crystalline lens, and is bathed on both sides by the aqueous humour. This little part, the office of which is to regulate the quantity of light admitted to the retina, is of exceeding interest in respect to its morbid as well as its healthy conditions. It is frequently the seat of inflammation : and, small as it is, the inflammation seems to be entirely confined to it, or to the surfaces immediately before and behind it. No doubt, with inflammation of the iris, there is in many cases inflammation of the choroid and retina also, and of the sclerotica. But the inflammation seems to make the iris its point of departure, and there it works its most striking changes. We cannot see so well what is the actual condition of the choroid and retina ; but we have this proof, either that they do not always participate in the disease, or that they often suffer less than the iris : viz., that when the natural pupil has been closed up by lymph, and a new or artificial one has been formed, vision has frequently been restored.

The little cavity across which the iris is vertically stretched, is lined by a smooth membrane, which secretes the watery fluid always contained in the cavity. This membrane is analogous in its smoothness, in its forming a shut sac, and in the nature of its secretion, to the serous membranes met with in other parts of the body ; it is analogous also to the serous membranes, in its beha-

viour under inflammation. It *is*, in fact, the serous membrane of the eye. Now we have the means of inspecting a portion at least of several of the *mucous* surfaces of the body; but this serous cavity, constituting the anterior chambers of the eye, is the only *serous* cavity into which we have the privilege of looking, and of noting what is going on, when the membrane that forms its boundary is inflamed; and this it is that makes iritis, to me, one of the most interesting of all diseases. There is no single part of the body from which you can derive so much instruction concerning some of the minuter processes of inflammation, and concerning the power of certain medicines over those processes, as you may by watching a few examples of inflammation of the iris.

All the changes which occur in iritis depend upon the circumstance that the inflammation, like that of the serous membranes generally, is of the adhesive kind; *i. e.* is attended with the effusion of coagulable lymph. By means of this lymph the form and the colour of the part are changed; the size and figure of the pupil undergo alterations, or that aperture is completely closed up; the motions of the iris are limited, or entirely put an end to.

The symptoms which characterize inflammation of the iris are very obvious; they require only to be looked at, to be perceived and understood: yet they long escaped notice, and even now are not always so carefully studied as they deserve to be. Not a great while ago I had to convince a surgeon of some pretensions, that he did not know this disease when he saw it. And English surgeons and physicians were all of them ignorant even of its existence as a distinct disease, until a most excellent account of it was published by a German, Schmidt, in the first year of the present century.

Symptoms. — What are these plain and obvious symptoms that were so long overlooked, or that were not understood when seen? They are the following: I will first enumerate them, and then speak of each rather more particularly: — redness of the sclerotica; a change in the colour of the iris itself, and in its general appearance: irregularity of the pupil produced by adhesion of the iris to the neighbouring parts; immobility sometimes of the pupil from such adhesion; a visible deposition of coagulable lymph: all these changes are apparent and conspicuous: scientific writers term them *objective* symptoms: then there are also the *subjective* symptoms, of which the patient alone is conscious — impaired sight, pain in the eye, and around it.

Redness. — The redness is such as I formerly described as resulting from the vascularity of the sclerotic. The cornea is surrounded by a zone of t n e, straight, converging

pink lines, very different in appearance from the tortuous, anastomosing, scarlet blood-vessels of the inflamed conjunctiva. These hair-like converging lines stop abruptly at the edge, or just before they reach the edge of the cornea; they dip through the sclerotic, in fact, to go to the iris. The vascular zone therefore is well defined in front, while it becomes fainter from before backwards, and is gradually shaded off: the posterior portion of the sclerotica being generally pale. As the disease advances, and in violent cases, the more superficial conjunctival vessels also sometimes enlarge, and mingle their tint of redness with that of the sclerotic, and more or less confuse or conceal it. Now this red zone or halo continues as long as the inflammation of the iris continues, and disappears when that ceases. It is an important symptom therefore.

Colour of the iris. — The change in the colour of the iris itself is also a remarkable circumstance: you know that what is called the colour of the *eye* is simply the colour of the *iris*. When lymph begins to be effused into the texture of this coloured part, it deepens, and at the same time alters, its tint: a grey or blue eye is thus rendered yellowish or greenish; a dark eye presents a reddish tinge. The change is such as would be produced by a mixture of the colour of the lymph with that which is natural to the iris. But besides a variation of colour, the peculiar brilliancy of the surface is spoiled; it becomes dull and tarnished as it were, and the fibrous arrangement, which is usually so evident, is confused or gone. The change commences at the inner or pupillary margin of the iris, and extends gradually towards the outer or ciliary edge. This is a symptom which you can scarcely overlook; it is rendered certain and unequivocal by comparing the sound eye with that which is inflamed.

Effused lymph. — The change of colour which I have been describing is occasioned by the effusion of lymph. But the same event of inflammation leads to various other changes, not less striking, and more important, in so far as the functions of the organ are concerned. The lymph becomes visible upon the surface of the iris. Its precise appearance varies considerably in different cases. Sometimes it presents little spots like freckles, or specks of rust; or a thin stratum of the same colour is deposited. Sometimes it exhibits the appearance of drops, or (as they have improperly been called) tubercles, embossing the surface, or projecting from its pupillary edge. These are commonly of a yellowish or reddish brown colour, and they vary in magnitude from the size of a small pin's head, to that of a large shot. There are seldom more than two or three of these masses. The lymph thus effused upon, or thrusting forward the surface, is confined

almost always to that part of the iris which is nearest to the pupil, to the annulus minor; while its ciliary portion or annulus major is dull and clouded. Sometimes, when the inflammation is very violent, or the disease has been neglected, actual suppuration takes place; a reddish yellow prominence arises from the surface of the iris, and at length breaks, and discharges matter which sinks down to the bottom of the anterior chamber, and presents the appearance that has been called *hypopyon*. All these changes I say become perceptible near the margin of the iris; its free edge, which in the natural state is clear and sharp, becomes rounded and blunt; and at the same time the pupil often begins to lose its jet-black colour.

Another very common consequence of the effusion of lymph from and upon the surface of the iris, (from its hinder surface, that is, which is called the uvea, or from its pupillary edge) is its adhesion to the capsule of the crystalline lens, which lies, you know, behind the iris and very near it. And the pupil itself is apt to become blocked up by lymph.

The motions of the iris are seriously impeded by the mere effusion of lymph into its texture; at first it moves sluggishly under variations of the light; gradually the pupil contracts, and becomes fixed and motionless. The adhesion of the iris to the capsule of the lens still more decidedly restrains the action of the part. When it adheres at one or more points of the margin, and remains free elsewhere, the pupil is deformed; loses its circular shape; becomes angular; and this deformity is the most marked when the eye is examined under either a weak light, which allows the pupil to dilate, except at the points where the iris is tied down to the lens; or under a very strong light, which forces the free portions of the margin, and those only, to approach the centre. Still more palpable does the alteration of figure become when the pupil is artificially dilated.

The vision is always impaired in this complaint: partly because the posterior tunics of the eye are liable to be implicated in the inflammatory process; partly by the detriment done to the proper function of the iris, which duly measures the quantity of light admitted to the retina; partly by the presence of more or less lymph filling up the pupil; and partly by a change, not yet mentioned, which is apt to take place, especially in violent cases, in the cornea, and perhaps in the aqueous humour. The cornea becomes hazy and dull, and loses its bright polish; it looks like a piece of glass that has just been breathed upon. It has been thought (on the ground of analogy chiefly) that the aqueous humour grows turbid under the inflammation of the membrane that secretes it; just as serous effusion into the pleura is often found to be troubled and thick: but there is no evidence that this is

the case. When the cornea remains transparent, the aqueous humour is seen to be clear; when the cornea is dim and semi-opaque, we cannot distinguish the state of the aqueous humour.

Acute iritis is attended with pain, and intolerance of light. To the latter circumstance is probably owing the contraction of the pupil during the progress of the inflammation; and then the lymph *fixes* the pupil in that state of smallness and contraction. There is pain in the eyeball itself, and in the parts about the eye, the brow and temple, most severe at night. There is much variety, however, in regard to the pain: sometimes it is constant and severe, but still more aggravated in nocturnal paroxysms. Sometimes, even when the quantity of mischief that is visible is very great, scarcely any pain at all has been experienced.

The same remark applies to the constitutional symptoms. In some instances these are but slightly pronounced: but in most cases, particularly in acute cases (for iritis, as I have hinted before, is sometimes a chronic disease) there is a good deal of fever and headache; the pulse is full and hard, and the tongue white, and the sleep is broken.

If the progress of the inflammation be not checked, it extends itself beyond its original seat. It creeps from the pupillary margin to the ciliary; and thence it passes on to the ciliary body, to the choroid coat, and to the retina; and as this takes place, the pain and the pyrexia increase, and blindness is usually the result. The delicate texture of the retina is spoiled for ever.

Treatment of iritis.—I have thus described the phenomena of iritis generally: and I will next consider, in the same manner, the treatment which it requires. It will afterwards be necessary for me to mention certain modifications of the disease, in respect to its rapidity, its causes, and the circumstances under which it occurs: I say it will be necessary to mention these modifications, because they require a corresponding modification in the plan of treatment.

When we have to deal with iritis alone—that is, when the inflammation and the changes to which it may have led, are confined to the iris, the disease is always, I believe, manageable; and affords a beautiful instance of the power of well-directed remedial measures. We cannot always tell whether the inflammation has been restricted to the iris or not.

We have three powerful weapons wherewith to combat iritis: *blood-letting; mercury;* and a remedy that hitherto has not been mentioned in these lectures, *belladonna*.

If I was restricted to the use of one of these means, I should choose mercury; if to two, mercury and belladonna; but the combined employment of the three has the most

powerful effect in curing the disease : and cases that have seemed almost desperate, have been retrieved and rescued by these remedies.

Blood-letting. — With respect to blood-letting, I shall not run the risk of fatiguing you by dwelling at any length upon the mode in which it should be employed, or the indications for its adoption. I shall content myself with saying that the intensity of the local symptoms, especially of the pain,—and the degree in which the general symptoms, the fever, and the hardness of pulse, are present,—offer the best measure, both of the necessity for bleeding, and of the amount to which it ought to be carried. Both will depend somewhat also upon the strength and constitution of the patient. Bleeding from the arm till some decided impression is made upon the circulation ; cupping from the temples ; or both these modes of taking blood, together or in succession, will often be required. At the same time active purgatives should be exhibited; and the whole of the antiphlogistic regimen strictly enforced.

But bleeding assisted by purgatives and the antiphlogistic regimen will not cure the disease ; or it will not cure one case in a hundred. It will *stop the inflammation* probably, but not till the organ has been spoiled. Such a termination cannot with any propriety be called a cure. We want not only to put an end to the inflammatory process, but to repair the mischief which may already have been done.

Yet bleeding is not to be despised or neglected because it is unequal to the cure of iritis : it is productive of direct benefit by abating the force of the circulation, and by checking the progress of the local inflammation : and it is productive of great indirect benefit by preparing the system to submit itself more readily and rapidly than it otherwise would, to the specific influence of mercury. Mercury is our sheet-anchor in this disease.

Mercury.—After free blood-letting then, or after such abstraction of blood from the system, or from the part, as the circumstances of the case may dictate, you must administer mercury in the manner that I formerly recommended. The object is, in acute cases, to affect the gums as speedily as possible ; the soreness of the gums, and the peculiar fœtor of the breath, being the warrant that the whole capillary system feels the specific influence of the remedy. Calomel with opium is, in most cases, the best form in which mercury can be introduced into the system ; the purpose of the opium being to prevent the calomel from running off by the bowels. Two, three, or four grains of calomel, with one-fourth, one-third, or one-half a grain of opium, should be given every

four, or six, or eight hours. Equal doses at equal intervals.

Some persons prefer giving the calomel still more frequently ; one grain, for instance, with one-tenth or one-eighth of a grain of opium, every hour. If the gums do not rise in the course of thirty-six or forty-eight hours, and a speedy effect is desirable, inunction of the mercurial ointment should be added. And in some cases mercurial frictions alone may be sufficient, and the most expedient. Or the hydrargyrum cum cretâ, five or ten grain doses.

You may have bled your patient freely, and purged him well, and yet, on looking into his eye, you perceive the mischief to be still going on, and the deposition of lymph increasing. But the instant that his gums and breath acknowledge the specific agency of mercury upon his system, a welcome change becomes visible : the red zone surrounding the cornea begins to fade ; the drops of lymph to lessen ; the iris to resume its proper tint ; and the puckered and irregular pupil once more to approach to the perfect circle : and, at length, in favourable cases, the eye is restored to its original integrity, and beauty, and usefulness.

I speak now of favourable cases : the changes for the better that I have been describing are sometimes rapidly accomplished, and sometimes slowly. If the disorder has been long neglected, irreparable damage may have been done ; the effused lymph may have become organized ; or firm adhesions may have been already contracted between the iris and the lens. But even in cases of some standing, when the inflammatory action has in a measure subsided, the use of mercury will sometimes greatly improve, sometimes altogether restore, the impaired vision.

Belladonna.—With the mercury, both before and while its specific influence is manifested, we combine the use of belladonna.

Doubtless you are all aware of the singular effect of this vegetable poison upon the iris. It dilates the pupil. Now it is of great importance in iritis to prevent that tendency to contraction which the pupil manifests. If we can artificially dilate the pupil, we may prevent the iris from forming adhesions with the capsule of the crystalline lens ; and if it has recently contracted such adhesions, we may, while the lymph is yet soft, stretch or break them. And this power of artificially dilating the pupil we possess in the agency of belladonna, and certain other narcotic vegetables. This remarkable effect of the belladonna was first discovered, accidentally, by our countryman, the celebrated Ray. He tells us that a noble lady of his acquaintance applied a leaf of the plant to a small ulcer, suspected to be cancerous, just below one of her eyes. The

pupil of that eye became greatly dilated, and the membrane remained motionless under the strongest light. This effect gradually subsided when the leaf was removed. But it took place on three several occasions, and was witnessed by Ray himself. Other vegetables have the same property ; henbane, for example, stramonium, and the cherry laurel. And there are others which have it not, although we might have expected that they would possess it, from the analogy they bear to the former in other respects. It has been ascertained that neither hemlock, nor aconite, nor foxglove, nor opium, have any such power.

Preparations of *belladonna* are chiefly, if not exclusively, employed in ophthalmic disorders in this country. It is used in two ways. The extract is rendered soft and semifluid by admixture with distilled water, and then is smeared freely around the eye, upon the lids, and brow, and forehead. It is washed off after remaining an hour : it generally produces a marked effect upon the pupil.

A more efficacious and speedy mode of dilating the pupil is to drop a solution of the extract *into* the eye itself. The solution is to be made by rubbing down a scruple of the extract in an ounce of distilled water, and filtering the fluid through linen. Two or three drops of this solution are to be introduced between the eyelids.

Some very interesting experiments have been made in Germany by Dr. Reisinger upon this property of belladonna and hyoscyamus, of contracting the iris—in other words, of dilating the pupil. The result of these experiments is given in the 24th volume of the *Edinburgh Medical and Surgical Journal*. Dr. Reisinger procured the active principles of these plants, *atropine* and *hyoscyamine*, and made comparative experiments with these principles, and with the coarser extracts ; and he concludes that the former are much to be preferred to the latter. Thus he dissolved a grain of hyoscyamine in ten minims of water, and introduced a small drop of the solution into the eyes of several dogs and cats. No irritation whatever of the eye was produced in any instance, but the pupil was so much widened by the application, that in an hour's time only a small ring of the iris could be seen beyond the edge of the cornea ; and after three hours, the pupil seemed as large as the cornea itself. The dilatation did not begin to diminish till after three days ; and the pupil did not recover its natural dimensions until the sixth day Then he applied a solution of the *extract* of hyoscyamus, made by mixing five grains with ten minims of water. This evidently caused irritation of the organ, which lasted from five to eight minutes, and was evinced by a discharge of tears, by the ani-

mal's shutting its eyes, and rubbing its eyebrows with its paws. Much less dilatation of the pupil followed, and lasted not more than six or eight hours in dogs, and about twenty-four hours in cats. As soon as Dr. Reisinger had satisfied himself that the hyoscyamine had no injurious influence either on the conjunctiva, or on the deeper seated textures of the organ, he applied it to the human eye. He dissolved a grain of hyoscyamine in a drachm of distilled water, and inserted a drop of the solution into the eye of an old lady of 71, who had cataract. So great was the consequent dilatation of the pupil, that only a narrow ring of the iris remained visible. No irritation whatever of any part of the eye was produced ; and the dilatation continued for seven days.

As chemistry is now furnishing us every day, in greater abundance, and with more ease, the active principles of various of our medicinal vegetable substances, we shall soon, in all probability, adopt hyoscyamine or atropine, for artificially dilating the pupil, instead of the preparations now in use. Till that time arrives, you had better smear the surrounding skin with the moistened extract of belladonna whenever the eye is painful or much inflamed. But under other circumstances, the solution dropped into the eye is to be preferred for its readier action, and its greater power. The use of this curious virtue possessed by certain plants is not confined to the cure of iritis : it enables the surgeon to introduce instruments through the pupil with greater facility and safety ; it affords us also the means of examining the deeper seated textures of the eye ; and it is of great service to many persons who are partially blind ; to such, for example, as have central specks on the cornea, or central opacities of the crystalline lens : it enables such persons to enlarge the window of the eye ; to receive more light ; and to have the images of objects painted upon the retina, and represented to the mind ; objects which, but for the mysterious agency of these poisonous vegetables, they could never hope to see at all. It is a very fortunate circumstance that the power of the belladonna over the iris does not diminish by repetition. Mr. Lawrence mentions two patients of his, one of whom had used it habitually for four or five years, and the other for fourteen or fifteen ; and it dilated the pupil just as well at the end of these periods as at the beginning. By carefully examining an eye in which lymph has recently been effused, we may distinctly see the good effects of the artificial dilatation of the pupil : little strings of adhesion are often visible, connecting the edge of the iris with the surface of the lens ; and these are stretched, and not unfrequently broken, under the influence of the belladonna : and minute black spots may sometimes be seen upon the

capsule, marking the points where the uvea had stuck, and where it left behind it, when it was detached by the belladonna, a portion of its peculiar pigment. These black points are indelible. There is one case recorded in which the pupil, after being dilated by belladonna, became fixed in that condition ; probably by lymph subsequently effused into its texture, and binding together its fibres. Even this is better than that the pupil should be *contracted* and fixed.

These three remedies, then — bleeding, mercury, and belladonna, are the means by which we are to subdue inflammation of the iris, and repair the ravages it has occasioned. With respect to the most important of the three, mercury, there are two or three points that require to be farther noticed.

You may ask to what extent the mercury should be pushed, and how long it should be continued ?

Why we have, in iritis, an illustration of what I have more than once mentioned before, viz. that the rapidity of a disease will require a corresponding haste in the use of its remedy. In acute and violent cases, the mouth should be made decidedly sore, as quickly as possible ; and when that has been done, the farther administration of the mercury may be suspended. " Full salivation," says Mr. Lawrence, " quickly produced, cuts short recent disease, as if by a charm." In cases of longer standing, or of slower progress, we must be slower in the introduction of the remedy : it will be enough to obtain any, the smallest certain evidence of its action, in the gums and breath ; and we must keep up that moderate influence for some time. For what precise time it is impossible to say ; but till the redness is gone, and the natural colour of the iris returns, and all the visible lymph has disappeared, and the sight is perfectly restored : and this *may* require a month or two.

When you look from day to day into the aqueous chamber of an eye in which iritis has recently produced its peculiar changes, and after the due effect of mercury upon the gums has been achieved, you will be surprised as well as delighted to see large masses of lymph rapidly disappear, melt away, as it were, from the surface of the iris, while that which had been deposited in its intimate texture, rendering it confused and discoloured, as quickly clears off. And you will be inclined to believe, as many have done, that mercury has a vast influence in promoting and accelerating absorption. It *may* have such a power ; I am not disposed to deny it : but that it really has so we cannot safely infer from such circumstances. It clearly has the power of arresting the deposition of lymph ; of putting an end to the adhesive inflammation : whether it does any thing more towards completing the cure, we have these

reasons for doubting. When blood happens to be effused into the anterior chamber ; or pus ; or when, as frequently happens, pieces of a cataract that has been broken up pass through the pupil, and shew themselves between the iris and cornea ; they (the blood, the pus, the fragments of the lens) disappear, *i. e.* are absorbed, just as rapidly as the lymph in iritis, although not a particle of mercury is taken. Mr. Lawrence even gives a case of syphilitic iritis, which got well without any affection of the gums by mercury, and which had been marked by the deposition of a large mass of lymph on the iris ; and he says that the lymph was immediately absorbed, as soon as the inflammation ceased ; and that he never saw it disappear more quickly under any circumstances.

There is one local use of mercury which I must not omit to mention, because though it probably has no share in *curing* the complaint, it is productive of great comfort and relief to the sufferings of the patient. It is adapted to those cases in which severe pain is felt round and over the orbit of the eye at night. Ten grains of the strong mercurial ointment, intimately mixed with two grains of finely powdered opium, and well rubbed into the temple a little while before the nocturnal pain is accustomed to recur, will in many cases completely prevent it. We owe this piece of practice to the Germans.

Causes of iritis.—Iritis is apt to occur from different causes, and in connection with different diseased states of the system. It is no uncommon accident from surgical operations performed upon the eye, the iris suffering mechanical injury. The inflammation thus excited is usually violent and acute, and requires that the whole plan of treatment that I have been sketching out should be actively prosecuted.

But inflammation of the iris sometimes arises slowly and insidiously, without vascularity enough to call attention to the eye, and without pain. This generally happens when the eye has been strained by over use : in women who occupy themselves with fine needle-work ; in engravers, and such as are accustomed to look at *minute* objects, or at *bright* objects. A more common effect of continued exertion of the eyes in this way, is a diseased state of the *retina ;* but (however the fact may be explained) the iris is sometimes the part that suffers. In this form of the disease mercury will often be found a successful remedy ; but its influence must be gradually brought about ; and it is not so certainly productive of benefit as when it is employed in acute iritis :—probably because the chronic inflammation has involved the posterior tunics also.

But most frequently iritis is met with in combination with syphilitic, or with rheumatic disease, which manifests itself at the same

time in other parts of the body.   Syphilitic iritis is more common than any other.   It is one of the *secondary* symptoms of syphilis ; and accordingly it is commonly associated with other *secondary* symptoms ; with syphilitic eruptions, nodes, pains in the limbs, and ulceration of the throat.   It is also one of the *earlier* of these secondary affections, and therefore is sometimes the only one to be seen ; and occasionally it declares itself before the primary disease is well.   The pain that attends this species of iritis is chiefly felt at night, but at that time it is apt to be very severe and distressing, so as entirely to prevent sleep until it takes its departure in the morning.   We cannot, I believe, distinguish syphilitic iritis with any certainty from other acute varieties of the same complaint, by mere inspection of the eye.   However, there are some points worth remembering in respect of the local phenomena it most commonly presents.   Syphilitic iritis is never attended (according to Mr. Lawrence) with *abscess* of the iris, and hypopyon ; the lymph is usually deposited *in distinct masses ;* and the pupil becomes angular, and is not unfrequently displaced towards the root of the nose, by the adhesions which the iris has contracted with the parts behind it.   In another variety of inflammation of the iris (which I shall mention to-morrow, *arthritic* iritis) lymph is equally effused from the margin of the iris, but it is not usually deposited in a distinct drop-like form.   We ascertain the variety of iritis with which we have to do by these peculiarities ; by the co-existence of other tokens of syphilis ; by the periodical character of the nightly pain ; by taking into our account the age, the constitutional habit, and the probable state of morals of our patient.   Syphilis, you know, is not uncommon in children : it is sometimes even congenital : but it very seldom affects the iris at that early period of life.   Among a large number of syphilitic children brought to Mr. Lawrence, he never witnessed iritis but once.   It was in *syphilitic* iritis that the curative power of mercury over adhesive inflammation was first distinctly recognized. But you must not fall into the error of supposing that the success of the remedy depended upon the specific character of the disorder ; upon its connection, I mean, with the venereal virus.   Mercury is fully as serviceable and as sure in common acute inflammation of the iris.   Upon this point all men of experience are agreed.   " Its influence (says Mr. Lawrence) is not confined to the syphilitic form of the disease, but extends *equally* to the idiopathic."   And Dr. Farre bears testimony to the same effect.

PULMONARY EMPHYSEMA.

To the Editor of the Medical Gazette.

Sir,

The attention of the medical public has recently been called to the subject of pulmonary emphysema, by an excellent paper on the subject by Dr. Budd, in the Medico-Chirurgical Transactions. A paper on the same subject was read at the Société de Physique et d'Histoire, in the year 1837, by Dr. Lombard, of Geneva, who favoured me with a copy of it.   As it contains a great deal that is still new upon the subject, I have endeavoured to give such an abridgement of it as will explain his views, which, being founded on anatomical investigations, I believe will be interesting to your readers.   The beautiful coloured illustrations are not the least valuable part of the work, and from them I have selected one figure which will serve to illustrate the author's views.—I have the honour to be, sir,

Your obedient servant,

R. H. Goolden, M.D.,
Fellow of the Roy. Coll. of Phys., Physician
to the Seamen's Hospital, Dreadnought.
8, John Street, Adelphi,
Jan. 19, 1841.

Magendie, in some papers published in 1821, has shown that the number of the *pulmonary vesicles* decreases, and that the dimensions of each vesicle increase with the advance of age, so that the lung which is dense in the infant is less so in the adult, and is still further rarified in old age.   This fact has been confirmed by the researches of MM. Hornman and De Chambre, especially in reference to the atrophy of the lung in old persons.

Pulmonary emphysema appears to be very like this atrophied state of lung, except that it affects adults and children, though more seldom than the aged. There is the same anatomical condition, but in the emphysematous lung the dilatation is greater than in the lungs of old persons.

The Anatomical Characters of Pulmonary Emphysema.

M. Lombard considers that there are three distinct forms of pulmonary emphysema, designated according to the extent of lung affected in each.

1. When the lesion is confined to

some isolated vesicles, the emphysema is then termed vesicular.

2. When a whole lobule is affected, which is the most common case, we then have lobular emphysema.

3. When the same lesion affects an entire lobe, it is called *lobal* emphysema.

1. *Vesicular emphysema.* — The air cells of the lungs, when they are emphysematous, may either be isolated or collected in groups of three or four. Their situation is usually at the border of the lung, though they are occasionally found elsewhere. They elevate the pleura, forming small vesicles very like pemphigus. These vesicles are larger than they appear, since the projecting portion is less than that which is excavated within the tissue of the lung.

When the vesicles acquire considerable size, they are invariably formed by the union of several air cells, the walls of which have been destroyed. The cases of simple dilatation of an air cell resulting from true hypertrophy must be very rare, as M. Lombard has not met with one ; and all those which he had an opportunity of dissecting, which were at first single in appearance, were found upon examination to consist of several cells, their internal surfaces presenting anfractuosities and lamellæ, traces of old intervesicular partitions.

2. *Lobular emphysema.*—This form consists in the dilatation of the air cells in an entire lobule ; not that they are all equally dilated, but that the whole lobule must be more or less in this morbid condition : the divisions of the lung, and the independence of each lobule, being easily traceable in this second form.

As the enlargement of isolated cells produces the vesicular appearance, which in the first form was compared to pemphigus, so in this second form the enlargement of an entire lobule causes a hernia from the lung, which projects like an additional lobule.

This explains the formation of the *lobular appendices* which are found attached to the margins of the lungs.

If we observe the pedicles by which they are united to the lung, we find them in some cases to be formed of dense cellular tissue, without any trace of air cells; in others we may detect the air cells unobliterated, shewing a communication between the emphyse-

matous appendix and the rest of the lung. The pedicles vary in length, but are usually so short that the appendix appears to be attached immediately to the lung.

In these hydatiform or lobular appendices are found all the varieties of emphysema, from the unequal dilatation of a few cellules to the destruction and coalescence of all the vesicles into one single cavity.

The *cavities* of emphysematous lobules differ in size, their diameters varying from the fraction of a line to one or two inches; their inner surface is anfractuous and lamellated, or else they are crossed in every direction by shreds of a tissue like small transparent laminæ, which, when detached, are of a pearly white colour like the laminæ of an onion. This indicates the formation of these cavities by the destruction of the walls of several smaller cells. When in an emphysematous lobule some of the cells only are increased in size, they are usually those which are the most superficial, and the lesion is the greater in proportion as the cells are situated further from the centre and more towards the surface of the lobule. A lobule is never found to be emphysematous in the centre, and normal at its periphery. The air cells which are situated at the surface of the lung are more easily and to a greater extent distensible than those at the centre, because at the surface of the lung the extension of the pulmonary tissue is opposed by the pleura alone, which, with all the serous membranes, has the properties of perfect flexibility and distensibility.

3. *Lobal emphysema.*—The emphysema which occupies an entire lobe presents two very distinct varieties.

In the *first* the lobules are all emphysematous, but in very different degrees.

The *second* is where all the tissue of a lobe or even of a whole lung is changed into a spongy mass, so bulky that one would imagine it to be hypertrophied ; but, as will be seen presently, this augmentation of bulk depends upon atrophy and not hypertrophy of the areolar tissue, which, having lost its elasticity, suffers itself to be distended by the air inspired.

The natural state of the lung in people of an advanced age approaches the second variety of emphysema lobare.

When the dilatation is uniform, and

throughout an entire lung, several cir-
cumstances are observed which it is im-
portant to remark.

1stly. The vesicles, although *appa-
rently* similar in form and size, *are not so,*
some being distended to three or four
times their natural state, whilst others
are scarcely enlarged at all. In some
portions of the lung the anfractuosities
are found very distinct, whilst in others
the tissue does not present any well
marked solution of continuity.

2dly. The obliteration of the blood-
vessels, or at least their diminution in
number and size. The tissue of the
lungs in its normal condition is of a
deep red colour, and traversed in all
directions by a number of capillaries,
whilst in the emphysematous state it
is like a honey-comb, and nearly blood-
less.

3dly. The destruction, or at least the
dissolution of the cellular tissue, which
in the normal state separates the lobules,
so that the divisions of the lung and
the independence of each lobule, which
were observed in the second class or
lobular emphysema, are no longer
traceable, whence the lung appears uni-
form and without intersections through-
out the whole extent of a lobe.

The Theory of the Formation of Pulmonary Emphysema.

The question is, whether the enlarge-
ment of the air cells depends upon hy-
pertrophy, or by the union of several
single cells, which are distinct in the
normal states, but united into a single
cavity by the obliteration of the inter-
vesicular walls. Laennec and Andral
considered that emphysema might re-
sult from either, but Louis and Stokes
attributed it to hypertrophy.

On examining a slice of lung pre-
viously dried, by the microscope, we
find that the increase of volume of the
lung does not at all depend upon the
thickening of its tissue, which, instead
of being dense and firm, as it would be
if it were hypertrophied, is light and
pervious ; the intersections of it are
either demolished, or are so much at-
tenuated, as to be transparent.

The figure represents the appearance
of a section as seen under the micro-
scope ; it has been sliced off with a
razor from an emphysematous lobe,
and placed on a black ground, in order
to bring out the details.

Superiorly and a little to the right

the pulmonary tissue is seen nearly in
a healthy state ; the vesicles continue
sound, and appear to occupy the whole
space. In the centre and towards the
left the large divisions only are observed,
most of the vesicles and intervesicular
walls having there disappeared, and at
the lower part even those large parti-
tions are broken up to give existence
to cavities of still larger dimensions ;
but there may be observed traces of
former partitions, having the appear-
ance of plates loose at one of their
edges, and attached by the other to the
internal surface of the cells ; they form
processes very like the alveolar parti-
tions of a honey-comb.

The attenuation and transparency of
the intervesicular walls, their loss of
colour, and elasticity, are evidently
caused by the destruction of the blood-
vessels which traverse the lung in every
direction when it is in a healthy state,
and form of it an erectile tissue, as it is
described by Bourgerie.

Obliteration of the capillaries is a
pathological condition invariably found
in emphysematous lungs : the figure
shews how the blood-vessels, which ap-
pear like threads, stop abruptly in the
large divisions, instead of being distri-
buted all over the vesicles.

Thus in pulmonary emphysema it is
shewn that there are two pathological
conditions which are essential to its
existence.

1st. The destruction of a consider-
able part of the intervesicular walls,
and the coalition of several air cells
which were originally distinct, into one
irregular cavity.

2d. The obliteration of nearly all the

capillaries in the emphysematous portion.

To complete the pathology we must trace the relation which these two conditions bear to each other as cause and effect, by ascertaining which of the two necessarily precedes the other.

Did the destruction of the intervesicular walls precede the obliteration of the blood-vessels, hæmoptysis would evidently be one of the most constant symptoms of the disease at its commencement; and this hæmorrhage would be considerable, for we see whole lobules of three or four inches circumference changed into single cavities, which remain constantly open, and are large enough to contain a walnut. But of 35 cases observed by M. Louis, only one was affected with hæmoptysis, and this one subsequently shewed signs of tubercles : from which it may be inferred that hæmoptysis is not one of the symptoms of emphysema, and, consequently, that the destruction of the intervesicular walls does not precede the obliteration of the blood-vessels.

According to the law in pathology that when an organ is no longer useful it becomes atrophied, shrinks, and at length disappears; when the pulmonary tissue ceases to be supplied with blood-vessels, the walls of the vesicles become attenuated, and finally disappear, leaving those anfractuous cavities which constitute emphysema; the walls of these cavities are atrophied, have lost their elasticity, and are consequently incapable of expelling the air.

From this result two important phenomena.

1st. The permanent state of tumefaction of an emphysematous lung.

When the chest is opened, and atmospheric pressure is allowed to act upon the lungs externally, their natural elasticity causes them to collapse; but when any portion of them is emphysematous its elasticity is destroyed, and there remains no force sufficient to expel the air from the diseased part. This gives it the appearance of being forcibly inflated, and accounts for the increase of volume which has led some anatomists to consider emphysema as an hypertrophy of the pulmonary tissue.

This increase of volume, even where the lungs protrude when the thorax is opened after death, is not repugnant to the supposition that the lung be in a state of hypertrophy, and consequent

inelasticity. For during life the thoracic cavity was preserved at its largest dimensions by the action of the inspiratory muscles, and the emphysema has progressively increased until even this preternaturally enlarged cavity was almost or entirely occupied by distended lung. When in death the inspiratory muscles are relaxed, the thoracic cavity would sink to its natural dimensions were it not supported by emphysematous lung, in which state it is firmer and more difficult to break down than when it is healthy and crepitant, for the same reason that the healthy lung is firmer under pressure than one which is engorged and hepatized.

2d. The lobular appendices, where the lobules instead of preserving their primitive forms become herniæ, and really increase its volume. But even in this case there is no true hypertrophy, for the pulmonary tissue, so far from being more dense and solid, as would be the case were it hypertrophied, is, on the contrary, preternaturally distended and almost destroyed. It has been supposed that the efforts of coughing play an important part in this distension of the lobules, and Laennec thought that emphysema was the result of bronchitis; but M. Louis' observations contradict this opinion, who ascertained that in one-fourth only of the subjects of emphysema observed by him, was there sufficient cough to account for the dilatation of the air cells until after the existence of dyspnœa, when the emphysema might be considered as already established.

The increase of volume is attributed by Dr. Lombard to the expansion of the air confined in a tissue of a much higher temperature than the atmosphere, where the tissue being no longer supplied by capillaries has lost its elasticity.

I think such an explanation far from satisfactory. If a stove be lighted in a cold room, as it raises the temperature of the atmosphere it does not increase the barometric pressure unless the room be first made air tight. I believe the emphysematous lobule to be in the same category with the warmed room. The lobule must be made air-tight by blocking up the entrances or bronchial tubes leading to it, before the increase of temperature can cause dilatation, and the evidence is rather against the

fact of there being obstructions in those tubes. But supposing (which is more probable) that the pressure of the atmosphere throughout the whole bronchial canals be very nearly equal, it is natural to expect that it would the most distend the weakest lobules, or rather those lobules which have the least elastic force to oppose the pressure ; and if there be a few lobules much less elastic than the rest, they would naturally be distended and left in a condition presenting the appearance of hydatiform appendices. This, I believe, would be a sufficient explanation of the mode in which emphysema is developed, without having recourse to bronchitis for an exciting cause ; at the same time we must admit that coughing, playing on wind instruments, straining for any length of time, when the breath is held, in order to fit the chest for athletic efforts, must tend more speedily to develop the disease.

Pulmonary emphysema is, therefore, a morbid condition of lung, commencing with the obliteration of the capillaries, which afterwards destroys the air cells, changing them into large membranous and irregular cavities : it is a partial destruction of the organ, which renders it perfectly useless for the purposes of respiration.

An Explanation of the Symptoms of Emphysema of the Lungs, by the nature of the Anatomical Lesion.

The symptoms may be divided into two groups.

The one is the immediate consequence of the retention of air within the lung. The other is produced by the obstruction of the circulation, and inaptness of the diseased portion to perform the function of respiration.

To the first group belong—

1. The sonorousness of the chest ; since a considerable quantity of air remains confined within the lung.

2. Distortion of the chest. It is a common observation, that the walls of cavities mould themselves to their contents; and if the lung continues permanently in a state of distension, the chest will be developed in the same proportion.

3. Absence of the respiratory murmur, the natural consequence of the fulness of the lung, which, being already distended to the utmost, can receive no more at each inspiration.

4. Atrophy of the inspiratory muscles, which Dr. Stokes has remarked as the consequence of the forced extension in which they are maintained by the morbid distension of the lung, and which may in a measure account for the weakness of the inspiratory sound.

To the second group belong—

1. Palpitations.

2. Hypertrophy and dilatation of the right ventricle.

3. Dropsy, resulting from the obstruction to the pulmonary circulation through the morbid lung.

4. Dyspnœa, where there is a greater supply of venous blood than the diseased lungs can arterialize. This explains the various causes producing a paroxysm of asthma ; such as exercise, mental emotion, stimulants, which increase the circulation, a full stomach, the recumbent posture, preventing the descent of the diaphragm, obstructions of the air-cells or lobes, which prevent the lungs from using their full power in performing the respiratory function.

5. The frequency of pulmonary catarrhs, the result of the increased activity of the healthy parts of the lung, in those patients in whom a whole lobe, and frequently a whole lung, is perfectly useless for the purpose of respiration.

AN ACCOUNT

OF SOME

CASES OF UNNATURAL NARROWNESS OF THE AORTA,

AND OF THE CONSEQUENCES OF THIS MALFORMATION ;

With Observations on the Causes which produce the Communications between the two sides of the Heart.

BY T. WILKINSON KING,

Lecturer on Pathology at Guy's Hospital.

[*For the Medical Gazette.*]

WRITERS on the heart do not appear to have noticed the fact that the aorta is every now and then to be found disproportionately small, and still less have they considered the consequences of this congenital defect, although it is probable that most museums contain some illustrations of these circumstances, which, however, have been hitherto overlooked. I have thought

it well to bring forward the present topic, in connection with some others which may appear naturally to belong to it, and I hope that the several points will assist to elucidate each other.

It is first proposed to relate the chief particulars of some cases in which the aorta was found unusually narrow, along with general signs of a difficult circulation, but without any perversion of the course of the blood; in the second place, to consider the circumstances which produce the communication of the ventricles; and thirdly, those which cause imperfection of the septum of the auricles. It seems scarcely necessary to say that these last explanations are still wanting in the pathological history of the heart.

Cases of Preternatural Narrowness of the Aorta.

M. Bouillaud relates the appearances of the heart of a leucophlegmatic girl, between 17 and 18 years of age; and in this case, probably, the primary difficulty in the circulation was in the aorta, which was 1 inch and 10 lines in circumference. The heart was nearly twice as large as the girl's foot, with general dilatation and some thickening. All the other orifices were dilated.

M. B. gives the circumference of the aorta, as deduced from measurement, in four men, between 16 and 24 years of age, as follows:—

Mean, 2 inches and 5½ lines French.
Max. 2   ,,   ,,   8   ,,   ,,
Min. 2   ,,   ,,   4   ,,   ,,

Dr. Guy, of King's College, has favoured me with the following results obtained by himself and Dr. Rankin, from careful examinations, made some years since at Guy's Hospital, on healthy adult hearts. The parts were measured in ten males and in nine females. The numbers express inches and lines:—

	Max.	Min.	Med.
In Males, the circum-			
ference of the aorta, 3	5	2 3	2 9
In Females 2	11	2 1	2 5

M. Bizot gives a mean for all adult males, of 45 lines; and for all adult females, 41 lines.

The last I quote from the Cyclopædia of Anatomy and Physiology. The measure is, I presume, French, since the same article contains the French measurements of Bouillaud.

Taking the French inch to be 1·13th

more than the English one, M. Bouillaud's case, quoted above, had the aorta a little less than two inches in circumference (of our computation), while his mean, taken from males, is pretty exactly as that of Drs. Guy and Rankin; which last, however, is more general.

M. Bizot's mean for all adult males is about half a line short of 3½ inches; that for females is about 3 inches and 2 lines (English).

With respect to the minimum circumference of the aorta, measured, as it is said, in healthy hearts, I make very little hesitation in concluding that it is estimated below the truth, being taken chiefly from cases of wasting disease: thus the calculation of the mean may be also reduced too low, especially when it is to be compared with the examples of which I treat, which are cases of undue arterial distension or tendency to dilatation.

Lastly, it ought to be remembered that the minimum is at least a disadvantageous state; and farther, in the cases of Drs. Guy and Rankin, which I have had the opportunity of observing, I suppose that it ought rather to be regarded as a morbid proportion, and liable, under other circumstances, to give rise to the consequence we are about to consider.

Case 1. (22d* 10th mo. 1840).—William Hogg, æt. 22, a labourer, from Essex, short and thickly set, with a short neck and full face, which is also florid and of a bluish tint. When a boy, his complexion led to his being called "the rising sun." His health and habits have been good. Last winter he was confined for months to his bed, with a rheumatic affection, from which he seemed to recover completely; but about the beginning of June he discovered that his abdomen and legs were swollen, and he had palpitations. Four months later he was universally dropsical, his urine coagulable, his pulse slow and weak. A communication between the two sides of the heart was anticipated, from the consideration of his bluish complexion and full face. At bed-time there seemed to be no immediate danger. He died at two in the morning.

The body was excessively œdematous and livid.

---

* The dates may serve for all purposes of reference to records or specimens in Guy's Museum.

The heart was adherent only about the left auricle posteriorly, by old and copious cellular membrane. The pericardium contained some ounces of fluid. All the cavities of the heart were greatly distended with blood; the two left, perhaps, the most. The auricles were hypertrophied very considerably, and the right ventricle still more so. The right auricle seemed the least altered of all the cavities. The tricuspid seemed only too close a valve. The valves of the pulmonary artery had full corpuscula; the circumference of the vessel here was above three inches, and its walls appeared thicker than those of the aorta, the circumference of which, above the coronary arteries, was just two inches. The coats of the aorta seemed quite natural; its crescents were rather thick and opaque, contracted and irregular; two corpuscula were large, the third was lost, and the free edge of its crescent had a granular fringe. The sinuses of Morgagni were a good deal dilated. The mitral valve was extensive, its orifice dilated, and its closure imperfect. The apices of the valvular muscles were acute and white, indicating much traction by the dilatation of the ventricle. The edges of the mitral were a little thickened and indurated, and slightly (minutely) granular. Parts of this valve, as well as the posterior lining of the auricle, presented a firm, reddish, translucent, rugous thickening. The septa of the heart were entire, but beneath the posterior and right aortic crescents the ventricular septum was membranous and thin, transmitting light, and at a point but just closed: this is the spot which perforations almost constantly occupy. There was much old pleuritic adhesion, and the lungs were full of fluids.

The remainder of the body was not examined.

Case II. (19th 6th mo. 1837).—Sarah A. C., æt. 22, a respectable young person, of fully developed frame, who had formerly had rheumatism, and had suffered with symptoms of diseased heart for five years. Bronchitis and anasarca supervened, and finally she became hemiplegic. The brain was vascular. The inferior grey plane of the right corpus straitum was softened, too translucent, and of a dull pale and somewhat yellow tint; it appeared also a little tumid. The neighbouring part of the thalamus was similarly, but less severely altered; and it was more injected.

The lungs were pretty generally and firmly adherent: they were emphysematous and watery, and contained three or four apoplectic masses about the size of small oranges, rather firm, and dark, and ill defined. One or two other spots were less dark and close-textured, and perhaps attributable to pneumonia. Some vessels were plugged with black clot.

The air tubes were much dilated, and clogged with firm mucus. The right auricle was widely dilated with recent coagulum. The safety valve, under experiment, closed very imperfectly: its curtains were a little thickened and contracted. The right ventricle was capacious, and in a very unusual degree hypertrophic. The left auricle was large, and seemed somewhat to compress the left bronchus.

The mitral opening was a pretty large button hole; its edges thick, rough, and osseous: it closed well under injection. The left ventricle was rather small, thin, and flabby, and of a dull hue. The arterial valves were all healthy: the aorta was decidedly small. The liver was indurated, and like nutmeg. The spleen too fleshy and very dark. The pancreas rather loose in texture. The kidneys were of fair size and colour, but firm. The generative organs were not large; the ovaries were enveloped in adhesions. The intestines were œdematous, and turgid with blood.

Case III.—The specimen 1391-25. In Guy's museum is a " heart enlarged, with its apex blunted, chiefly in consequence of the dilatation of right ventricle, the parietes of which are somewhat thickened, and altered in texture: the right auricle is likewise dilated. From a young man, 22 years of age, who had laboured for some months under palpitation, anxiety, and dyspnœa, with effusion into the thorax." In this heart there is general dilatation. The aorta, in comparison with the pulmonary arteries, is decidedly narrow. The fossa ovalis seems imperforate. This person had a somewhat misshapen chest; his occupation was in cutting whale-bone for brushes; and he had been long in a cachectic state from mercury. The principal change in his lungs consisted in emphysema. There was some general serous effusion. The

kidneys are stated to have been only a little too firm, and the abdomen generally congested.

Case IV. (21st 11th mo. 1840).—John N., æt. 20, suffered some years ago with inflammation and thickening about the atlas, which subsided. The last five or six months of his life he had general dropsy, with symptoms of thoracic obstruction, and at times coagulable urine. He was tapped a few days before his death.

On inspection the face was sharp and livid; the body and legs tumid. The pericardium was adherent, and the lungs partially so; and the pleuræ presented recent fibrinous layers, with watery and puriform secretions. The lungs were emphysematous and turgid. The bronchial secretion was watery, and the smaller tubes were large, and very thick and red.

More than one-half of the lung substance was in a state of hepatization, uniformly airless, dark, red, and fleshy, but scarcely distended, and very little lacerable or watery. The trachea was narrow: the left bronchus decidedly flattened. The heart was about twice as large as is natural, and its substance dark and hard. The aorta was remarkably narrow. The left ventricle was capacious and thick. The mitral orifice was equally expanded, and the curtains wide and thick. The auricle dilated and strong. The pulmonary artery was wide and clear. The right ventricle seemed altered as the left, but in a less degree. The auricle strong and too capacious. The fossa ovalis appeared only wide and thin. There was much fluid in the abdomen, with albuminous flakes. There were various chronic alterations of the serous membrane. The liver was too membranous and pale, yet flabby and a little like nutmeg. The kidneys were a little dark, firm, and granular.

Remarks.—The foregoing cases are placed by themselves, as a set of simpler examples than those which will be hereafter related in connection with imperfections of the septa of the heart. I by no means would have it supposed that I have brought forward all the instances that have occurred to me.

It is worthy of notice that the three first cases were fatal at the age of twenty-two, and the fourth at twenty *, and

* The case of M. Bouillaud, in the previous remarks, died between 17 and 18.

that it is about this period that congenital impediments are also commonly fatal, if not destructive in still earlier life.

In the first case, that of Hogg, there is evidence of something wrong in the complexion, without any communication of the two sides of the heart. The state of the right ventricle, of the pulmonary sigmoid valves and of the aorta, indicates that the affection was congenital. The obstruction seems first and most to have implicated the left cavities of the heart, and least of all the right auricle. An account of the kidneys, &c., might doubtless have assisted to explain the dropsy.

Sarah A. C. had also had rheumatism, and the alteration of the mitral valve was evidently old, but as an impediment it was by no means equal to what is often met with. The state of the left ventricle was peculiar, receiving less than formerly, and yet not so much diminished in cavity as in firmness. The very thick right ventricle I regard as almost necessarily congenital.

The third case, like the rest, was one of dilatation, but some thickening of the right ventricle is still to be noted, not as an actual hypertrophy, but as the remains of the congenital proportions.

The fourth case is perhaps the most genuine and unmixed instance, but the whole should be compared with another series. In these cases the affection of the lungs is sufficiently accounted for by reference to the obstruction in the left side of the heart, and the undue impulse from the right ventricle.

The preceding examples may serve to prove the occurrence of too small an aorta, and lead, as I expect, to the frequent observation of the fact, and also to point out some of the chief alterations to which the narrow aorta gives rise. It has not appeared to me available to seek for specific indications of the cases in question. A degree of obstruction, not very severe, with other symptoms of difficulty, which are essentially variable, in dependence on casual external influences, seems to me all the character that diagnosis may appreciate.

Palpitation I have long concluded to be the same thing as dilatation or temporary distension of either or both ventricles: but this will bring the observer very little nearer to discriminating a narrow aorta, which, however, I sup-

pose to be always attended both by dilatation and palpitation in evident if not in severe degrees. I need not say that the heart is not at all times over full. How many things must disturb the regularity of events: — repletion, exertion, and especially climate, must necessarily produce far greater changes in the disturbed apparatus than on the healthy body; but even these last are rarely well reflected on. With respect to climate, I think I have noticed great differences in the progress of very many different kinds of disease, when comparing my own experience in England with the medical records of the south of Europe, and still more with examples before me in the West Indies. A little girl in Jamaica had had no sensible disorder in the chest, yet there was a constant sound to the ear, (and hand, if I may so speak), strong, sharp, and aneurismal, with wiry ventricular systole, which I attributed to a congenital contraction of the pulmonary sigmoid valves. Wasted by the heat, and performing all the superficial functions, at least, with great facility, such an obstruction might be without any notable ill effects to one who never caught cold.

COLOURLESS GLOBULES IN THE BUFFY COAT OF THE BLOOD.

[Continued from p. 479.]

By William Addison, Esq.

Case V.—M. W., a woman aged 68, troubled for twelve months with dry scurfy exfoliation of the cuticle of the head, and very irritable red patches of eruption on the thighs, and various other parts of the body. She has had recourse to all kinds of remedies, and been bled two or three times with only partial relief for short periods.

V. S. to ℥x.

In three minutes the surface of the blood appeared blue or purplish; this gradually changed to a full bright buff, which at length became clouded and opaque, entirely obscuring all the red particles.

Immediately on tying up the arm I removed a little of the purplish looking portion with the point of a penknife, and transferred a clear pellucid drop to a slip of glass; several colourless glo-

bules were seen floating in it by the lens. Portions were subsequently taken up, when the surface had assumed the full buff colour, and the globules were found much more numerous, as if their number had increased by standing. In ten minutes a delicate, thin, almost transparent pellicle, could be drawn up by the point of the knife, but the portions below were not coagulated in half an hour.

Case VI.—A. H., a man aged 42, ill several days with dry cough; not feverish; pulse quick and feeble: ten ounces of blood taken from the arm: the first portion in a small silver cup holding half an ounce, and the remainder in a common bleeding-basin. An hour after, the first exhibited over the whole surface a flocculent greenish-brown appearance, without any red portion, excepting a thin line round the circumference of the vessel, and a few red globules entangled in some air bubbles; the blood in the basin had a flocculent appearance, chiefly of a bright scarlet colour, with patches of greenish brown buff. After standing twenty-four hours the clot of the first, in the silver cup, presented a ragged buffy coat.

The figure of the clot is here represented, shewing the thickness of the buffy coat, and the bulging out of the lower red portion.

Specific gravity of the blood, 1060; of the serum, 1032.

The form of the clot shews the greater contractile force of the fibrinous portion forming the buffy coat, which is denser and much tougher than the red portion: the red particles apparently oppose the contractility of the clot; hence the bulging of this portion.

794 grains of blood gave 504 coagulum, and 290 serum—that is, 63·4 per cent. coagulum; 36·6 serum.

The blood circulating in the body consists of the liquor sanguinis (a clear limpid viscid fluid), and the red corpuscules. In health these two constituents of the blood, in a few minutes after their removal from the circulation, form a soft coagulum, from which the serum gradually separates, leaving the crassa-

mentum or clot of a bright red on the surface, and of a deeper red at the bottom. In rheumatic, inflammatory, or diseased blood, the red corpuscules subside more quickly, leaving the liquor sanguinis swimming at the surface, which at the first moment of its appearing is clear and limpid, looking like oil; but as it is momentarily losing its vital properties, its transparency is impaired, and numerous colourless globules are developed. The red corpuscules below, seen through this now imperfectly transparent medium, have a purplish or bluish appearance. As the liquor sanguinis (still losing its vital properties), it grows more opaque; the colourless (or yellowish?) globules become more numerous; and the colour of the red corpuscules, still less perfectly shaded through it, assume a dirty yellowish red or brown. When, at length, from further rest, a still thicker layer of liquor sanguinis accumulates, it becomes quite opaque; the colour of the red portion below can no longer be seen at all, and the surface then assumes a full yellowish buff or green. The vital properties of the mass still diminishing, a film forms, and at length perfect coagulation takes place by the thickening of the film, and the firm aggregation of the globules; more or less serum is pressed out, and the buffy coat is complete.

On viewing the circulation of the blood through the capillary vessels in the web of a frog's foot, we observe that the very frequent inosculation of these vessels forms a complete network; the meshes or spaces between them being from four to six times their diameter, which is just sufficient for the red corpuscules of the blood to pass in single rows or files: the distance between the corpuscules being unequal, sometimes two, three, or even four, appear so close as to touch or crowd upon each other; frequently a string of them will pass through a capillary in this manner; more often there are spaces between the corpuscules equal to more than the diameter of any single corpuscule. The liquid (liquor sanguinis) in which they move cannot be seen under the microscope; it is perfectly clear and colourless. I have for half an hour attentively studied this circulation, and I have seen three distinct forms of globules; the first oval, or rice-shaped; the second layer with a circular and rather irregu-

lar outline; the third with a smaller more regular circular outline, with little specks or spots.

$$1 \qquad 2 \qquad 3$$
No. 1 has a strong well-marked outline, and is the most frequent form. No. 3 has also a well-defined strong outline. No. 2 has a fainter one; and 1 and 2 may be frequently seen changing into each other. No. 3 is never seen assuming the figure of either 1 or 2: they are distinctly smaller, with specks on them.

The following notes were penned with a microscope before me:—

When a particle of salt is applied to the web of the frog's foot, the current of blood in the capillaries within its influence is retarded: the globules seem to have some difficulty in getting on; they are pushed and heaped together, and the vessels appear somewhat gorged. Where the action of the salt is more considerable, the vessels are more enlarged, and the globules are quite stationary. After a short time the globules in some of the smaller capillaries, where the salt has had only a feeble effect, begin to move more quickly, seeming to answer an impulse from behind, and a number of them may be seen to make a sudden rush through a capillary; then, for a moment or two, the vessels appear quite empty of globules, and then another lot rush through with great rapidity; next, without any apparent reason, they hold back, and are heaped together for a moment; again the channel of the vessel seems suddenly to admit them, and they hurry through it in the same manner.

On examining the web two days afterwards, one or two inflamed or enlarged red vessels were seen by the naked eye, produced by the action of the salt: the web was placed under the microscope, and the following notes penned at the time:—

In some of the larger capillaries, or smaller veins, i. e. in some of the larger vessels seen in the field, there are a great number of globules, No. 3; and it is quite extraordinary to observe the difference in movement between these round speckled globules and the oval ones: the blood globules pass in a continued stream, while, in the same fluid, in the same vessel, are a great multitude of other (lymph, No. 3) glo-

bules, which do not move, or do so very sluggishly: every now and then they move slowly, apparently urged on by the repeated knocks they receive from the blood globules. It would appear that after the capillary vessels have been acted on by the salt, that the round (lymph) globules accumulate in an unusual manner, and the blood globules repeatedly slide over and knock against them. In some of the vessels there is a rapid stream of blood in the centre, whilst at the circumference there are many stationary round spotted globules, which do not obey the impulse which urges the stream of blood, but remain or move on slowly by little starts at uncertain intervals, and with unequal pace.

The action of the salt disturbs the reciprocal action between the blood and the capillaries; under its influence the blood globules that have been passing one way in a capillary will sometimes become stationary; they are frequently seen to oscillate to and fro, apparently hesitating which way to go, and then they very often actually pass in a retrograde manner.

It is after the disturbance or inflammation produced by the salt that the three forms of globules are seen.

I infer from these observations that the blood corpuscules, in the normal condition of the circulation, move through the capillaries with a flat surface perpendicular to the axis of the vessel; hence when the circulation is seen in the microscope, the edge of each corpuscule will be turned towards the observer, and they will all appear oblong or oat-shaped: a few lymph globules may occasionally be seen interspersed among them. When inflammation is excited, various changes take place. After the lapse of a short time more lymph globules are developed, and the blood corpuscules, instead of circulating with their flat faces perpendicular to the axis of the vessel, and the edge more or less perfectly turned to the observer, turn round and pass edgeways through the vessel, so that frequently the circular form, No. 2, is seen.

As the blood corpuscule in all animals has a determinate form, and as they pass singly, one after another, in the minuter ramifications of the capillaries, it is probable that in a normal condition of the circulation they move along the vessel in a certain fixed mode. In the human subject the blood corpuscule is of a flat circular figure, like a penny-piece; and such a body in passing along a tube must do so either with the thin edge or with one of the flat faces in its axis: if in the former manner, only two points of the corpuscule will impinge on the coats of the capillary; if in the latter, it is evident that in an elastic channel, which embraces the corpuscule, the whole circumference of the vessel will be impinged on by each passing globule; the interior of the vessel will be, as it were, scraped clean, and kept clean by every passing corpuscule.

In the rheumatic case (No. 3) mentioned in my last communication[*], I separated the lower red portions of the clot from the upper buffy coat by maceration in water, and by breaking down gently the friable coloured clot. I then obtained a rose coloured cake, smooth on the upper surface, but on the under surface, from which the red portions had been washed away, there were numerous flakes, flocculi, and tufts seen, as the cake lay in clean water. This surface also felt granulated and rough to the finger; it was very similar in the sensation conveyed by the touch, and in appearance, to the inner surface of the pericardium, and to the exterior of the heart, in some of those cases where the rheumatic inflammatory action attacking these organs has proved fatal with dropsical symptoms. The feel and appearance of the under surface of the buffy coat, after being cleansed of the red portions, reminded me of the following two cases which occurred in 1838.

Case VII.—J. P., aged 28, two years ago was attacked with acute rheumatism in a very severe form, which confined him to bed for several weeks; he was treated by bleeding, leeches, and colchicum, and had a protracted convalescence. A short time after, working rather harder than usual at his trade (a carpenter), he first found his breathing short, with some tendency to swelling at the ankles, and he applied at the Dispensary for relief from these symptoms. The usual treatment by purgatives, mercurial alteratives, and diuretics, removed them, and he was able to go on with light work. After some time, however, they again in-

creased; the ankles were more swollen, the breath easily disturbed, and the abdomen had evidently some fluid in it. Two or three doses of elaterium, with two small bleedings, relieved him greatly; and after a little while he resumed his occupation. The amendment did not continue long; he became more troubled with the shortness of breath and ana-sarca, together with cough; the urine was scanty, and coagulated by heat. Elaterium and digitalis afforded him marked relief. At length, after pro-tracted suffering, having been twice tapped, &c., he died.

Two days after the body was ex-amined: the surface was of an intense yellow hue; the lips, thighs, and abdo-men, were covered with petechial spots, which had been evident some time pre-vious to death. Upon cutting through the cartilages of the ribs, a great quan-tity of bloody serum flowed out, which was found to be issuing from the peri-cardium, wounded by the point of the scalpel. Upon raising the sternum the pericardium was found entirely covering the lungs, both left and right, occu-pying the entire front of the chest; and quite a gallon of the bloody serum (estimating that which was lost) was found contained in it. The fluid was in fact of a deep chocolate colour, and the whole internal surface of the membrane was of the same dark colour, and studded all over with shreds and flocculi of lymph. The heart was enormously enlarged, and entirely and thickly covered with a similar shaggy coating. The parietes of the left ventricle were nearly an inch in thickness; the peri-cardium also was much thickened. The heart, with the adhering pericardium, after having been well washed and drained of blood and coagula, and dried with a cloth, weighed 2lb. 6oz. avoirdu-pois. The liver was much enlarged, and looked when cut into like porphyry. The spleen was firm, with a dense white external coating. The kidneys were quite healthy, and the bladder empty.

CASE VIII.—W. D., a lad aged 17, had rheumatism three years ago, and has been subject to the disease occasionally ever since, particularly during the winter. Was attacked severely in the autumn of 1837, and remained ill more or less during the winter. When I first saw him, in February 1838, there was considerable difficulty of breathing, a quick pulse, and feverish symptoms;

altogether sufficiently indicative of dis-eased heart. Various remedies were had recourse to, but the disease went on; the breath became more and more em-barrassed, notwithstanding occasional periods of relief from the measures em-ployed; the ankles began to swell, the face puffed, and he died on the 25th of March.

The left lung was hepatized; the liver enlarged, and mottled yellow. The heart exhibited an interesting specimen of rheumatic disease, very different from the former case, just related. The peri-cardium was firmly adherent to the heart throughout, so that it was diffi-cult to separate them, requiring to be dissected off; and in doing so the knife cut through a dense cartilaginous con-nection, with points of almost bony hardness. After well washing and drying, the pericardium and heart to-gether weighed 1¾ lb. avoirdupois.

There can be no doubt that in these, and similar cases, the flocculi and shreds of lymph are formed of the same material as the buffy crust of the blood.

CASE IX. — M. G., a woman aged 74, ill four days with oppression of the breath, pain in the chest, cough, thirst, and loss of appetite; tongue furred; pulse 108, weak, small, and oppressed.

Venæsect. ad ʒviij.

Blood drawn into two cups; in four minutes the surface had assumed a dirty yellow clouded appearance. The liquor sanguinis, to which this appearance was owing, was full of globules, and the clouded opaque aspect which ob-scured the view of the red particles was attributable to their development. In six minutes the surface was still fluid, and I skimmed off something more than a fluid ounce, without any red particles, or so few of them as only sufficient to tinge the fluid of a pale pink colour.

On the succeeding day the patient was not seen. On the next following, or forty-two hours after the bleeding, I examined the cups, and no serum had separated in either of them: in two, the blood was a soft jelly, and the liquor sanguinis in the other was the same, but much firmer, and of a pale rose colour; so firm, indeed, that I inverted the cup on the table, and left it so for a minute or two, without a single drop of serum escaping, or without any separation of the coagulum from the

cup. I could not do this with the blood in the other two cups; the surface of which, on turning the cups on one side, was so soft as to be thrown into a fold, and if the cup had been inverted it would have fallen out. The coagulated liquor sanguinis weighed 587 grains, and upon being freed from the sides of the cup and turned out, a drop or two of serum only escaped; it was then placed on a piece of muslin and gently pressed, when a quantity of clear straw-coloured serum flowed out, like water out of a sponge; and notwithstanding the firm pressure I used, it escaped without the slightest opacity or tinge of red whatever. Several times after pressing it firmly, and getting all the serum I could out, more would escape, after allowing the clot to rest for a few minutes, on pressing it again. This left a firm, elastic, tough, pink clot, or mass of fibrine, about 1-10th its original size, not at all broken down by the firm pressure, but retaining precisely the plano-convex form it originally assumed in the cup.

On examining by the lens some of the last drops of the serum which separated, I found in them a great many globules or granules of large size; these might have been loose particles of fibrine—if so, they had a definite globular figure, more numerous and larger. This mass or clot of fibrine weighed 109·5 grains: hence 587 grains being the original weight, 478·5 grains (or very nearly seven fluid drachms) of serum had been squeezed out. The serum (478·5 grains) was heated in a cup over the fire, previously mixed with a little water; coagulation did not readily take place. I therefore added to it a few drops of vinegar, which gave rise to a strong urinous odour, and the albumen immediately separated like curds. The fluid was then strained off, and the coagulum squeezed dry; it weighed 233·5 grains.

The fibrine and albumen were then dried by a gentle heat. The former became a tough horny solid, shrinking very much: when dry not being more than a fifth or sixth of the bulk it was after being squeezed dry, and not a twentieth of its original bulk, it now weighed 16 grains. The albumen, by drying, did not shrink in bulk more than one-half, and formed a brittle transparent resinous solid, weighing 33·5 grains. The fibrine, by drying,

shrinks in a singular manner. Hence 587 grains of the buffy coat of the blood contained 109·5 grains of moist fibrine, or 16 grains of dry fibrine; and 233·5 grains of moist, or 33·5 grains of dry albumen.

In this case, then, 16 grains of fibrine were sufficient to solidify 587 grains of the liquor sanguinis, the serum being retained by or contained in the pores or interstices of the mass, and flowing out only under considerable pressure. On removing the pressure the mass retained its original shape, but did not, like a sponge, exhibit the least tendency to resume any portion of its original bulk; on the contrary, it had more the appearance and mechanical texture of soft caoutchouc.

Great Malvern,
Jan. 12, 1841.

DEATH FROM CARBONIC ACID.

To the Editor of the Medical Gazette.

Sir,

I send you the following case for insertion in your valuable journal, if you consider it of sufficient interest.

I am, sir,
Your obedient servant,
Charles Collambell.

Canterbury Place, Lambeth,
Jan. 20, 1841.

The subject of the following case was by trade a painter, ætat. 23. On the morning of the 6th of January, at half-past eleven A.M., he was employed at the Archbishop's palace to clean the windows in some small rooms on the basement story. These rooms are three in number, and are of the following dimensions :—Length, 8 feet 10 inches; height, 7 feet 6 inches; width, 11 feet 11 inches; the first or external having a door opening into a court-yard, and all communicating with each other by a central door, having each a window, but no fire-place.

A brazier of burning charcoal had been placed in the first room, for the purpose of drying it; but upon the deceased going to work he had shut the outer door, and removed the brazier from the first into the third room, leaving the other two communicating doors open. At half-past one P.M., he was found lying on the floor in the middle room, and apparently dead. My attendance was immediately requested, and

on my arrival I found the deceased on a table supported by some of his fellow-workmen, and quite dead. The countenance pale, eyes very bright and staring, pupils widely dilated, lips exsanguine, jaw firmly fixed, tongue not protruding, face and extremities cold. When first discovered a very considerable quantity of frothy mucus had escaped from the mouth : no other person had been in the same apartment, and from the deceased having been up all the preceding night, it was supposed that, feeling fatigued, he had laid down to sleep, which was confirmed by his not having commenced his work. He had been in the room two hours when discovered, and the ashes in the brazier were in a very low state of combustion. The person who first entered the room felt considerable oppression in breathing, from the state of the atmosphere. The deceased was perfectly sober when last seen alive.

An inquest was held on the 11th instant, and a verdict of " Accidental Death" returned.

After the inquiry I obtained permission to examine the body, but was obliged to do it very hastily, as the friends were waiting to remove it into the country.

No appearance of decomposition ; slight discoloration of depending parts from gravitation : in other situations the body was unusually pale.

Head.—On cutting through the scalp a small quantity of dark fluid blood escaped. Vessels on the surface of the brain highly distended with dark fluid blood. Pia mater bedewed with serum. Brain of unusually firm consistence; and upon slicing it numerous bloody points issued from its medullary structure, upon wiping the surface of which the blood immediately reappeared from the divided vessels. Lateral ventricles distended with about an ounce and a half of pale serum ; vessels of plexus choroides much congested. Cerebellum of a very firm consistence, and upon being cut into also presented numerous bloody points. About two ounces of serum, tinged with blood, collected at the base of the skull, much of which had flowed from the theca spinalis.

Muscles rigid ; some fat under integuments of chest and abdomen; pectoral and abdominal muscles finely developed, and of a very bright red colour.

Chest.—Both lungs entirely filled their respective spaces, and did not collapse upon raising the sternum; their anterior aspect of a dark slate colour; the posterior of a very deep livid colour; universal crepitation upon pressure; eight ounces of serum tinged with blood on the left side of the chest, and about six ounces of similar fluid on the right. Upon cutting into the lungs an amazing quantity of serous fluid, mixed with blood, escaped ; and although this appearance was most decided at the posterior and inferior parts, it was very apparent at the superior and anterior portions of each lung. Bronchial tubes filled with frothy fluid tinged with blood.

The pericardium contained about an ounce of pale serum.

Heart much enlarged; very considerable hypertrophy of left ventricle, with dilatation of left auricle and ventricle. All the cavities free from blood ; but upon pressing on the course of the aorta some very dark fluid blood returned into the left ventricle. Valves healthy. Four or five pounds of dark fluid blood were removed from the chest, which had escaped from the divided vessels.

Abdomen.—Liver very large, and much congested with dark fluid blood. Kidneys also very large, and similarly congested. Mesenteric vessels distended with dark fluid blood, and the minute branches supplying the small intestines highly injected, diffusing over them a general blush of redness.

The congested state of the lungs and brain might partly have arisen from the dilatation and hypertrophy of the heart; but I think the general post-mortem appearances leave little doubt that the inhalation of carbonic acid gas was the immediate cause of death.

ON THE

MEANS OF IMPROVING THE FINANCES AND EXTENDING THE PROTECTION

OF THE

COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

SIR,

THE *Quarterly* says, the College of Physicians is " poor even to bankruptcy*.'' Arrangements are said to be going on for the self-reform of an institution

* We suspect it was a much less authority than the *Quarterly*, viz. the MEDICAL GAZETTE, which used this expression.—ED. GAZ.

capable of being rendered the most powerful instrument for upholding the dignity and honour of our noble profession. Whatever may be the nature of the changes contemplated, the following hints may not be thrown away upon that portion of your readers connected with the College council.

Let the College obtain the power of rendering its license necessary for every man in England who practises as a physician.

There are 118 physicians to the provincial hospitals and dispensaries : 25, only, of these gentlemen are licentiates of the London College, (Farr's Medical Almanack). Among the many hundreds of provincial physicians, but very few are on the College list: indeed, scarcely any but those who are looking forward to the metropolis. Many lecturers in the recognised medical schools, and many contributors to the Cyclopædia of Practical Medicine, are without the license.

The reason of the indifference to the possession of the license in the provinces is the contagious example of celebrity and prosperity enjoyed by the Pritchards, Hastings', Barons, Barlows, Headlams, Bardsleys, &c. &c. These eminent practitioners are the medical attendants of our nobility during the parliamentary recess, and their well-earned reputations render them *nullis secundi*.

English law is rarely or never retrospective ; but should the College exercise a just lenity towards the regular graduates of Edinburgh, and other universities, who have been some years settled in actual practice,—in the same spirit as they grant degrees to practitioners beyond forty years of age,— and limiting the examination (unpreceded by regular grinding) to one or two days, instead of requiring three or four journies to town during a period of as many months, there can be no doubt that the greater portion of the physicians, established in country practice, would feel it an honour to be enrolled as members of the College under its new constitution.

Similar regulations might be enforced in Scotland and Ireland, and an *ad eundem* license secured from their respective Colleges secured throughout the united kingdom.

The College, however, might even extend its power of national and professional utility. The legal compulsion to receive its license would raise the moral and intellectual standard of the profession, and place it on a footing with the admirable organization of the Prussian Faculty, which allows no M.D. to practise on the strength of his diploma *per se*, but enjoins the ordeal of another examination as a qualification for practice.

The object of the intelligent Perceval, moreover, might be carried out by the stamp of legal authority vested in the College. The College might establish a court or courts of arbitration or appeal (as in France and Germany), for settling the various disputes which occur every day in the absence of an established code of medical ethics. The old laws of the College endeavoured to regulate such matters in the metropolis, and why should not protection be extended to the provinces ? Under collegiate arbitration the various relations of physicians with each other in consultation, and the relative position and duties of physicians in connection with general practitioners, would be imperatively fixed, and the disputes from personal jealousy, owing to the peculiar nature of the profession, and which in law and divinity are comparatively unknown, would cease to be the opprobrium of medical society in every large town and city throughout the empire.

Your obedient servant,
A PROVINCIAL PHYSICIAN.

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Elements of Electro-Metallurgy, or the Art of working in Metals by the Galvanic Fluid. Illustrated with Woodcuts. By ALFRED SMEE, Surgeon. London : E. Palmer, and Longman, Orme, & Co. 1841.

MEDICAL men in active practice cannot reasonably be expected to keep up a very familiar acquaintance with new discoveries in natural philosophy. Yet if there is one branch which deserves a little more than ordinary study, it is electricity. Its energetic effects upon our nerves and muscles : its connection with chemical combinations and decompositions ; its power of accelerating

the flow of fluids through capillary tubes; its mysterious connection with the cause of heat; the existence of a palpable electrical force in certain animals; the influence of peculiar states of atmospheric electricity upon our feelings, not to mention its asserted power of supplying the place of the nervous energy: these, and a multitude of other facts, seem to shew that much aid might reasonably be expected from it in controlling the operations of the animal economy. And although its success hitherto has not been commensurate with these expectations, may not its apparent failure be fairly attributed to our imperfect acquaintance with the laws of its operations, and to a hasty and violent mode of using it, rather than to its intrinsic inefficacy? Ought it to be entirely neglected because a few shocks or sparks will not cure an inveterately palsied limb, or amaurotic eye: for it cannot be denied that its most frequent use is as a last and desperate remedy for cases that admit of no cure from it or anything else.

Now however, when, as Mr. Smee says, " a person may enter a room by a door having finger plates of the most costly device made by the agency of the galvanic fluid—when the walls of the room may be covered with engravings, printed from plates originally etched by galvanism, and multiplied by the same fluid—the chimney-piece may be covered with ornaments made in a similar manner—at dinner the plates may have devices given by electrotype engravings, and the spoons gilt by the galvanic fluid,"—we may reasonably hope that medicine will not be behind the other arts in enlarging the application of electricity to the increase of human health and comfort. For now it seems that galvanic batteries are no longer to be confined to smoky laboratories, or to be stared at in fruitless wonder from the benches of a lecture-room; but will be the prime movers of manufactories and the indispensable appendages of ladies' boudoirs; etchings may be made on plates of pure galvanic copper, and these may be *bitten in* by galvanism, without the suffocating nuisance of nitrous fumes. Pictures, coins, statues, woodcuts, and daguerréotypes, will all be multiplied with ease; antiquities need never perish, and novelties need never be scarce.

Mr. Smee's book is not a mere com-

pilation from other men's labours, but it consists principally of the results of his own experiments, by which he has fully developed the laws of metallic precipitation. To the manufacturer and the artist it must be invaluable, from the multiplicity of information it conveys on the subjects of gilding, plating, making coins and medals, copying seals and plaster casts, sculpture, printing, and engraving. The botanist may learn from it how to make an imperishable *hortus siccus.*

" A pretty application of the art of coppering," says our author, " is suitable to horticulturists, as, by its means, fruit, vegetables, leaves, seeds, and various other specimens, may be coated with copper, either for ornament, or for the purpose of illustrating the size, form, and other pecularities of the object. Apples and pears may be very readily coppered. They are to be brushed over with black lead, and then a small pin is to be thrust in at the stalk; to this a wire should be attached, which is connected with the zinc of the battery. It may then be placed in the solution, and the whole arrangement completed by a piece of copper, which is to be connected to the silver of the battery. In a similar manner cucumbers, gourds, potatoes, carrots, and a hundred other vegetables, seeds, and roots, may be covered. The form after the process is so characteristic, as to mark strongly the individual characters of each. The condition in which the copper is thrown down can of course be varied according to the laws set forth in the last chapter. For ornamental purposes the crystalline copper is the most beautiful; but for a specimen intended to illustrate the form of the object the smooth copper is best adapted. After the objects are completely covered the pin is to be withdrawn, which will leave a little hole, and that enables the evaporating juices of the vegetable to pass freely out, and thus promotes the complete drying of the encased object. A cucumber which I coated during the past summer appears now to contain scarcely any thing inside the copper; and the pears, apples, &c. consist of little but the metallic coat. The botanist will readily perceive in what way this process may be used to his advantage."—P. 97.

Mr. Smee tells us, moreover, that he has not neglected his medical brethren :—

" The dentist requires, for artificial teeth, an exact cast of the mouth in gold, platina, or palladium. Now the cost of the manufacture of this is so expensive, that many are prevented from availing themselves of these valuable appendages. It is absolutely necessary that the gold should fit very accurately, or else the wearer is not able to use them. Electro-metallurgy might be brought to aid the mechanic."

" Even to the surgeon electro-metallurgy seems likely, in many cases, to be very valuable ; for when he is desirous of exerting constant pressure on any part, or of confining any part in a particular position, he can make a copper instrument exactly to suit any individual case that may occur, by first taking a cast in plaster of Paris, or, which will be more simple, by a piece of gummed sheeting."—P. 116.

We may conclude, by recommending Mr. Smee's book to all who wish for a compendious *resumé* of the science of galvanism in general, as well as an account of his most interesting application of it to the arts. But, to be candid, we must object to two faults which it possesses : one is, that it is far too short; the other, that it is exorbitantly dear. Half-a-guinea is rather too much for not quite 150 octavo pages ! But we can scarcely attribute this fault to the author. In fact, the mystery is explained, when we find that the book is published by a chemist, who has filled more than a third of it with gilt-edged advertisements for which he obtains, no doubt, a good share of the half-guinea.

MEDICAL GAZETTE.

Friday, January 29, 1841.

MEDICAL REFORM.—THE APPRENTICESHIP SYSTEM.

THAT there will very soon be legislation in medical matters cannot now be doubted. The article in the *Quarterly* will already have attracted to them more attention than all the annual outpourings of the few public legislators who have hitherto monopolized the subject, and who shining only where they are not rivalled, have hitherto spoken to deaf ears or empty benches. We have often lamented the lukewarmness or total neglect with which the affairs of one of the most important of professions have hitherto been treated; but we have reason to believe that this will be the case no longer ; and this change has come, not from the increased urgency of the case, not from any new light cast upon the difficulties of the question, either by this journal or its rival, but, strange condition of society ! because a popular and influential periodical, devoted to general literature and politics, has admitted the subject into its pages, and has presented it to the minds of hundreds who, so long as it was urged on them only by those who were immediately interested in it, would have turned from it with carelessness or disdain.

Seeing, therefore, that changes must come, it is manifestly the best course for those who have reflected on the subject to offer at once such suggestions as may best be suited to render those changes beneficial. With this view we shall take occasion to notice in succession certain of the points which seem most to need amendment, and especially those which, in the bustle of approaching change, are likely to escape the attention of the more active and less reflecting. Of these one of the most important is the question of apprenticeships; that is, whether the great majority of those who enter the profession should be compelled to undergo an apprenticeship before they commence their attendance on lectures and hospital practice. We have often expressed our opinion in the negative ; and the excellent writer in the *Quarterly* coincides with us, and, we believe, with

the large majority of those who have thought impartially on the subject. However, we are far from hoping that the system of apprenticeships will be utterly abolished : and it is for the fear lest, in the speed and often thoughtless process of law-making in these days, the total abolition of them should take place, that we now offer some remarks on them.

It must never be forgotten that the laws for medical practitioners are not to be applied to a homogeneous multitude. They must be adapted as widely as any laws that should have for their object the direction of the practice of the whole body of lawyers, from Parliamentary pleaders to Insolvent Debtors' Court attorneys, with all the intermediate grades included. In neither profession can these differences be obliterated ; if styles and titles were equalized in both to-morrow, there would be the same differences of practices and remunerations the next day ; unless, indeed, all distinctions of rich and poor were destroyed at the same time, in which case a somewhat longer period might be necessary to bring things back to a state like the present. But back they would come : differences of professional remuneration (in themselves sufficient to lead to corresponding differences of professional rank) have risen from the gradual progress of society ; and if they are ever obliterated, it will only be in that happy time when all will be perfection.

We repeat, therefore, the future medical laws must be adapted for a society composed of many kinds of members ; and, as far as the system of apprenticeships is concerned, it is as plain that it, or something equivalent to it, must exist, as it is that it has hitherto done great mischief by being made almost universally compulsory. What are the chief evils of the system of apprenticeships ? Let us answer this deliberately.

First, it prevents many of the best educated of our profession from earning their living in the way which circumstances may render most convenient—viz. as general practitioners. Those of the students intended for physicians or pure surgeons, whose health forbids their residing in large towns—those whose talent or self-confidence falls just short of that necessary for metropolitan success —those whose chief connections reside in the provinces—those whose means fall short of what are necessary to bear up against the absence of practice in their first years' residence in the great cities, —all these, and many more, are subjected to great inconvenience, because they cannot betake themselves to the sure profits of provincial general practice, in consequence of not having been apprenticed to apothecaries. Nor are they the only parties injured : the public also suffer severely ; for these are of the class who would, by their superior knowledge, and their high attainments, both in medicine and general learning, tend most of all to exalt the character of provincial practitioners, and to level that difference, which, on the whole, now exists between those of large cities and those of smaller towns. So severely is this inconvenience felt, that we know it is a common thing for one intending to practise as a physician or a surgeon only, quietly to apprentice himself to an apothecary, of whom he perhaps afterwards sees nothing, in order that, in case of need, he may not be prevented from obtaining at any time the license of the Apothecaries' Company. And the Company in their turn wink at this, satisfied, as many of their leaders confess themselves to be, of the mischief of a compulsory system of apprenticeship. Now, to avoid all this—to enable any one who can obtain the license, after a competent examination, to practise as an apothecary—to give the best educated members of the profession an opportunity of carrying

on a profitable practice in the country—to remove the deceit and folly of mock indentures, let the serving of an apprenticeship cease to be compulsory.

The second great evil of apprenticeships is, that it compels students to enter the profession at too early an age. With the majority, three or four years must be spent in dispensing in the surgery; then come the three years more of attendance in hospitals; and thus, on an average, the whole time of medical study occupies not less than seven years. Now, with most fathers, it is an object that their sons should begin to earn their own bread by the time they are 22; and for this purpose they must be taken too early from the acquirement of general knowledge, and from the studies by which their mind is disciplined, and ought to attain the vigour so necessary for the study of a more difficult science. They must be taken from these at the callow age of fifteen, and put into a profession for the right study of which they are commonly by no means competent. For a well-disciplined mind, seven years' study is more than enough to make its possessor fit to commence the practice of his profession; four years would be sufficient if the best opportunities were taken; five would be ample. How much better, then, would it be for young men to commence their hospital studies with the vigour of mind that may be acquired in a long-continued education —to begin them when they have some knowledge how to distinguish facts from fallacies: in short, when they have learned how to observe and to reflect for themselves.

To avoid this evil, which affects even a more numerous class than the preceding, and is therefore still more injurious than it to the public interest—to avoid the bringing of pupils into the profession before they have learned to learn, and to insure that,

among the majority of practitioners, the standard of general knowledge should be the highest possible under the circumstances, we say again, let the apprenticeship be no longer compulsory on those who would become apothecaries or general practitioners.

We might add others to these, the most palpable evils of the system; but let these suffice: they prove that it often presents an obstacle to the entrance of gentlemen into a branch of the profession, on which their association would confer honour, and in which their practice would be advantageous both to themselves and to the public. But is the system so bad that it is invariably productive of harm? Far from it; it is in many cases necessary, and in some beneficial.

The system of apprenticeships is necessary for the supply of assistants to those who are in extensive practice. It is impossible for such an apothecary to dispense his own medicines, or, in some cases, even to see all his own patients. What, then, can be better than that he should have his pupils, his apprentices, to perform these minor offices for him? It may be said that he must keep paid assistants; we can only answer, ask an assistant whether he finds his occupation so agreeable that he would wish the number of his class increased. The system that would make the employment of assistants compulsory (and this would of necessity be the early effect of the abolition of apprenticeships) would be worse and more full of hardship than the present.

And again, the serving of apprenticeships is beneficial in many cases in which, but for them, he who should be a student would be receiving no education at all, or one of an inferior kind. It cannot be doubted that unless, from the age of fifteen to that of seventeen or eighteen, a lad is sent to

a good school, where he may gain sound knowledge and have his mind healthily strengthened, he had better be learning those parts of his future profession which he can acquire in his master's surgery. Now there are hundreds in this case, whose fathers are not rich enough or wise enough to send them to a first-rate school, or who are themselves anxious (sometimes for good reasons) to be early commencing the real work of their lives—to whom an apprenticeship presents the best possible advantages : for let it not be thought that apprentices learn nothing. It may be true that they do not acquire such an amount of knowledge as the occupation of three or four years ought to have brought them ; but still we know many very excellent practitioners who will confess that they learnt much more of real practical medicine and surgery in their apprenticeships than ever they did amid the bustle and hurry of lectures and dissections, and the unprofitable excitement of rare cases and great operations. And many are the young physicians and surgeons who would give half (their *fees*, we were going to say, but we will call them rather) their hopes of practice, to possess the familiarity with the private sick-room, and the facility of planning and executing *little* things, which the apprentice never fails to acquire. He learns, in a word, much of the every-day work of the private practitioner : the hospital student too often learns only the wonders and rarities of the art.

While, therefore, there are these benefits connected with the apprenticeship system, it would be absurd and injurious to put utterly an end to it— to make the time occupied in the service of it count as nothing. If a student does not enter the profession till he is eighteen, let four years' study suffice for him, and let all this time be occupied in the pursuit of medical knowledge, under the best possible circumstances—a well-directed attendance on lectures and hospital practice, dissecting, dressing, clinical study, and so on. But if he prefers commencing earlier, then let a number of years, spent as an apprentice, count at a somewhat lower rate ; let each year be deemed equivalent to a certain portion of attendance on lectures and hospital practice, and let a shorter time of actual attendance on these be deemed sufficient. To do otherwise, will be to shut out of the profession a considerable number of its most useful members, for the performance of whose services the public will resort to druggists, and the rest of the tribe who already feed on the abundant sources of profit that members of the profession are apt to treat with contempt.

DEATH OF MR. HOWSHIP.

WE regret to announce the death of Mr. Howship, which took place on the 22d inst., in consequence of disease of the tibia, followed by abscess. The deceased enjoyed rather an extensive practice, and was one of the Council of the College of Surgeons.

By the way, we rather think Mr. Wakley comes next in the list. Let our readers just fancy the honourable M.P. for Finsbury walking in, and taking his seat, as their new colleague, among the present members of the Council of the Royal College of Surgeons !

We presume that Mr. Arnott will be the new member.

CASES OF POPLITEAL ANEURISM.

CASE I.—Henry Williams, aged thirtysix, a weaver, was admitted on the 20th of May, 1830, on the recommendation of Mr. Cunningham, of Kirkcaldy, to have the femoral artery tied for popliteal aneurism. The tumor occupied the hollow of the ham —it was circumscribed in form—and, from the distinctness of its pulsation, seemed to contain little coagulum. The patient's at-

tention had been first directed to the complaint about two months before, by an uneasy feeling of stiffness in the part, after a particularly severe day's work.

He was confined to bed, and ordered a laxative to prepare him for the operation. Next day, the pulsation had become extremely obscure, and though it slightly returned the following day, at the end of two days more it could not be perceived at all. The articular arteries were then felt much enlarged, and the tumor quickly diminished in size, while it increased in firmness, until merely a small knot the size of an olive remained. He was dismissed at his own desire on the 31st of May.

CASE II.—William Sinclair, aged twenty-six, was admitted on the 20th of November, 1839, on account of a pulsating tumor in the popliteal space of his left leg. It was about the size of an egg, and distinctly circumscribed. The patient stated he had first remarked the swelling and beating in the month of August, while serving as carpenter on board a whale-ship in the North Seas.

The femoral artery was tied on the 3d of December. The ligature separated on the 28th, and the patient was dismissed quite well on the 9th of January.

CASE III.—John Lockie, aged twenty-nine, a shopkeeper in Edinburgh, was admitted on the 17th of April, 1840, on account of a large pulsating tumor occupying the ham and calf of the right leg. There was considerable œdematous swelling of the limb from the knee downwards, and over the shin-bone there were some dark-coloured spots, which had been produced by the pressure of a carefully applied flannel bandage, thus denoting a great degree of weakness in the part. The patient stated, that, about a month before admission, while walking down to Leith, he had strained the knee, and, in consequence, almost immediately afterwards perceived a beating tumor in the ham.

The artery was tied on the 30th of April, and though no unpleasant symptom followed, the swelling was slow in undergoing absorption; so that when he was dismissed, on the 3d of June, there still remained some enlargement of the limb. He nevertheless was able to resume his employment, and perform a full share of active duty: but about a fortnight ago observed a swelling in the calf of the leg, which has since opened spontaneously, and discharged a large quantity of matter, mixed with coagulated blood, —no doubt the remains of the extensive effusion which existed previously to the ligature of the vessel.

The first of these cases is curious, from the spontaneous cure occurring while the aneurism was still small and circumscribed, and the circumstances consequently unfavourable for coagulation. The second case was very similar to it, and I delayed the operation for a fortnight, to afford the chance of recovery without its performance, which might be derived from perfect rest and the pressure of a bandage. The third case seemed rather unfavourable, from the large size and sudden extension of the swelling : and the recovery was accordingly much slower than usual, though ultimately effected. It has been a question, whether an early or advanced stage of the disease is more favourable for success,—the undilated state of the anastomosing vessels being considered adverse in the former, and the quantity of extravasated blood an obstacle in the latter. From all that has fallen within my own observation, I should have no hesitation in preferring to operate at an early period, having never witnessed in my own practice the slightest unpleasant symptom of defective circulation, however small and recent the tumor might be.

Of all the operations performed for aneurism, ligature of the femoral artery is, I believe, justly regarded the easiest, either on the dead subject or on the living body, and yet the bad consequences which attend it are distinguished by their severity as well as frequency. For my own part I have been fortunate, having tied the vessel seven times for aneurism with success. But within the period of doing so, I am not aware of any case that has terminated favourably in this city, while I have either seen or heard of four that ended badly, viz. one by inflammation of the vein, one by mortification, one by hemorrhage, and one by amputation. It is usual to attribute untoward occurrences to some peculiarity in the constitution of the part or patient ; and there can be little doubt that varieties of this kind may have some influence over the result. But I feel quite sure that attention to some minute points in performing the operation has a much larger share in determining whether it shall be favourable or unfavourable.

It is established that the great sources of danger from the ligature of large arteries, are, undue laceration and separation of the connections of the vessel, whence hemorrhage is apt to ensue ; and injury to the coats of the veins, which is apt to occasion inflammation, and an obstructing coagulation, causing mortification of the limb. The subclavian artery, when tied at the external edge of the *scalenus*, lies at some distance from the vein, and neither the carotid nor the external iliac artery adheres so intimately to its accompanying venous trunk as to render it at all difficult or dangerous to pass the needle. But the femoral artery has a closer connection with the vein, and though it is felt by the operator's finger, after the fascia has been

opened, round and distinct, and as if insu-
lated from the surrounding parts, except by
the loosest connections, any attempt to pass
the ligature, without further dissection,
either proves abortive, or if executed by
force, exposes the patient to the greatest
danger. I have seen a gush of dark-coloured
blood proclaim transfixion of the vein ; I
have seen on dissection a portion of this
vessel included in the ligature ; and I have
also seen the external coat alone grazed, as it
were, by the needle, but nevertheless excited
to fatal inflammation. If, on the other hand,
this danger be avoided by using blunt instru-
ments, or the finger, to detach the artery
from its connections, the patient is exposed
to the hardly less disastrous consequence of
hemorrhage, through ulceration or sloughing
of the vessel.

To tie the femoral artery safely, the sur-
geon should be impressed with the conviction
that the operation is one not of difficulty,
but of great nicety. He should make an in-
cision between two and a half and three inches
long in the proper situation, cut through the
fascia to a smaller extent, and expose the
sheath of the vessels. So far he can hardly
go wrong ; but then, instead of hastening to
pass his needle, he should, by ligature, or
the temporary application of spring forceps,
close every little vessel that discharges enough
of blood to obscure distinct vision of the
object he has in view. Let him now seize
the sheath with dissecting forceps, and gently
raising it, make a small opening by means of
a straight narrow sharp-pointed knife. The
cellular and fatty substances which envelop
the vessels in variable quantity are next to
be elevated and divided in successive por-
tions, until the external coat of the artery
appears quite distinct and *white*, when the
needle may be passed without the slightest
difficulty or danger. I am quite aware that
instructions to the same effect are contained
in the common books of surgery ; but be-
lieving, for the reasons above stated, that
sufficient attention in practice is not be-
stowed on the point concerned, I think it
right thus seriously, and diffusely as it may
seem, to repeat and enforce these directions.
—*Prof. Syme, in the Edin. Monthly Journal
of Med. Science.*

EFFECTS OF OVER-EATING.

By Dr. Ritter.

A GIRL, three years old, went with her father
to gather plums ; as they fell from the trees
she kept eating an enormous quantity of them,
and then, feeling very thirsty, drank cold
water from a spring close by. Soon after
returning home, having seemed previously
quite well, she suddenly fell down as if struck
dead by lightning ; her eyes were convulsively

pulled about, and she lay quite. senseless.
The author being immediately sent for, found
her with her eyes staring wildly, unconscious,
insensible, and speechless ; her pulse was
suppressed, scarcely perceptible, and small ;
her respiration short and quick, frequently
interrupted by sighing, and her face pale.
The precordial region was distended and very
tense. An emetic, containing one eighth of a
drachm of vinum antimonii, and one eighth of
a grain of tartar emetic, was immediately
given, and was repeated every five minutes ;
but after several doses, produced no effect.
Three powders were then given at intervals
of ten minutes, each of which contained a
grain of tartar emetic, and six grains of
ipecacuan ; but these excited only retching.
Vomiting was at last brought on by tickling
the pharynx with a feather.   The materials
discharged consisted of a huge mass of
tough half-digested plums, with some frothy
fluid.   The severest convulsions now en-
sued, especially on the right side of the body.
The eyes rolled irregularly and convulsively
in their orbits ; the mouth was drawn over to the
right side, and watery froth kept running
from it ; the right arm and foot were set into
a constant swinging motion ; the face was
earthy, the glance obliqu , and the nose
pointed ; in short, there were all the appear-
ances of closely impending death.   Some
strong coffee and wine and water were given,
but the convulsions still continued.   A mix-
ture of equal parts of castor oil and almond
oil was next prescribed, and a spoonful of it
was given every ten minutes ; clysters, con-
taining oil, vinegar, and salt, were also ad-
ministered.   Soon after the second of these,
borborygmi commenced, and were presently
followed by the discharge of an enormous
mass of half-digested plums, which was
again repeated for several times.   The child
not long after came to herself again, and
though weak was still free from danger.   She
slept well during the night, and next morn-
ing, with the exception of dulness and re-
peated diarrhœa, was well and in good spirits.

Med. Rev.*

THE EPIDEMIC AT ATHENS IN
THE SUMMER OF 1835.

By Dr. Rothlauf.

FOR the following account of this little work,
printed at the Royal Press at Athens in 1836,
we are indebted to our Hamburgh contem-
porary, the *Zeitschrift für die gesammte
Medicin* :—

Soon after the appearance of this book the
author went to a better world. A granite
column was erected to his memory at Poros,
with the following inscription—" His friends

and fellow-citizens to Rothlauf, the Bavarian physician, who died at Poros, a victim to his philanthropy during the plague in 1837."

At the end of June, when the sea-breezes ceased, the inflammatory character of diseases changed to a bilio-nervous one; wounds became erysipelatous; dysenteries and bilious fevers became nervous. On the 25th of June, and the following days, several persons died, in spite of all remedies, with an inexplicable extinction of the vital powers. The spinal marrow and the abdominal nerves seemed to suffer, and to be the cause of an abdominal typhus. The phenomena of the three stages of the disease were those of *typhus gravis;* but it was often complicated—1st, with intermittent fever, which made the diagnosis difficult; 2d, with real inflammations. In August the intermittent type predominated, and at a later period the epidemic concluded with intermittents. Dr. Rothlauf rejects the opinions that this epidemic was merely an intense ague, or that it originated in inflammation, or in bilio-nervous fever. We should be glad, says the German reviewer, if he were right; and if inflammation, typhus, and ague, did not occur together in marsh fevers or typhus fevers.

Terminations.—Twenty-five in a hundred died, many of them from mistakes in diet during convalescence, particularly when there was ague with some complication. As in all nervous fevers, crises were rare, and resolution ordinarily took place. In the third stage, when the patient was already looking like a corpse, his life was sometimes saved by sweats, stools, and swellings of the parotid glands, which it was always necessary to bring to speedy suppuration. The common sequelæ were weakness of the chest, *hydrops pericardii, phthisis intestinorum,* amaurosis, and purulent otorrhœa. After the fever all the cavities were inclined to dropsy. Death generally proceeded from below upwards, and consciousness was free to the last, except when a rapid paralysis of the abdominal nerves was produced by acute hydrorachitis, and caused apoplexy. Some died asphyxiated, from spasm of the chest, in the first or second stage of the fever.

Dissection.—Besides the characteristics of putridity, which were very complicated, the nervous sheaths were of an almost inflammatory redness, the nerves softened, the ganglia œdematous, the membranes of the spinal marrow dropsical, and the periosteum showed injected spots. Probably the marrow had suffered also.

The author does not consider infection the obvious cause. Peculiar states of the weather had destroyed the vegetative life of the nerves; reaction was prostrate, and there were mere commencements of inflammation, congestions which soon ended in dropsies.

The epidemic consisted of an abdominal, ganglio-spinal typhus.

Of 412 deaths, 401 were foreigners, and only 11 Greeks. Men were the chief sufferers—the poor, and the troops encamped in the olive-wood, close to marshes : in the town the part which suffered was the one opposite this wood. As the town did not suffer till fourteen or eighteen days later, when the epidemic was mingled with intermittents, the picture of the disease in the town becomes obscure. The etiology of the fever, as given by the author, reaches from the stars to the graves of the dead, and is a sensible enumeration of the exciting causes of epidemics. His treatment is rich in remedies, but poor in efficacious ones. In conclusion, the author is of opinion, that by draining the marsh in the olive wood, by building wholesome houses on the ruins (so that pernicious excavations might be checked, as well as the unhealthiness of the town), by restoring aqueducts, and supervising the state of provisions by laying out plantations, and rooting out poisonous plants, and by founding better hospitals, &c., a similar epidemic need not again be dreaded.

BIRMINGHAM SCHOOL OF MEDICINE.

To the Editor of the Medical Gazette.

Sir,

Will you oblige the Royal School of Medicine by the insertion of the following paragraph.—I am, sir,

Your obedient servant,
William Sands Cox.

Birmingham Royal School of Medicine and Surgery and Queen's Hospital.—The very generous and philanthropic divine, the Rev. Dr. Warneford, has presented, through the medium of Mr. Sands Cox, the sum of one thousand pounds, in addition to his two former donations of one thousand pounds each, to enable the Council of the Royal School of Medicine and Queen's Hospital to carry out the object he has so much at heart, viz. "to combine religious with scientific studies and pursuits, and to make medical and surgical students good Christians as well as able practitioners in medicine and surgery." The Royal School of Medicine has also to acknowledge from the same generous patron, in addition to the valuable works presented by him to their library on subjects connected with natural and revealed religion, and selected by the Reverend Vaughan Thomas, a sum to be devoted to the execution of a die for two gold medals, as the annual prizes instituted by him for the two best essays "on a subject

to be taken out of any branch of Anatomical, Physiological, or Pathological Science, to be treated of in a practical and professional manner, but always and especially with a view to exemplify or set forth, by instance or example, the wisdom, power, and goodness, of God, as revealed and declared in Holy Writ."

NAVAL ASSISTANT SURGEONS.

(From a Correspondent.)

THE Naval and Military Commission has omitted to make, among others, the following improvements in the condition of naval assistant surgeons.

The Assistant Surgeon has not a cabin; but has to sleep and dress among a number of others, instead of having a private room, as one of his station and age ought to have.

For the purpose of study there is no place except the mess-room, which is always full of noise from the boys with whom he is compelled to mess, instead of messing with the lieutenants and surgeon as he ought to do.

Captains and lieutenants are styled " commissioned" officers, while assistant surgeons are degradingly denominated " warrant" officers.

These, and other grievances, lessen the respectability of the whole medical profession, and are felt to be unjust, insulting, and degrading, by the four or five hundred members of the College of Surgeons who are in the situation of

A NAVAL ASSISTANT SURGEON.

COPLAND'S DICTIONARY.

To the Editor of the Medical Gazette.
SIR,

As many of your subscribers and correspondents have complained frequently of the long delay in continuing the publication of Dr. Copland's Dictionary, we shall esteem it a favour if you will insert in the MEDICAL GAZETTE the inclosed copy of a letter which we have just received from Dr. Copland on the subject.—We are, sir,

Your obedient servants,
LONGMAN & Co.

39, Paternoster Row,
Jan. 21, 1841.

To Messrs. Longman & Co.

Dear Sirs,

The chief causes of my delay in bringing out the Sixth and Seventh Parts of my Dictionary have been the revising and reprinting the Parts already published, and the serious interruptions arising out of my removal to a new residence; the lease of my former house having expired.

I am now constantly engaged on the work,

and shall have the *Seventh Part* out in a very few weeks. A large portion of the remaining Parts is already written, so that I anticipate an early completion of the work— a consummation as earnestly desired by me as by yourselves.

Yours very truly,
JAMES COPLAND.
5, Old Burlington Street,

Winds, N.W. and S.W.

On the 20th, afternoon clear, otherwise cloudy; a little snow fell during the morning. The 21st, clear. The 22nd, morning clear, otherwise overcast. The 23rd, evening hazy, otherwise clear. The 24th, generally clear; snow and sleet fell during the morning; wind very boisterous during the evening. The 25th, clear. The 26th, afternoon clear, otherwise cloudy.

Rain fallen, ·1 of an inch.
CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XX.

Iritis concluded. Rheumatic ophthalmia. Amaurosis.

THE principal theme of the last lecture was that most interesting disease, inflammation of the iris.

The symptoms of iritis are these : a radiating zone of vascular redness situated in the sclerotica, and surrounding the cornea ; a change in the colour of the iris, from grey or blue to a yellow or greenish tint, from brown or hazel to a dusky reddish hue ; a visible deposit of lymph upon the anterior and innermost portion of the iris ; a thickening of its free edge ; contraction, irregularity, and immobility of the pupil ; *closure* of the pupil by lymph ; adhesion of the uvea to the membrane of the crystalline lens. All these we can see and ascertain for ourselves. We can ascertain also the presence of fever, which attends the acute forms of the disease. And we learn from the testimony of our patient that his sight is impaired ; that the influx of light into the eye hurts him ; and that he experiences pain in and around the organ, especially at night.

The grand remedies in iritis are three.

1. *Blood-letting :* of which the objects are to abate the force of the heart's action ; to moderate the febrile disturbance ; and to facilitate the operation of the second remedy : which is

2. *Mercury.* This is to be given so as to produce soreness of the gums, and the peculiar fœtor of the breath : and these effects are to be sought for rapidly or gradually, accord-

ing as the inflammation of the iris is acute and violent, or moderate and chronic. The object of this remedy is to arrest the effusion of coagulable lymph ; to put a stop to the adhesive inflammation.

3. The application of the extract of *belladonna*, to the conjunctiva or to the skin around the eye, so as to dilate the pupil. The objects of this measure are to prevent the adhesion of the iris to the parts in its neighbourhood ; to detach it from the lens when it has already been glued thereto by soft lymph ; and to stretch and elongate the bands of adhesion when they cannot be broken : and thus to obviate any impairment of the free movements of the iris, and any deformity of the pupil, after the inflammation shall have ceased.

I began to speak of the causes of iritis.

I say it may be occasioned by mechanical injury ; as during the operation for the extraction of a cataract. A clean cut, however, is frequently followed by no bad consequences : a portion of the iris has been shaved off by the knife in making the section of the cornea, without any injurious result. When iritis is excited by mechanical violence, it is acute.

2dly. A chronic form of iritis is sometimes brought on by excessive employment of the eye, in looking at minute or bright objects.

3dly. The most common species of iritis is that which arises in connexion with syphilitic disease. It is one of the early secondary symptoms of syphilis. It is marked by the co-existence of other secondary consequences of the introduction into the system of the syphilitic poison, and by the periodical character of the nightly pain : it is never attended with abscess of the iris and hypopyon ; the lymph that is effused is deposited in separate masses : and the pupil is often displaced towards the root of the nose, as well as rendered irregular, by the adhesion of the iris to the capsule behind it.

4thly. It is curious enough that iritis has

actually been ascribed to *mercury*, as a cause. This notion can only have arisen from that loose kind of logic, and hasty generalization, for which, I am sorry to say, medical reasoners are too often distinguished. Mercury is perpetually exhibited for the cure of syphilis; and people who have been treated for syphilis are very liable to iritis. This seems to be the only foundation for the opinion in question. When we come to appeal to facts, we find no ground for believing that this mineral is thus, *both bane and antidote*. If it were so, Benvolio's advice to the slighted Romeo might be very pertinently offered to the *patient* in such a case :

" Take thou some *new* infection to *thine eye*,
    And the rank poison of the old will die."

Mr. Lawrence has seen no instance of iritis, of whatever kind, in which there has appeared to him any reason for attributing the occurrence of the complaint to this cause. I have never heard it alleged that persons who have taken large quantities of mercury for other diseases, as for affections of the liver in India, are particularly subject to inflammation of the iris. On the other hand, iritis has come on, in hundreds of cases, in connexion with syphilis, though not a particle of mercury had been swallowed by the patients.

Lastly, there is a peculiar form or variety of iritis, called the *arthritic*, or *rheumatic*.

Arthritic iritis.—This affection is characterized by the following *general* features :—It occurs in persons who are subject to gout or rheumatism, and often forms a part of the attack of the one or the other of these diseases. Like them, it is liable to return again and again ; and this circumstance it is which makes arthritic iritis a serious disease. It is seldom that much or permanent damage to vision is effected by a single attack ; but adhesions readily form under it, and lymph is effused : and in each successive attack fresh effusion takes place ; the pupil becomes more and more contracted ; and it may be filled up, at last, by an opaque plug of lymph. Some patients, however, will suffer ten or a dozen recurrences of the disease, and recover almost completely, and enjoy perfect vision in the intervals, before the sight becomes much impaired.

Some of the *local* appearances are more or less characteristic of this variety of iritis. It is less frequently attended than the syphilitic variety by a deposition of lymph in distinct masses ; the contracted pupil keeps its central position, and is not displaced towards the root of the nose, as it is apt to be in syphilitic iritis. The adhesions that bind the iris to the neighbouring parts are said to be *whiter* in this variety of iritis than in others. It is also a very remarkable circumstance

that the zone of red vessels encircling the conjunctiva does not run up so close to the cornea as in other species of iritis, but a white ring is left between the cornea and the anterior margin of the zone. Sometimes this circular white stripe is partial, being most marked towards the angles of the eye ; sometimes, on the other hand, it is as perfect as if it had been described with a pair of compasses. I believe, with Mr. Welbank, that the appearance of this bluish ring depends upon the less intense degree of the sclerotic inflammation. He says that he has noticed its coming on, when syphilitic inflammation of the iris was beginning to yield to the action of mercury ; although there had been no such interval during the height of the inflammation. Again, the colour of the zone is not so bright as in other forms of iritis ; it is of a somewhat livid, or slightly purplish tint : and the larger vessels at the back part of the eye, belonging to the conjunctiva, are apt to become tortuous and varicose.

Rheumatic *iritis* is often met with in combination with what is called rheumatic *ophthalmia :* a disease which I have not before mentioned. But each may exist alone. And as rheumatic iritis, though frequently an independent disease, does also in many instances grow (as it were) out of rheumatic ophthalmia, I will take this opportunity of shortly describing the latter complaint.

Rheumatic ophthalmia.—What is called rheumatic ophthalmia, then, is inflammation affecting the fibrous coat of the eye, the sclerotica. We know that the fibrous tissues throughout the body are frequently the seat of rheumatic inflammation. Some persons are more liable to rheumatism than others—are more readily affected by its exciting causes, which are vicissitudes of external temperature, and exposure to cold and wet. In such persons there seems a tendency to take on inflammatory action in all the structures of the same kind, and most particularly in the fibrous membranes and tendons that help to form the various joints ; and as the sclerotica partakes of this fibrous texture, so it is apt to suffer, in its turn, from rheumatic inflammation. The connexion of the moveable eyeball with the head may be considered as a kind of *joint.* The local symptoms are not in general of a violent kind ; and, as in other parts, the rheumatism seldom leads to any permanent alteration of structure ; seldom, at least, when the ophthalmia is confined, as it often is, to the sclerotica alone. Perhaps the best way to put you in possession of the features that belong to rheumatic ophthalmia will be to describe an actual instance of it. I will take a well-marked example, related by Mr. Lawrence. He was sent for to see a gentleman who was suffering from what is commonly called rheumatic gout : swelling, some redness, and

severe pain of one foot and knee, and one hand; aching of the back; and great constitutional excitement. He got well under the treatment adopted. After a short interval, upon Mr. Lawrence's calling to enquire how he was, he said there was something the matter with his eyes; and asked to have them examined. "I looked at them hastily," says Mr. Lawrence; "the room was dark, and the day dull; and I saw no appearance of disease. When I called again, after a few days, as the complaint was repeated, I examined more attentively. On bringing him towards the window, he obviously felt the light troublesome; he drew down the eyebrows, and half closed the lids, to avoid it. The conjunctiva was natural; but the whole of the sclerotica had a livid red, and mottled appearance, which might have been called dull, or almost dirty, in comparison with the red colour of common active inflammation. The sclerotic vessels were partially distended; the redness terminated short of the cornea, so that there was a distinct white rim round the latter. Vision was perfect; there was no pain so long as the eye remained at rest, but exertion of the organ, particularly under strong light, brought on uneasiness. The nature of this gentleman's occupations, and of his tastes, which were literary, prevented him from giving his eye the necessary repose; and the condition of the sclerotica just described lasted for three or four months;" so that Mr. Lawrence was apprehensive that some serious mischief would ensue to the organ. The affection remained confined, however, to its original seat, evincing only that obstinate character which belongs to disorders of such structures; and at last it disappeared completely, leaving the eyes with their organization and powers unimpaired.

The treatment that appears to answer best in simple rheumatic ophthalmia of this kind, consists in moderate topical bleedings, and counter-irritation; with such *other* measures as conduce to improve the general health; and among these, change of air and scene have sometimes a decided effect. Those remedies also are to be given which have been found by experience to be beneficial in rheumatic inflammation, although we cannot always *depend* upon finding them useful: colchicum, I mean; bark; sarsaparilla; the iodide of potassium. In these abiding or frequently recurring forms of disease, you will often be obliged to try the so-called specific remedies one after the other.

Now when the rheumatic inflammation is not confined to the sclerotic, but creeps inward, as by their vascular connexions it easily may, to the *iris*, we name the disease according to the most important part that it occupies—arthritic *iritis*. On the other hand,

when, with the affection of the sclerotic that I have been describing, there is combined a moderate degree of inflammation of the *conjunctiva*, this complex disorder receives a compound denomination; it is called *catarrho-rheumatic ophthalmia*.

Dr. Mackenzie states it as the result of his experience, that arthritic iritis seldom occurs in connexion with the earlier appearance of gout, while the patients still retain strong powers of digestion, and have the means of indulging their appetites: but rather with the asthenic and irregular forms of gout and rheumatism; when repeated attacks have been followed by mental depression, indigestion, flatulence, and languor. He has generally met with the disease in subjects beyond the age of fifty, very often in tobacco-smokers, and whisky drinkers, who have often suffered rheumatic affections, who are teased by headaches, acidity of stomach, bad gums and teeth, and lowness of spirits: in persons, that is, whose health has been impaired and broken by intemperate habits. I believe you will find this to be a very correct statement; although arthritic iritis *may* also take place in those who are more robust.

After what has now been stated you will be prepared to believe that arthritic iritis neither requires nor bears those free emissions of blood, and that liberal use of mercury, which are necessary for the cure of other varieties of the complaint. Mercury, pushed to salivation, is sometimes found to do more harm to the system than good to the eye; and in a disease which is so apt to recur, we must not be continually salivating our patient. I can only say that the treatment must be conducted on the *principles* already laid down, and adapted to circumstances. If there be any fever, and a hard pulse, and a white tongue, you should bleed and purge your patient, and afterwards give him from twenty minims to half a drachm of the wine of colchicum two or three times a day. When the symptoms are less active, you must be less active too: strive to set the disordered digestive organs right, and to correct the bad habits of the patient: give small doses of mercury (such as five grains of Plummer's pill) three or four times a week; excite counter-irritation by blisters, or the tartar emetic ointment. After the use of bleeding or leeches, and the regulation of the bowels, preparations of iron, the sulphate of quina—tonics, in short—have been found, in different cases, extremely beneficial.

I should have mentioned another remedy, which of late years has been recommended in iritis, and especially in syphilitic iritis, by Mr. Carmichael, of Dublin: not as being a better remedy in itself than mercury, or so good, but as having considerable power over

the disease, and, therefore, as affording a valuable resource when from any cause the exhibition of mercury is forbidden. This remedy is the *oil of turpentine*. He gives it in drachm doses, three times a day. He relates cases of syphilitic iritis in which the pain, redness, and other symptoms, were quickly removed, and effused lymph absorbed, and vision restored, under the use of this medicine. It is necessary to its beneficial action that the bowels should not be confined. In other cases of the same disease Mr. Carmichael was not so successful. Mr. Guthrie, who has also tried this remedy, reports of it that " in some cases it succeeded admirably, in others it has been of little service, and in some unequal to the cure of the complaint." I do not know that it has been fairly put to the test in arthritic iritis.

I proceed next to quite a different kind of ophthalmic disease from any that we have yet considered. I have spoken of inflammation of the exterior membrane of the eye occurring separately; and of inflammation of certain internal parts, and particularly of the iris, occurring separately. Between these exterior and interior tunics, the sclerotica forms a sort of natural barrier or shield, the chief point of connexion between them being near the edge of the cornea, where the sclerotic vessels dive through to reach the iris. Inflammation of the sclerotica itself has also been described. When vision is impaired or destroyed in consequence of any of the complaints that have hitherto engaged our attention, that effect results from the partial or total exclusion of light from the retina. The cornea is left opaque, or it bursts; the pupil, or aperture in the iris, is shut up by a web of lymph; or the capsule of the lens to which the iris adheres has undergone a change, and lost its transparency. In each case the retina suffers an eclipse.

But light may be freely admitted, and yet no vision ensue. The transparent parts of the eye, the several media, so skilfully and exquisitely adjusted for the due refraction and collection of the rays of light into an image of the object from which they flow, may all be perfect and in order; the beautiful apparatus is useless; the patient cannot see with it. The fault is in the *nervous* matter that should receive and transmit, and *perceive* the impression.

Amaurosis.—Now persons in this condition are said to have *amaurosis.* The term is derived from the Greek word αμαυϲος, which signifies obscure or dark. It expresses various degrees of imperfect vision, from defective nervous function. The words *gutta serena* are applied to that form of amaurosis in which vision is totally lost. It was formerly supposed that this sort of blindness was caused

by the effusion of some humour or fluid behind the pupil: and this was held to be a clear fluid, because the natural blackness of the pupil is sometimes not troubled in amaurosis. Milton has literally translated this term when, speaking of his own eyes, he says, " So thick a *drop serene* hath quenched their orbs."

Amaurosis is a very *obscure* disease. It is capable of being caused by various changes, the exact seat and nature of which we often have no means of determining during life, and which frequently leave no traces behind them in the dead body. It would take a much larger space than I can possibly devote to it in these lectures, thoroughly to discuss this difficult but interesting subject. I shall endeavour to give you such a sketch of it as you may fill up and complete by future observation, and reading, for yourselves. It will be something to learn the direction and objects of our enquiries into what is yet unknown in the pathology of this affection.

There is one division of the disorder which immediately suggests itself. The cause of defect may exist in the brain, at or beyond the origin of the optic nerve; or it may be situated in any part of the course of that nerve, from its commencement at the base of the brain to its termination in the retina : or it may be confined to the retina itself.

There is reason to believe that the functions of the retina itself may be impaired or suspended, by deviations from the natural quantity of blood sent to it; by disturbances of its circulation. Various degrees of amaurosis are common among persons who employ the sense of vision overmuch, and strain the eye. This over-use is likely to produce congestion, or chronic inflammation, in the vessels of the retina ; and very slight changes of that kind may seriously affect the function of a part so delicate and tender. I say we frequently meet with amaurosis among those whose occupations oblige them to look attentively at small or bright objects during many hours of the day ; or what is still more pernicious, during many hours of lamp or candle light ; so as habitually to fatigue the eye. Engravers, printers, watchmakers, tailors and milliners, mathematical instrument makers, persons who gain their bread by writing, miniature painters, cooks who are exposed to the heat and glare of large fires, men who have the charge of forges and furnaces, and so on. Here a continual stimulus leads to a chronic disorder, which increasing in intensity may terminate in total blindness. We call these cases of *amaurosis,* but they may be justly considered to be instances of chronic inflammation of the retina : we cannot see the suffering part indeed during life ; and the complaint is not a fatal one, and, therefore, we have few opportunities or none of examining after death the

condition of the retina while the amaurosis is yet recent. But judging from the nature of the *causes* that precede the defect of vision, and from the nature of the *remedies* that are often found to remove it, we are warranted in regarding the essence of the disease to be *retinitis*. The same condition, apparently, may be suddenly produced by the transient operation of some more powerful cause of congestion; such as intense light. I will illustrate this form of amaurosis—amaurosis, that is, dependent upon congestion which perhaps amounts to inflammation, sometimes slowly established, and sometimes very suddenly, by the narration of a few cases. I may as well premise, however, that the treatment which *promises* most, or I should rather say, which has *performed* most, in this form and kind of amaurosis, is very nearly the same (excepting the use of belladonna) that I have already recommended for chronic and acute iritis. *Blood-letting*, general or topical, according as there is more or less pain, and fever, and fulness of the system, and according as the amaurosis is more or less recent; and above all *mercury*, so administered as to affect the gums, and rapidly introduced into the system in the acuter cases; more slowly in proportion as the disease has crept on more gradually and lasted longer. This treatment is very often quite successful: the mercury is the most important part of it; and we have in this fact a strong corroboration of the inference drawn from the nature of the exciting causes, viz. that the complaint is essentially inflammatory. And again, supposing it inflammatory, we need not be surprised that a remedy, the curative effect of which we can *see* in inflammation of the iris, should be equally serviceable when the same diseased process is set up in the retina, which we *cannot* see. Purgatives, counter-irritation, and perfect repose of the organ, are necessary parts of the treatment in both forms of disease.

Mr. Allan gives the following account of the master of a printing office, who became blind. He had corrected the press, and was otherwise engaged in reading, for eighteen hours daily out of the twenty-four. He continued this practice for twelve months, notwithstanding an evident failure of his sight. At the end of that time the amaurosis was so complete that he could not distinguish one object from another, but was merely capable of just perceiving the light, so as to grope his way along the streets. He continued in this state for several years, but ultimately recovered his vision.

The next instance that I shall cite is recorded, in these words, by Mr. Lawrence. " A young woman, of florid complexion and full habit, came to the London Ophthalmic Infirmary, complaining that she had lost the sight of one eye. She was cook in a family,

and occupied for several hours daily before large fires, supporting her strength by free living. The pupil was slightly dilated; the iris motionless. A faint and scarcely perceptible pink tint was observed in the sclerotica, near the cornea. Vision was dim, and had been so for three days. There was headache, flushed countenance, heat of skin, whitish tongue, and thirst. I considered the case to be pure retinitis; and to afford a favourable opportunity for showing whether the affection could be arrested by antiphlogistic treatment. At that time (now many years ago) I did not possess the knowledge of the powers of mercury in inflammation of the retina, which subsequent experience has given me. I directed a full bleeding from the arm, free purging, low diet, repose of the organ, and general rest. At the end of two days the sight was worse: cupping and a blister were now ordered; but there was no improvement at the end of two days more. I now determined on trying mercury, and ordered two grains of calomel every four hours. Before the remedy had affected the system, vision was quite lost, or at least reduced to the mere power of distinguishing light from darkness. Full salivation, which took place in about a week from the first application of this patient at the infirmary, suspended all the symptoms; the sight immediately improved, and was soon completely restored."

A soldier, unacquainted with the proper method of observing an eclipse of the sun, employed for that purpose a piece of opaque glass, with a transparent point in its centre. Notwithstanding the vivid and painful impression he experienced from the rays that passed through the lucid part of the glass, he continued to look at the sun till the eclipse was over, using his right eye. He was soon after seized with vertigo, and pain in the right side of the head, and found himself almost entirely deprived of the sight of the right eye. Some weeks afterwards, the pain in the head continuing, he came under the care of Baron Larrey, who observed that the vessels of the eye were injected, the pupil somewhat smaller than that of the other eye, retaining, however, its natural free motions; the vision very obscure or almost gone. This man recovered his sight completely after two bleedings, one from the temporal artery, the other from the jugular vein; blisters to the temple and nape of the neck: ice to the head, and moxas *(Mackenzie*, from the *Memoires de Chirurgie)*.

In the year 1832, a young man standing in a door-way, by a lamp-iron, in a thunderstorm, was struck by the lightning, fell backwards, and was convulsed. He said afterwards that the lightning appeared to enter his eye with a scorching sensation. During the night vision was quite lost. The next morning there was no redness, nor any

unusual appearance of the eye. The iris was motionless, however, and the patient could not see even the sun. He was treated with calomel, and his sight returned; but the retina remained extremely irritable, and unable to bear the light. A month afterwards, when this account was written, he could see distinctly enough, but he could not use the eyes without the protection of blue glasses *(Lawrence)*.

In these cases the nervous apparatus that ministers to vision is not, I believe, in general, the only part of the nervous system that is injured. In August 1839, Phoebe Judge, a delicate looking girl, eleven years old, became my patient in the Middlesex Hospital. She had lost, in a great degree, the power of using her legs: when she attempted to stand they separated, and she sank down. She had not perfect control over her bladder. The desire to make water was frequent, and if not immediately attended to the urine escaped in spite of her efforts to retain it. The same urgency, and inability to wait, occurred whenever her bowels were about to act. Sensibility in the legs and thighs was impaired, but not extinct.

Her parents informed me that some time previously, while stooping to raise up a sister in a room at Hampstead, she had been struck by lightning, fell backwards, became blind, and remained so for ten days. She did not lose her consciousness, but complained immediately that the lightning had hurt her eyes. They presented no visible injury or defect, but the upper lids fell, and she was unable to raise them. It was soon found, however, that when pressure was made on the right eyelid she could open the other eye. The palsy of her limbs commenced, by degrees, two or three days afterwards. The power of vision returned suddenly, and at the same moment the power of moving her limbs was restored; but it gradually went again. When she lay down her limbs were still, but they began to tremble, and to be agitated, as soon as she sat up. Even when lying in bed, she had, occasionally, a sensation and dread, as if she were falling down. She had been in this state nearly three weeks.

She was put upon steel, and a tonic plan of treatment, and in ten days she could walk, dragging her left leg a little after her. In ten days more she was dismissed quite well, and able to run from one end of a long ward to the other.

The greater number of the cases of amaurosis depending upon a morbid condition of the retina itself, belong to the class that I have now been mentioning: there is congestion of the vessels of the retina; or inflammation, chronic or acute. In a few instances a totally opposite condition of the blood-vessels is presumed to exist. I say presumed to exist, because our judgment of this matter is founded, as before, on the nature of the circumstances that have caused the affection, and on the nature of the treatment that removes it. On these grounds some cases of amaurosis (few in number, speaking comparatively) may fairly be ascribed to a deficient supply of blood to the vessels of the retina. We know that a temporary defect of sight may be produced by a diminished circulation through the retina, as in approaching syncope under hæmorrhage; and we can therefore the more readily believe that more permanent amaurosis may be occasioned by causes that gradually lessen the quantity of blood circulating in the body, and debilitate the whole system. "It is well known (says the late Dr. Gooch) that large losses of blood enfeeble vision. I saw a striking instance of this in a lady who flooded to death. When I entered the chamber she had no pulse, and she was tossing about in that restless state which is so fatal a sign in these terrific cases. She could still speak; asked whether I was come? (she knew I had been sent for) and said, "Am I in any danger? —How dark the room is! I can't see." The shutters were open, the blind up, and the light from the window facing the bed fell strong on her face. I had the curiosity to lift the lid, and to observe the state of the eye. The pupil was completely dilated, and perfectly motionless, though the light fell full upon it. Who can doubt that here the insensibility of the retina depended on the deficiency of its circulation?"

One might ask, also, who can doubt that the retina *may* become insensible from a similar state of the circulation in it, brought on by some *long-continued* drain upon the system? Amaurosis of this kind, proceeding from too profuse and protracted a secretion (which may be considered a kind of hæmorrhage), is sometimes noticed in nurses. Mr. Lawrence describes the case of a young mother of slender make, who suckled her first child, which was strong, and took the breast very often: her milk was abundant. After two or three months she began to feel very weak, could not lift a weight, and cried frequently, without having any reason for uneasiness or complaint. She became totally blind, and was led to his house by a friend. He found her pallid, with a small feeble pulse. The pupils were of middle size, and the irides moved slightly. The retina was completely insensible. She could not discern the situation of the window, nor see a lighted candle held close to her. After weaning the child, and using generous diet, she got perfectly well. Some counter-irritation was employed in this instance, but I question whether it had any thing to do with the recovery. Such cases are not uncommon, and their well-known occurrence has probably tended to encourage the notion

—too prevalent among both patients and practitioners—that amaurosis is always essentially a disease of debility, and requires tonic and stimulant remedies; bark, and high feeding, and strychnia, and electricity. "Our eyes are *weak*," say they, "and we require strengthening medicines." You must perceive from what has already been said, how necessary it is to *discriminate* in such cases: to look closely into all the circumstances under which the disease has occurred.

When amaurosis is the result of pressure, or disease, in the course of the optic nerve, or in the sensorium, the complaint is generally less within the power of remedial measures. We cannot say, indeed, in many instances, where the cause of defect lies; and in obscure cases, I should always advise that a trial be made of the mercurial treatment. I have again and again seen slight palsy of some of the voluntary muscles, evidently depending upon some morbid condition of the brain, clear away rapidly upon the affection of the gums by mercury; and the lost power of the retina will sometimes return under the same plan of treatment.

There is something very peculiar in the expression of countenance, and in the gait, of an amaurotic person, by attending to which alone, you may almost recognize his disease. He comes into a room with an air of uncertainty in his movements; the eyes are not directed towards surrounding objects; the eyelids are wide open; to use a strange but common and intelligible phrase, the patient seems gazing upon vacancy; has an unmeaning stare; and there is a want of that harmony of movement and expression which results in a great measure from the information obtained by the exercise of vision. This seeming stare at nothing at all, is not observed in patients who are blind in consequence of opacity of the crystalline lens or its capsule, *i. e.* in consequence of cataract. They, on the contrary, although they cannot see, still seem to look about them, as if they were conscious that the power of sight remained to the retina, although light was shut out from it.

When the amaurosis is incomplete, the motions of the iris are sluggish, and the pupil larger than ordinary. When the blindness is total, the commonest condition of the eye is that of great dilatation of the pupil, so that a mere ring of the iris is visible; and complete immobility of the iris. No change takes place in the diameter of the pupil, under the greatest variation of the light that falls upon it.

Sometimes, on the other hand, though the amaurosis is total, the iris is as active as ever; and this is a very interesting circumstance, and may enable us, in some degree, to conjecture the actual seat of the malady. When the amaurosis is confined to one eye,

this may happen. You examine the diseased eye, and you find that the pupil enlarges, or contracts, as you diminish or increase the light. But the other eye is open. Shut the sound eye, and try the amaurotic eye again, and you find the pupil fixed, although you vary the light. The motion formerly noticed was sympathetic of the motion of the iris in the healthy eye. We express this otherwise by saying that the *associated* movements of the iris were natural and lively, but its *independent* movements were lost. But sometimes the independent movement is unaffected; nay the motions of both irides may be perfect, although both eyes are completely amaurotic. I may state, by the way, that *cæteris paribus*, when both eyes are affected, that is a ground for supposing the cause of the disease to be situated within the cranium. And I should come to the same conclusion if, in the case where one eye alone was amaurotic, I found the independent motion of the iris of that eye unimpaired. We know that in the healthy condition of the parts, the brightness of the light admitted to the retina determines the size of the pupil; but the motions of the iris do not depend solely or directly on the retina. It has been ascertained, by experiments made on animals, that the pupil can be made to contract either by mechanical irritation of the *optic* nerve within the cranium, or by irritation of the *third* nerve; a motor nerve which sends filaments to the ophthalmic ganglion, whence the ciliary nerves, passing to the iris, are derived. Now the optic and the third nerves have some link of connexion within the brain; and if the morbid condition upon which the amaurosis depends is situate deeper than that point of connexion, we may understand, I think, how disease so placed may destroy the power of vision, and yet leave the connexion between the retina and the third pair unaffected: and then the influence of light falling on the retina, though it fails to create a perception in the mind, will be reflected back upon the third pair of nerves, and so continue to govern the motions of the pupil. In conformity with these views, M. Andral relates cases in which amaurosis resulting from disease in the cerebellum was attended with brisk movements of the iris.

There are other causes of amaurosis besides those that I have already adverted to. It is sometimes produced by the presence of worms in the alimentary canal. It has some obscure connexion with teething, probably through irritation of the facial branches of the fifth pair. A physician of my acquaintance, residing in London, has a young son, who on two or three occasions has caused him great uneasiness, by becoming blind in one eye without any obvious cause, and with no visible change in the organ; but the blindness

on each occasion has gone off again, appa-
rently in consequence of the extraction of
some teeth which had grown irregularly. I am
assured by Dr. Ashburner that such cases are
common. Mr. Lawrence relates a very sin-
gular instance of *dental irritation* giving rise
to amaurosis. A man, thirty years old, was
suddenly attacked with violent pain in the
left temple near the eye, and in that side of
the face generally. · The pain continued to
recur from time to time, and at length he
discovered that he was blind in the left eye.
By and by the cheek swelled, and some
spoonfuls of bloody matter were discharged
by a spontaneous opening in the lower eye-
lid, and then the pain subsided ; but after
some months it returned with great severity.
The patient then went to Wilna, with
the view of having his eye extirpated,
and consulted Professor Galenzowski, who
found the left eye totally insensible to
light, with the pupil dilated, and no
other visible alteration. He ascertained,
however, that the first molar tooth on that side
was carious : it had never caused the patient
much uneasiness ; and the toothache which he
had occasionally suffered had not been coin-
cident, in point of time, with the pains in
the head and eye. Dr. Galenzowski thought
fit to extract this tooth, and was greatly
surprised at seeing a small substance pro-
truding from the extremity of the fang.
This proved to be a little splinter of wood
about three lines in length, which had per-
forated the centre of the tooth, and had pro-
bably been introduced in using a wooden
toothpick. A probe passed from the socket
into the antrum, from which a few drops of
a thin purulent fluid escaped. The pain
ceased almost entirely, and on the same
evening the eye began to be sensible to light.
The vision gradually improved, and on the
ninth day from that time, after thirteen
months' blindness in that eye, he was able to
see with it as perfectly as with the other.
M. Galenzowski has since been in England,
and he shewed Mr. Lawrence the tooth, and
the splinter of wood. Doubtless he felt some
pride in exhibiting these trophies of his ex-
ploit.

Amaurosis is said also to occur as an
hysterical affection : and I am certain that
I have seen this myself. An unmarried
lady, of a very nervous and susceptible habit,
came to town in great apprehension about
her eyes, the sight of one of them being
quite gone. I could perceive no defect in
the eye itself. I saw her in consultation
with Mr. Travers, who took an unfavourable
view of the case, and thought the chance of
recovery was very slender. I had one
reason for hoping a better result, in the
knowledge of some facts which Mr. Travers
was not aware of till I mentioned them to
him. I had been acquainted with this lady

for some years, and during that period she
had several times almost entirely lost, and
again recovered, the use of her lower ex-
tremities. On two occasions she had
been affected with aphonia, and unable to
speak, except in a whisper, for months
together ; and then, on a sudden, without
any apparent cause, her voice returned. I
trusted, therefore, that this suspension of
the power of vision in one eye might be a
similar freak ; and so it turned out. After
a few weeks the sight returned, she knew
not how ; and she has since lost it a second
time, and a second time regained it.

Certain poisons will produce temporary
amaurosis ; and the suppression of certain
natural evacuations, as of the perspiration,
of the menstrual fluid, and of the bleeding
from piles, and the repulsion of certain erup-
tions, have been charged, by authors, with
producing the same complaint.

In those cases in which amaurosis creeps
on slowly and insidiously, as it is apt to do
from various causes, and more particularly
when it depends upon a low and chronic in-
flammation, engrafted upon habitual con-
gestion of the vessels of the internal tunics
of the eye, its approach is marked by sundry
curious affections of the vision. The eye
feels full or stiff, and sometimes there is pain
of the head in its neighbourhood ; the pa-
tient complains that he sees things through
a fog or mist, or as if a thick piece of gauze
were interposed between his eye and the
object he is looking at. In the daylight,
the gauze or fog seems dull and murky, but
in the dark it often appears shining, reddish,
and fiery : the flame of a candle is seen sur-
rounded with a halo of prismatic colours.
That amaurosis of this kind is often really
dependent upon local congestion we are
taught by the *lædentia;* by the circum-
stances that aggravate it : thus *straining* of
any kind, which augments for the time
the fulness of the vessels about the head,
will make the mist appear more dense ;
the same effect may be produced by tying
the neckcloth tight ; or even by stoop-
ing. Boerhaave relates the case of a man
who, whenever he was intoxicated, laboured
under complete amaurosis : it came on by
degrees, increasing according to the quantity
of wine he drank ; and after the drunken-
ness went off, his vision returned. Surely
these phænomena are very illustrative of the
way in which nervous disorders may arise, or
be made worse, from mere local plethora, in
almost any part of the body.

Sometimes the perfect amaurosis is pre-
ceded by a remarkable diminution of the
apparent *size* of the objects looked at. A
patient told Dr. Farre that a carriage, which
happened to pass the window, seemed to him
as small as a wheelbarrow, and the horses no
bigger than dogs. More commonly ocular

spectra become visible : that is, parts of the retina lose their power, or perhaps are eclipsed by turgid vessels: the patient sees flies in the air, *muscæ volitantes*, particles of soot, *blacks*, as we, who live in London, call them, which always float before his eyes, and seem to follow their motions ; and which are especially plain and troublesome when he is looking upon a white surface. They multiply in number till the whole becomes dark.

Do not, however, suppose that the appearance of these muscæ volitantes, even when they are permanent, necessarily implies the approach of amaurosis. I should be sorry if it were so, for I see two of them every morning, when my eyes are directed towards a white basin, while I am washing my face. I can find them at other times if I look for them : else, I am not sensible of their presence. They bode no farther evil, if they are associated with no other defect, in function or in appearance, of the instrument of vision.

It is obvious that no particular rules, no rules, that is, which will fit all cases, can be laid down for the treatment of so multiform a complaint as amaurosis. When it manifestly results from disease of the brain, as when it accompanies hydrocephalus, or remains after a stroke of apoplexy, our attention must be directed to the disease from which it has sprung. When there is any reason to suppose that congestion or chronic inflammation of the internal tunics of the eye itself is concerned in the production of the amaurosis, we must adopt the measures that I have already described, as the most likely to remove the congestion ; and especially the mercurial plan. When there is ground for suspecting that the blindness takes its rise in vascular exhaustion, and nervous debility, we must have recourse to tonics ; bark, preparations of iron, nourishing diet, the cold bath.

After all, you will find too many cases, which will baffle your best directed attempts, and in which you will be required and warranted to try other expedients. When what I may call rational measures have been expended in vain, you may have recourse to such as are empirical and tentative. There are various *stimulants* which have occasionally been found serviceable : but most of them, I believe, fail much oftener than they succeed. Electricity is one of these : it is applied by taking small sparks from the eyelids, and the integuments round the orbit. The object of this is to rouse the dormant energies of the impassive nerve : and it appears sometimes to do this for the retina, as well as for the nerves supplying voluntary muscles. Mr. Ware tells us that electricity is most beneficial in those cases in which amaurosis has succeeded a stroke of lightning. You must take great care not to

employ this remedy when there is any inflammatory action at the bottom of the complaint : it should seldom be tried therefore when the affection is recent.

Strychnia has, of late years, been used for the cure of amaurosis. I shall hereafter take an opportunity of telling you the ordinary effects of that substance upon the body, when given in a certain dose—what is its poisonous operation, and what may sometimes be hoped from it as a remedy. In amaurosis it does good, when it is useful at all, by stimulating the exhausted or atonic nerve into action. With respect to this remedy also I may say—first endeavour to ascertain that it is not likely to do harm : that is, that the blindness is not dependant upon any condition akin to inflammation. Mr. Middlemore, of Birmingham, has probably given this remedy an ampler trial than any other person, and he speaks very favourably of its effects in certain cases : in others he found it to produce so much pain, and spasm, and distress, that he was obliged to discontinue its use. It is not given, in these cases, by the mouth, but applied locally, and Mr. Middlemore considers that it is most efficient when placed over the supra-orbitary nerve. He puts a narrow blister over the eyebrow ; when it has risen he cuts off the cuticle, and applies a piece of linen, for half an hour, to absorb the serum that continues to ooze forth ; then he sprinkles the strychnia, finely powdered, upon the raw part, and covers it with linen smeared with the *unguentum cetacei*. He repeats this every twenty-four hours, cautiously increasing the dose till the vision improves, or some sensible evidence of the agency of the strychnia becomes apparent. He commences with the sixth part of a grain.

I must here leave this subject of diseases of the eye.

In addition to the lessons which I pointed out before as capable of being learned by attending to the disorders of this small organ, I may now mention a few others, of no little moment, since we shall meet with their application again and again, as we proceed to investigate the morbid conditions of other parts. We have seen enough to convince us that mercury, properly administered, has the invaluable power of stopping adhesive inflammation ; of arresting the effusion of coagulable lymph from the blood-vessels : that inflammation of the same part may be sensibly modified by the simultaneous agency of some specific poison upon the system, as that of syphilis ; or by the presence of constitutional tendencies to disease, such as are observable in gouty and rheumatic people. And we have seen that the functions of a nerve may be perverted, suspended, or abolished, in various ways : by *pressure* made upon it ; by a *plethoric* state of its blood-vessels, or by an

empty state of them ; by *inflammation* of its texture, chronic or acute ; or even, in some mysterious, or hitherto unexplained manner, by mere irritation of a distant part ; by worms, for example, in the alimentary canal ; by poisonous substances introduced into the stomach ; and by what, in our ignorance, we denominate the freaks and caprices of hysterical disorder.   All these lessons we shall find repeated, as the course advances.

LECTURES
ON

MORTIFICATION,
Delivered at the Medical Theatre of St. George's Hospital.

By Sir Benjamin C. Brodie, Bart.
F.R.S. &c.

Lecture V.—Jan. 13, 1841.

Senile Gangrene.

Persons advanced in life are liable to mortification of the toes and feet ; generally beginning in the former, and extending to the latter.   By persons advanced in life I mean those who bear upon them the marks of old age, which may, however, occur at various periods of human existence.   One of the worst cases of mortification of the toes which I ever witnessed, connected with what might truly be considered old age, occurred in a man of six-and-thirty, worn out by the operation of bad habits upon an originally bad constitution.

The question here arises, *in limine,* why is it that old persons are liable to this disease ?   Morbid anatomy enables us to answer this question.   I have examined the bodies of a great many old persons who have died with mortification of the toes, and I have always found some morbid condition of the arteries of the affected limb. In the great majority of cases there is extensive ossification of the arteries of the thigh and leg.   In many cases the arteries are not only ossified, but some of them are contracted and obliterated.   Thus I have known the femoral artery to be obliterated from the origin of the *profunda* down to the ham. In other cases one or more of the arteries of the leg are obliterated, while the femoral artery is still pervious.   In one case, of which I have preserved notes, the arteries were not ossified in any part of their course, but the femoral artery was converted into a gristly cord, and quite impervious from the origin of the profunda to the point at which it perforates the tendon of the great head of the triceps adductor muscle.   In none of these cases in which the arteries were contracted and impervious were there any such appearances as would have indicated that the contraction had been the result of previous

inflammation ; and it appeared to me that the change which had taken place in their condition was best to be explained by supposing it to be the result of a process corresponding to that which produces stricture of the urethra or œsophagus.

It has been said that mortification of the toes in old persons is often the result of disease in the heart itself.   This does not, however, exactly correspond with the results of my own experience.   It is true that I have known persons who had disease in the heart to die of mortification of the toes ; but then there was always enough in the condition of the arteries of the limb to account for the mortification, independently of the other disease.   Thus in one case in which there was mortification of the right foot, the muscular structure of the heart was soft, thin, flaccid, and easily torn ; one coronary artery was impervious ; and the right iliac artery, for the extent of three inches, was impervious also in consequence of it being completely filled by a mass of firmly coagulated blood. In another case, in which there had been mortification of the right foot, the muscular structure of the heart was pale and flaccid ; one coronary artery was contracted and impervious ; the cavities were dilated ; a mass of dense coagulum, resembling that found in the sac of an aneurism, occupied the appendix of the left auricle, and there was a similar coagulum obstructing the popliteal artery and vein of the right side, and extending some way down the branches of those vessels in the leg.

You are not, however, to suppose that mortification of the toes is a necessary consequence of ossification or obliteration of the arteries, and that it occurs in all such cases. I have no doubt that many persons have the arteries thus altered in structure for many years, although mortification never supervenes.   I have already explained to you that in some cases the arteries are ossified, and at the same time either contracted or obliterated ; that in others they are obliterated without being ossified, or ossified without being obliterated, even retaining their natural diameter.   It is evident that the quantity of blood admitted into the limb must be different in these different cases, and that the liability to mortification must vary accordingly.   But further than this : even where the arteries are rendered narrower, or actually obliterated, it seems that in general something more must happen to bring on mortification ; and you will almost invariably find that the immediate cause is an attack of inflammation. Perhaps the following is not an unreasonable explanation of the phenomena which occur. The arteries are ossified, or they are partially obliterated ; but still a sufficient supply of blood for ordinary purposes goes to the limb.   By and by, from some cause or another, the

foot becomes inflamed. I observed to you, in a former lecture, that during inflammation an increased supply of arterial blood seems to be required, and that the arterial trunks leading to the inflamed part become dilated, so as to allow this increased quantity of blood to enter ; but if the arteries are ossified, they lose the power of dilatation ; they cannot expand ; the greater supply of blood required in consequence of the inflammation is withheld, and so the part perishes.

You might suppose, *à priori*, that persons in the lower condition of life, who live hard by their daily labour, would be more liable to mortification of the toes than other persons ; but such is not the case ; at least it has fallen to my lot to see comparatively few cases of this disease in the hospital ; whereas, in private practice, I have met with a great number ; so that for one case under my care in the former I have had three or four in the latter. It is one of the penalties paid by those who enjoy the advantages of ease and affluence, and who live luxuriously. It is persons who eat too much, and drink too much fermented liquor, and do not take sufficient exercise, that are especially liable to this disease, and not the labouring poor.

Ossification of the arteries is a change that can take place only gradually ; and the obliteration of those vessels which I mentioned as occurring in some cases, probably takes place gradually also. You will easily believe that, under those circumstances, certain premonitory symptoms may arise in the lower limb before the disease is gone so far as to produce mortification. If you cross-examine a patient who has mortification of the toes, he will generally tell you, that for three or four years preceding he has had occasional pains in the lower limbs ; a sense of numbness in them ; that his feet were liable to be cold ; that when they again become warm, after having been cold, they have been very painful ; and that he has had a sense of weakness of the muscles. Such patients walk a short distance very well, but when they walk further the muscles seem to be unequal to the task, so that they cannot get on. The muscles are not absolutely paralysed, but in a state approaching to it. All this is easily explained. The lower limbs require sometimes a larger and sometimes a smaller supply of blood. When more blood is wanted, the arteries cannot open to let it in, and hence arise both pain and numbness. In walking, the muscles ought to receive an increased supply of blood, but, the arteries being ossified or obliterated, they are incapable of transmitting it ; and this explains the sense of weakness. This last circumstance may be illustrated by what you observe in a particular disease of the heart. Dr. Jenner first, and Dr. Parry, of Bath, afterwards, published observations which were supposed to prove that the disease which is usually

called *angina pectoris* depends on ossification of the coronary arteries. I will not say that such symptoms as those of *angina pectoris* can arise from no other cause, but I know that they do arise from it in certain instances. In two cases in which I examined the bodies of persons who died from the disease in question, I found ossification of the coronary arteries to a great extent, so that they were converted into complete bony tubes, while there was no disease of any consequence besides. When the coronary arteries are in this condition, they may be capable of admitting a moderate supply of blood to the muscular structure of the heart, and so long as the patient makes no unusual exertion, the circulation goes on well enough. When, however, the heart is excited to increased action, whether it be during a fit of passion, or in running or walking up stairs, or lifting weights, then, the ossified arteries being incapable of expanding to let in the additional quantity of blood which, under these circumstances, is required, its action stops, and there is syncope ; and I say, that something like this may be observed in persons who have ossified or obstructed arteries of the legs.

These premonitory symptoms, as I have said, may exist for three or four years, until at last some accidental attack of inflammation occurs which induces the mortification. A very frequent occurrence is this : the patient cuts a corn, the knife goes below it, makes the toe bleed, and a little inflammation follows : or it may be, that the foot gets chilled by exposure to cold, and the patient goes to the fire to warm it, and that this is followed by a degree of inflammation which, if the arteries were healthy, would be a chilblain and nothing more, but which, in their present condition, lays the foundation of mortification. A slight degree of inflammation of the toes almost invariably precedes the mortification ; vesications then take place, the vesicles burst, and at the bottom of them you find the cutis to be dead. This may take place in one toe, or in many toes at the same time. Most frequently, the disease having commenced in one toe, extends to the others, and then to the feet. Frequently, in the beginning of the complaint, there is a most intense pain, but sometimes the pain is very trifling. The mortification having once begun, a little inflammation is kept up on its margin, which slowly creeps up the foot, and the mortification follows it ; the constitution being probably little or not at all disturbed, the pulse remaining at its natural standard, and the patient in all other respects thinking himself well. The disease, in fact, generally has, in the first instance, a chronic form ; but sometimes it is otherwise, so that it exhibits all the characters of an acute disease. The man to whom I before alluded

as old in constitution, though not in years, being only thirty-six, had been a soldier, and had served in Canada and in the East Indies—that is, in cold climates and in hot. He had, by his own acknowledgment, been a drunken fellow, and dissipated in other ways. Having been dismissed from the army as superannuated, he gained his livelihood by working as a labourer in the Edgware Road. Many times, on going to work, he suffered from cold and numbness of the feet, followed by violent pain. One morning in September (not a very cold time of the year) these sensations took place to a very great extent ; severe pain and shivering followed, and his friends took him home in a coach. Two days afterwards he was brought to the hospital, and then all the toes of one foot were mortified, and one or two of the other. Under the treatment which was employed, and which I need not explain at this moment, he recovered. The dead toes came away, the sores healed, and he left the hospital as cured. Two years afterwards he was re-admitted with an abscess on one instep, and a sinus running under the skin. This occurred the year after I had been elected assistant-surgeon to the hospital ; and not knowing any better at that time, I introduced a director under the skin and along the sinus, and, according to what I had been taught to do in a case of this kind, I slit open the sinus with a lancet, making an incision two inches in length. With my present knowledge I should have acted otherwise. Some inflammation followed the wound, which extended to the foot. The next day mortification had extended up the whole foot to the leg, the pulse was frequent and weak, the skin hot, and the patient lay in a state of stupor. Two days afterwards he died. You will observe that in each of these attacks the disease had the acute form, and that in the second attack it terminated life in about four days. I examined the body after death, and found extensive ossification of the arteries of both limbs.

The more common history of the disease, however, is this : in its origin it has the chronic form, but if it goes on it sooner or later assumes the acute form. The mortification may gradually spread up the toes and feet without any urgent symptoms, and this may be going on for weeks, and even for months : then, all at once, a fresh attack of inflammation takes place, the mortification extends rapidly, the constitution suffers, the pulse becomes feeble and rapid, the patient falls into a state of stupor, and dies in the course of a few days.

There is no form of mortification which is more dangerous than that of which I am now speaking. A large proportion, indeed, of the patients who are so affected, under any mode of treatment, die. You will

not be surprised, then, that a great many different modes of treatment have been proposed. Where there is a disease that always gets well under a certain system, medical men have little inducement to make experiments ; and the wisest make none at all. But in an intractable disease like this it is natural that practitioners should be always looking out for new remedies. I do not pretend to speak of all the variety of remedies that have been used or recommended ; but I shall allude to the principal ones.

In the first place, those who have observed that the disease is preceded by inflammation have said, "bleed the patient ; treat it like an inflammatory disease." I have no doubt that some have been led to recommend this from a mistake respecting the pathology of the disease, which I noticed in the last lecture ; that is, from having supposed that this peculiar kind of mortification of the toes depends on inflammation of the arteries. I have, however, explained to you that the two cases are quite different. Bleeding has, however, been proposed, and in one instance I saw it tried. The mortification was to a very small extent ; there was but very little inflammation round it, and the patient seemed to have a very fair chance of recovery. But immediately after the bleeding the mortification extended rapidly up the foot, and he died. Indeed, it appears to me that we have no right to expect that we shall cure this disease by taking away blood. There is inflammation, it is true ; but if the inflammation terminates in mortification, it is because the part, on the principle which I just now explained, cannot get that additional supply of blood which an inflamed part requires. Now, if you abstract blood, and thereby lessen the quantity in the system and weaken the action of the heart, the supply of blood to the limb must be diminished, and the cause of the disease aggravated.

An opposite plan of treatment to this has been recommended by others. They have said, "this is a disease of weakness ; give bark, quinine, serpentaria, and other tonics." Now there are certain kinds of debility which will be relieved by these remedies, but here there is only a local weakness, depending on disease of the blood-vessels. Will such remedies as these mend the condition of the arteries ? Certainly they will not : but they will interfere with the digestion ; they will prevent so much food from being converted into nourishment as would be converted into it otherwise ; they will prevent the exhibition of stimulants which really are useful, as I shall explain presently. I own that I have very little, I may almost say no faith, derived either from theory or from practice, in the good supposed to be produced by the exhibition of what are called tonics. If you give

anything of the kind, let it be ammonia, combined with the compound infusion of orange peel. Ammonia for a little time may be useful; but I think that there are objections to its long-continued use in this and in every other case. It appears to me that patients who take it for a long time are at last rendered weaker by it instead of stronger. It is an alkali, and produces the same effect on the blood that is produced by other alkalies. If it be taken, however, for a short time, it may be useful.

In the management of these cases there can be no doubt that one principal object to be kept in view is the maintenance of a sufficient supply of blood in the system. As the abstraction of blood is mischievous, so the opposite treatment is likely to be beneficial. Let the patient, then, be put on a system of nutritious diet, not overloading his stomach so as to produce a red or yellow sediment in the urine, but taking as much food as can be easily assimilated, and no more. Let him live chiefly, but not entirely, on animal food, which makes blood—if I may use the expression—of a better or stronger quality than that derived from vegetables alone. In addition to this the patient will require the use of some such stimulants as ale, wine, or brandy. You will generally find that persons who have mortification of the toes are such as have been accustomed to take a good deal of fermented or spirituous liquor, and being accustomed to it, that they cannot do without it. Nor is this all. Those whose mode of life has been different will require the exhibition of stimulants under these new circumstances. The question, however, will arise in each individual case, what is the proper quantity to be exhibited? Some persons may want a bottle of wine daily; but very few, on this, or on other occasions, are benefited by so large an allowance as this. In the majority of cases from half a pint to a pint daily will be sufficient. You should ascertain what have been your patient's previous habits, and then give him wine or ale cautiously, observing the effect produced. There is one good rule of conduct in this respect, both in health and in disease: wine that does not occasion heat of skin, that does not raise the pulse, nor make the mouth clammy, nor render the patient nervous or irritable, any quantity that does not produce these effects, may be given with advantage; but otherwise it does mischief.

In all cases of mortification of the toes I have observed it to be of great consequence to attend to the state of the digestive organs. If the bowels are not in a proper state, the food cannot be properly assimilated; and the patient being confined, as he must be, to his bed, the bowels will not act without assistance. I do not advise you to give purgatives every day, but rather an active dose may be required once in three or four days; such as two or three grains of calomel at bed-time, with an aperient draught on the following morning, or blue pill with compound extract of colocynth; and all my experience leads me to believe that this is a very essential part of the treatment.

Mr. Pott was either the first who recommended, or the first who brought into general use, the exhibition of opium in cases of senile gangrene. What is the *modus operandi* of opium here I will not pretend to say; but I can have no doubt, from all the experience that I have had, that there is really no internal remedy so useful as this. I can scarcely remember meeting with a single case of recovery in an old man, from mortification of the toes, in which opium had not been exhibited. But it is with opium as with wine; a good deal of discretion is necessary as to the exhibition of it. You must not begin with very large doses of opium; they are too powerful for the constitution, and opium is mischievous if it keeps the patient dozing all the day. You may at first exhibit half a grain three times daily, and keep him slightly under its influence, but nothing more. If he continues to take it (and sometimes this may be necessary for months together), the dose will require to be increased; but you will never be able to persevere in the use of opium except you employ in combination with it those remedies which I last mentioned. Not only purgatives, but mercurial purgatives, are required by all persons who take opium in this manner, otherwise it stops the secretion of bile, and does mischief. The result of the case will very much depend on this—whether opium does or does not agree with the patient. If opium induces a feverish state of system, if it disturbs the sensorium, if it interferes in any way with the digestion of the food, and especially if it makes the tongue brown and dry, it can do no good; while the mere healthy action of it will be almost certainly beneficial.

With respect to the local treatment, the first thing is to keep the patient in bed. Not feeling very ill, he probably will wish merely to lie on the sofa; but this never answers; therefore send him to bed at once. If he strives against it for the first few days, he will be driven to bed at last, and will be worse than if he had gone there in the first instance. I think a great deal of the success of the treatment will depend on his being placed in the uniform warmth of bed at the very commencement of the attack. Rest in bed in the recumbent posture is essential. Then, what local treatment is required besides? It is common to apply poultices made of grounds of stale beer, or of red wine and oatmeal, and some recommend a solution of chloride of soda. I was accustomed

formerly to rub the legs and thighs with a stimulating liniment, but I soon left off this practice, finding that it did no good ; and I believe now that, if it does anything, it does harm. Why do the toes mortify ? Because when inflamed they do not get a sufficient supply of blood. Rub the thigh and leg with a stimulating liniment, and it is the same thing, only less in degree, as blistering them : and what would be the consequence of applying blisters ? It would draw the blood to another part. You want it in the foot, and you draw it elsewhere. It is something like taking blood from the arm, not indeed so mischievous : less in degree, but the same in kind. Then, I must say, that I have never seen any good from it in practice. Neither have I any reason, from what I have seen, to believe that those other applications which I have mentioned used as poultices and lotions are of any use.

Some few years ago I was in consultation with the late Mr. Vance, of Sackville Street. He had been surgeon for many years to Greenwich Hospital. Being always anxious to obtain what information I can from others, I observed to him, " You must have seen among the old men at Greenwich a great number of cases of mortification of the toes. What have you found, on the whole, to be the best local treatment ?" He answered, that he had found nothing to answer so well as wrapping up the parts in carded wool. I did not understand from him whether he wrapped up merely the foot or leg, or the whole limb ; but he added that he usually left it on for many days. It struck me that this was a very reasonable kind of practice. Wool is a very bad conductor of heat, and wrapped round a limb it must keep it of very uniform temperature, and at any rate save, in a great degree, expense and trouble of generating animal heat. Soon afterwards I had an opportunity of adopting Mr. Vance's mode of treatment. I had been poulticing a foot as usual, and the disease was going on spreading from one toe to another, and up the foot. Carded wool is so prepared that it may be drawn out in long flakes several feet in length, and in these I wrapped up the foot ; and then, thinking that I had better proceed further, I wrapped up the leg and the thigh also, as high as the middle of the thigh. I applied it rather loosely, one flake over another, until the limb appeared to be three or four times more bulky than it was in its natural state. The result was excellent. The mortification never spread from the time that the wool was applied, and the patient recovered. I have employed the same local treatment since in other cases, and although, of course, it would be absurd to represent it as always successful, yet I feel bound to say that I am satisfied that it produces much better results than any which I have ever employed.

In employing the wool, recollect that you should apply it loosely and uniformly, and plenty of it. You may afterwards sew it all up in a silk handkerchief, and leave it unopened for several days, sometimes a week. You may lay a simple dressing of calamine cerate on the mortified parts, replacing it whenever you change the wool. If the mortification stops, and the slough is coming away, you may, on account of the discharge which takes place, change the wool every other day. The carded wool possesses, as a little consideration will prove to you, many advantages over the poultices. In the first place, if you use poultices the limb is exposed alternately to cold air and hot poultices three times every twenty-four hours, that is, to repeated changes of temperature. In the intervals it is at any rate left to generate heat as usual. But if you wrap it up in carded wool, both these things are avoided. In another respect, also, this mode of treatment is a great comfort to the surgeon, the patient, and the whole family. Two or three times daily, whenever the poultices are changed, the family inquire, " Is he better ? is he worse ? is the mortification stopped ?" You are called upon to answer these unanswerable questions, and the patient's mind is kept in a constant state of excitement. But if you put on the carded wool, and leave it there, his mind in the interval is tolerably tranquil : he lives upon the hope that when the wool is next taken off the parts will be found better ; and such a state of mind is much more favourable to his recovery than the nervous anxiety which he experiences when the limb is examined more frequently. I believe that there are very few cases to which you will not find this method of treatment applicable. If there be any, it is those in which there is great inflammation and heat of skin, and in these it may be prudent to defer the application of the wool until these symptoms are abated.

Whenever the mortification is arrested, you will be made aware of it by a line of separation on the margin. The process of separation proceeds, in favourable cases, until the bones of the toes come away. You may have to cut through some dead ligaments and tendons, in order to promote the separation of the offensive and putrid parts, but you must cut through nothing else. If you apply your knife to living parts, you will certainly bring on a fresh attack of mortification. Leave the separation altogether to nature, and the natural process will do all that is required.

But there is another question. A man has mortification of the toes, and, independently of experience, you might naturally say,—here is a most dangerous disease ; why not at once amputate the limb ? It is probably unnecessary for me to tell you that it would

be contrary to all the old rules of surgery (for which I have great respect) to amputate a limb under such circumstances. I have never seen it done : I have never done it myself, but I have heard of cases in which the surgeon was, shall I say fool enough or ignorant enough ? to venture on this summary proceeding of cutting off the leg, because the toes were beginning to mortify. In every instance the stump mortified directly, and the patient died. The chance of recovery from mortification of the toes is not very considerable—that is to say, there is a great chance of the patient dying ; but still, under proper treatment, there is also a fair chance of recovery, and you ought not to risk this chance by inflicting on the diseased limb so severe a local injury as belongs to amputation.

I have told you that disease of the arteries lays the foundation of mortification ; but the disease may exist many years without mortification supervening, until some accidental circumstance brings on inflammation. I have known persons with disease of the arteries, and several toes mortified in consequence of it, in whom the mortification has stopped, the sloughs have separated, the sores have healed, and who have lived for years afterwards. I know a gentleman who is now alive, and in good bodily health, at least he was so not long since, whom I attended for mortification of the toes nearly five years ago. This patient was treated on the carded wool plan, and I cannot but suspect that it did something more than relieve the disease at the time. At all events, it may be admitted as a question, whether the keeping the limb wrapped up in the carded wool, which is like keeping it in a vapour bath, may not ultimately produce some beneficial change in the condition of the diseased arteries ; not indeed removing the phosphate of lime, which is deposited in their structure, but leading to their becoming gradually and slowly expanded, so as to allow of a more liberal supply of blood to the limb. Whether this suspicion be or be not well founded, I suppose that no one will doubt that it will be prudent in all cases to advise the patient after his recovery, always to wear a thick fleecy hosiery stocking, or to use some other kind of warm clothing, so as to preserve the limb from the influence of the external cold.

I must add a very few words respecting the treatment during the process of separation of the dead parts. Bark, quinine, and other tonics, may be useful now, though they were not so before. Wine, and a generous diet, are still required ; and some stimulating dressings, such as the unguentum elemi compositum, may be useful applications to the sores.

———

MUSCÆ VOLITANTES.

To the Editor of the Medical Gazette.

Sir,

Having ascertained, beyond a possibility of doubt, the nature of this annoying defect of vision, a few words of explanation may relieve the anxiety of many a nervous patient, and also be satisfactory to the profession. It is possible that others have made similar observations ; but if so, they have not been communicated to the public in any work that has ever attracted my notice. I have often heard even medical men express a dread of ultimate consequences from this simple, evanescent, and unimportant malady.

I received my first knowledge of this disease (if indeed it can be called disease) from the celebrated oculist, Mr. Ware ; and not doubting that a man so well acquainted with the organ of vision, its physiology and pathology, must be correct in his opinions, I made, during many years, futile attempts at cure, without investigating the matter for myself. Having, however, suffered annoyance in my own person from this cause, I was induced to examine it with more attention, and I then found that all the ingenious explanations which had been offered were absolutely without a shadow of foundation, and that the case was nothing more than an opacity of the lachrymal fluid.

To be convinced of this it is only necessary to fix the eyes steadily on some stationary object, and abstain from letting fall the eyelids. Chains of luminous rings, black spots, little brilliant annular specks, and other fantastic forms, gradually and slowly fall down in a sort of shower. The moment the lid is dipped into the groove conveying the tears to the punctum lachrymale, all these objects are dispersed into fresh forms, infinitely varied, to fall down again gradually, as before, over the eye, while kept steady, or to be spread right and left by the slightest lateral motion ; the chains of luminous rings, more especially, being broken and re-arranged *ad infinitum*.

The conviction produced by this simple experiment is at once so complete and so instantaneous, that I never yet met with a man who required a single word to be added to confirm his belief ; and when it is considered how

minute a substance, so near the axis of vision, may produce such an effect, and how naturally different degrees of opacity and adhesiveness may give the form of black spots, annular specks of light (single or in chains), &c., the phenomena are easily explained.

The causes of this malady are various; disordered stomach, fatigue, want of sleep, long fasting, and many others, may be enumerated, each of which must be addressed by its appropriate remedies; but in the immense majority of cases the disease is not connected with constitutional or general disturbance, but is completely local, and may be removed by a collyrium of sea water, or the application of a blister not larger than a sixpence near the lachrymal gland, and a collyrium composed of one grain of sulphate of quinine to three ounces of distilled water, with just sufficient excess of sulphuric acid to keep the fluid transparent.

Perhaps I have said too much on so trifling a malady; it is, however, sufficient to give great annoyance and alarm to those who have leisure to attend to minute sensations interfering with their comfort.—I am, sir,

Your obedient servant,

A. L. WIGAN.

Brighton, Jan. 30, 1841.

OPERATION FOR THE CURE OF WRY-NECK.

To the Editor of the Medical Gazette.

SIR,

THE following account contains the particulars connected with an operation which I performed, on Saturday, the 2d of January last, for the cure of wry-neck: should you consider it sufficiently interesting, as the operation is somewhat novel in this country, I should feel obliged by your insertion of it in your next number.—I am, sir,

Your obedient servant,

HENRY SYMES, M.R.C.S.L.

Bridgewater, Jan. 27, 1841.

Jane Irish, a delicate girl, aged 16, was the subject of congenital contraction of the right sterno-cleido mastoid muscle, and, on examination, the following appearances presented themselves:—The head was closely approximated to the shoulder, the right

mastoid process lying within two inches of the clavicle. The face was drawn to the opposite side, looking obliquely upwards. The right clavicle was extremely convex, and seemed as if pulled upwards; the right shoulder was raised at least three inches higher than the left; the trapezius muscle of that side being exceedingly prominent, forming, when the head was bent to the opposite side, a large ball. The deformity (as will appear) was not at all connected with any spinal affection, for, on tracing the spinous processes of the vertebræ, they were found to preserve their normal direction. There was a lateral curve in the cervical region, but this depended *solely* upon the contracted state of the muscle. Being satisfied, from this examination, that the spine had no share in the deformity, I determined on the division of the muscle, which I performed after the following manner, and which has been, on several occasions, so successfully performed by Professor Dieffenbach, of Berlin.

The patient being placed in a chair, I caused the head to be drawn to the opposite side by one assistant, whilst a second depressed the shoulder of the affected side. The muscle being thus rendered more prominent, I passed a narrow curved bistoury about an inch above the clavicle behind the muscle, dividing both its origins as I withdrew the knife, without causing any further wound of the skin, when scarcely a drop of blood followed. At the moment of the division there was an audible sound; and the head not only became immediately erect, but the prominence also greatly diminished, and the shoulder itself fell at least an inch. A dossil of lint was firmly applied by adhesive plaster, so as to prevent extravasation, or if any, by its pressure to cause its speedy absorption. The patient, who seemed to suffer but slightly from the operation, was then sent to bed, where she remained until the following Friday, during which time the head was kept in its new position by the use of bandages. On the removal of the lint, &c. (which had not been previously disturbed), I found the wound quite healed, and there was not even the slightest discoloration of the skin. I now applied a stiff pasteboard collar, in such a manner as to oblige the patient to incline

the head to the opposite side, which served to elongate the callus. By the use of straps, and by confinement to an inclined plane during a greater portion of the day, for a fortnight, the prominence has nearly disappeared. The shoulder is now on a level with its fellow, and the head is perfectly upright ; so that, to an ordinary observer, the patient presents no vestige of her previous deformity.

HIP DISEASE AND LUMBAR ABSCESS.

To the Editor of the Medical Gazette.

SIR,

ENCLOSED is the first of a series of papers containing observations on the diagnosis, pathology, treatment, &c. of hip disease and lumbar or psoas abscess, which I shall feel obliged by your inserting in your valuable and widely circulating journal, provided you think them of sufficient practical utility and importance to merit your attention. I am the more anxious to secure your acquiescence, because a day or two since a work, by Mr. W. Coulson, on Diseases of the Hip Joint, second edit. 1841, with "alterations and additions," came under my notice. I was not a little surprised to find, on a casual inspection of its contents, that many of these "alterations and additions," consisted in observations and allusions to the practice pursued by me in these disorders at the Royal Sea-Bathing Infirmary, without the most distant acknowledgment of the source from whence they were derived, save and except through the medium of the following note, on the first page of the advertisement :— "One of my sources of information, and perhaps it is the most extensive field in the world for the observation of scrofulous diseases generally, has been the Royal Sea-Bathing Infirmary*, at Margate," &c. I am fully aware, sir, that your journal is obnoxious to subjects purely controversial, and no one can be more sensible than myself to the propriety of excluding from a journal, devoted like yours to science only, matters of a like tendency. My intention on this occasion being to secure to myself whatever title to originality these papers may justly possess, before I

* Mr. Coulson has passed on an average about 36 hours at the Infirmary during nine years.

688.—XXVII.

offer them to the public through the medium of your pages ; but to do this it is necessary that I should produce the following verbatim copy of a letter in my possession, which I received from Mr. Wm. Coulson in April 1836, in order to expose the proceedings of himself, and Mr. G. B. Childs, his friend and relative :—

2, Frederick's Place, Old Jewry,
April 22d, 1836.

My dear Sir,—I am preparing a second edition of my treatise on the Hip Joint, and you will very much oblige me by giving me the result of your experience in the following queries, or any other point which may strike you connected with the disease :—

1. What are the appearances of the joint and the surrounding parts which you have observed in those who have died of hip disease ?

2. Have you ever found, on dissection, the head of the bone dislocated, and a new acetabulum formed ?

3. What viscera or internal organs have been principally affected in those who have died*, and the nature of the affection ?

4. Upon an average of the last five years, how many hip cases per annum ?

5. In what stage of the disease are they chiefly admitted ?

6. Can you form any opinion as to the age or sex at which hip disease most frequently occurs ?

7. The usual situation of the abscess ?

8. Have you observed any unusual direction to the exit of matters, as through the bladder or rectum ?

9. Is there often much superficial ulceration (I mean of the skin) in hip disease ; in what class of cases does it occur ; what effect does it exercise on diseases of the joint ?

10. What treatment do you adopt in the infirmary in cases of hip disease, as regards local and constitutional remedies in the various stages ; the application to the superficial ulcers, injections to the sinuses ; whether you find early opening of the abscess advisable ; the cases in which you recommend bathing, and the kind of baths ; the diet ; the iodine formulæ ; in fact, every particular connected with your treatment of hip disease, which has always appeared to me very judicious †. You must have seen some cases many seasons. Can you say any thing about the duration of the disease ? I know that you have some theory respecting lumbar abscess ; for many cases which I regard as hip disease you were inclined to regard as lumbar disease. What are your

* I recollect, last season, a man called Ford very ill with hip disease and ascites ; did he die ?
† Your opinion as to the effect of sea air, &c.

3 A

views on this point ? Have you ever seen a case of congenital dislocation of the hip-joint ? Have you seen both hip-joints affected at the same time ?

I am afraid that you will think me very troublesome, but I shall acknowledge with gratitude what you communicate. I shall be obliged by your writing to me on one side only of the page (leaving the back blank), and I shall most cheerfully pay double, treble, or quadruple postage.

I hope to be with you in the course of the season.

An early answer will oblige, dear sir,
                Yours very truly,
                        WILLIAM COULSON.

P.S. Have you found the knee-joint affected at the same time as the hip ? Does the disease in your opinion most frequently commence in the cartilage or bone ?

My reply was to the following effect, that I was too much occupied by my duties at the Infirmary to afford him the desired information, especially as his questions referred to very important topics, added to which I had been for some years past collecting notes on the same subject with a view to publication, and that, under these circumstances, I trusted he would hold me excused. I will not encumber your columns or trouble myself by detailing the various devices, to which that gentlemen resorted in order to obtain from me that information which I felt it was only justice to myself at that time to withhold, but pass on to the period of May 1838, when Mr. G. B. Childs was appointed my assistant in the capacity of Dispenser, and, if his his services were required in that department, of Dresser. Bearing in mind what had passed between myself and his relative Mr. Coulson, I at once assured him that I should feel most happy to impart to him whatever knowledge a somewhat lengthened experience had obtained for me in the treatment of the various and numerous cases that had come under my observation, at the same time I begged he would distinctly understand that, whatever remarks I might make on these particular diseases, were to be considered by him exclusively as my own, and as the reason of my request, I showed him Mr. C.'s letter, and stated what had passed between us.

He expressed himself obliged to me for my candour, assured me of a strict adherence to my wishes, and admitted

that he had been requested by Mr. Coulson to furnish him with a report of these particular cases under my care. Pleased with so much apparent just and proper feeling, and relying upon his honour, I henceforth treated him in the light of an intimate friend, affording him every opportunity and facility of obtaining whatever information he desired, in these and all other cases over which I held control. How he has kept his promise and repaid the offices of friendship will appear from the "following note," at page 75, of the work already alluded to. Mr. Coulson observes, "for the following note I am indebted to my friend Mr. Childs, who was House Surgeon (?) at the Infirmary in 1838." Hereupon follows a rather copious description of the mode of treatment peculiar to myself, more especially with reference to that which I have ventured to term the hepatic (which I shall have occasion to dwell on hereafter), the mode of exhibiting internally the iodide of mercury*, warm bathing, its effects on scrofulous sores, &c. and this, without stating that he was indebted to myself alone for the information ; but as I prefer becoming the exponent of my own particular views and treatment to the garbled statements of others, I shall recur to these particular topics, thinking it probable that your readers may chance to prefer the opinions resulting from 14 years' experience, to those of a young man who passed six months only at the Infirmary, in a subordinate situation.

Ere I finally dismiss this subject, I cannot help observing how much I have been amused, or withhold myself from the pleasure of extracting a sentence or two that occurs in the course of this note : "It is astonishing how the symptoms are frequently aggravated from the colon being overloaded. From torpor of the colon, I have seen the patient endure the most agonizing pains, which were immediately relieved by the action of a simple injection :"— Indeed ! I entertain a very strong opinion that Mr. G. B. Childs might have remained in blissful ignorance of the cause of these "agonizing pains," if I had not taken some trouble, and that not a little, to enlighten him on the cause of these "agonizing pains."

* The iodine treatment was first introduced at the Infirmary, by Dr. Canham, in the year 1833.

Again, he says, "a word or two with regard to sea-bathing." Modest young gentleman ! "There is a certain description of sores in which salt water bathing is inadmissible, and over which the salt produces a decidedly baneful effect, retarding the healing process, and setting up such a degree of local irritation, as, proves highly injurious to the patients health in general."—" In lepra the irritation is so great as to be scarcely endurable; and not only is this the case, but I never found the symptoms in the least degree ameliorated, but otherwise:" Really! who told him this? Now if Mr. G. B. Childs, like his relative, had only been candid enough to say from whom he had derived his information, it would have passed well enough.

Should any of your readers feel sufficient curiosity to compare Mr. Coulson's knowledge of hip disease in 1836, as shown by his letter to myself, with that of his works in 1837 and 1841, especially the latter, they will perceive that from one source or another, he has picked up a respectable stock of information.

At page 5, 2nd edition, 1841, he says, "It is often difficult to distinguish this stage of hip disease from incipient caries of the spine:" we are to infer, I presume, that this refers to caries of the lumbar vertebræ. Again, at page 34, "the disease of the hip at this stage may be mistaken for psoas abscess;" and then follow the diagnostic distinctions. On reverting to that paragraph of Mr. Coulson's letter which refers to this particular point, and runs thus:—"I know that you have some theory respecting lumbar abscess, for many cases that I regarded as hip disease, you were inclined to regard as lumbar disease—what are your views on this point ?" I have only to observe that our views differ very materially, as will appear hereafter. P. 57, "the liver, the largest secreting organ, seems almost universally to be affected in this disease." From whom did he learn this ? Page 75, "in every case of this kind an accurate examination should be made of the viscera," &c. At page 89, Mr. Coulson "thinks that the officers of the infirmary will bear him out in saying, that they have never seen any good arise from the use of moxæ, setons, &c." Considering that I have abandoned that practice ever since the

year 1829*, I, for one, shall feel most happy, and, I think I may venture to assure him that the rest of the "officers+," will readily bear him out, and will do the same kind office for myself.

It is needless for me to pursue these observations further; and I trust, sir, that your readers will consider Mr. Coulson's letter of 1836 decisive of whatever claim to originality I may possess, and which I have elsewhere stated is my sole object on the present occasion : and as I shall on no account, or under any circumstances whatever, revert to these topics as far as concerns Mr. Coulson and his friend Mr. G. B. Childs, I shall conclude this by assuring you that I am with every sentiment of respect,

<div align="center">Your obedient servant,
WM. OLIVER CHALK,
Resident Surgeon to the R. S. B. Infirmary.</div>

No. 7, Milton Street, Dorset Square,
North Side.

ARSENIC IN SULPHURIC ACID.

To the Editor of the Medical Gazette.

SIR.

HAVING been recently engaged in some toxicological experiments, I was surprised by observing that the sulphuric acid employed contained arsenic in considerable quantity. The acid had been purchased of an operative chemist in this city: the price eight pence per pint, which is the sum usually paid for pure acid ; the more expensive at four shillings and sixpence per pint being rarely required, even by analytical chemists. The quantity of white arsenic (as deduced from the weight of the sulphuret) in 20 fluid oz. of this eightpenny acid was 22·58 grs., a degree of contamination which becomes a matter for most grave consideration, when we reflect how many of our most common remedies are prepared with sulphuric acid. I may mention sulphate of magnesia and muriate of ammonia, the latter of which can scarcely escape contamination, if an arsenical sulphuric acid be employed. I lately obtained

* Mr. Coulson was made acquainted with this fact at his first visit to the Infirmary in the year 1832, in his capacity of a Member of the Medical Board.

† Drs. Canham, Dennison, and J. Waddington, Esq. Consulting Surgeon, have, for many years been acquainted with my particular views and practice.

from Apothecaries' Hall a specimen of
acid at eightpence per pint, and found
it to contain even more arsenic than
that which I have mentioned above.
The acid, however, sold by the com-
pany at four shillings and sixpence per
pint yielded no distinct evidence of the
metal. It appears almost certain that
there is a great abundance of arsenical
acid in our market at present, which
may probably be attributable to the
use of pyrites instead of Sicilian sul-
phur in the manufacture of acid—
the high price of the latter article
having provoked competition. I have
recently examined specimens of hy-
drochloric acid, and found them arseni-
cal, but in far less degree than the
sulphuric. I should not have published
these observations until I had made
further experiments on other articles
used in medicine for the preparation of
which sulphuric acid is necessary;
but the important nature of the subject
has prompted me to take the earliest
opportunity of communicating these
first results. It has been long known
that arsenic exists in minute quantity
in some varieties of acid, though that
from the English market has been re-
garded as particularly pure. I am not
aware, however, that the startling
quantity of 22·58 grains in a pint has
ever been suspected to exist in any
acid whatever.— I am, sir,

Your obedient servant,

G. O. REES.

Feb. 3d, 1841.

P.S. I may mention that arsenical
candles are again in the market: it is
only to-day that, from the symptoms
observed in several individuals of one
family, I was induced to examine the
candles in use, and obtained from them
a considerable quantity of arsenic.

MEDICAL GAZETTE.

Friday, February 5, 1841.

PAMPHLETS ON MEDICAL REFORM.

UNDER ordinary circumstances we
should apologize for returning so soon
to a subject so often discussed; but

medical reform is the great topic of the
day, and we should ill discharge our
office as faithful chroniclers, if we failed
to record, in addition to our own
opinions, those that come to us from
every quarter of the compass. Among
the late writers on this engrossing sub-
ject are Dr. Kidd, of Oxford*, and " A
Provincial Physician," whose name it
is not very difficult to guess†.

The first is a moderate reformer; the
latter would prefer to let well alone,
being almost or quite satisfied in an
age of general discontent.

" Genuine reform," says Dr. Kidd,
" is genuine conservatism;" or, if we
might be allowed to translate his phrase
into the language of Bacon, " A froward
retention of custom is as turbulent a
thing as an innovation; and they that
reverence too much old times, are but a
scorn to the new‡."

In order to understand the character
of the present desire for Medical Re-
form, the Professor thinks it right to
begin by an abstract of the history of
the College of Physicians.   At the
period of its foundation almost all phy-
sicians of London were graduates of
the Italian universities, which were
then the best schools of medicine in
Europe.

The often quoted words of the char-
ter, *omnesque homines ejusdem facultatis,*
comprehended all who had graduated
in medicine at any university, or who
had been approved by the Bishop of
London; and even as late as Charles
the Second's time, it seems that all
who had been examined and approved
by the College were *collegæ,* or *socii.*
The term "licentiates," indeed, appears
to have been used as early as 1555; but
at that period it signified those who
were licensed to practise only in parti-

cular branches of medicine—for example, as oculists.

Gradually, however, bye-laws were passed, making a distinction between fellows and licentiates, the former alone being eligible to College offices. Dr. Kidd does not know why these distinctions were made, nor why in time the doctors of Cambridge and Oxford alone were eligible to the fellowship. One sometimes errs strangely when attributing motives to one's *abavi* and *atavi* ; but we conjecture that the fellows of that day believed the innovation to be forced on them by time, " the greatest innovator."

When the College was founded, the Italian universities, as we have seen above, were in great repute, and their degrees were esteemed accordingly ; is there any thing unreasonable in supposing that the College of Physicians began to grow exclusive, when continental academies had grown too facile? At the present moment we do not recollect a single foreign university whose degree, whether in medicine or arts, is considered, in this country, a feather in a man's cap. We do not pretend to weigh the merits of Paris and Dorpat, Copenhagen and Coimbra, in the critical balance, but merely register the general feeling of English society; and give it as a solution of Professor Kidd's difficulty. This ignorance of the merits of foreign universities may be wilful blindness and perversity ; but it has been growing with England's growth, and strengthening with England's strength, and it is consequently not very wonderful that the London College, which in 1575 had more foreign than English degrees on its rolls, should afterwards have been more chary in their reception.

In the reign of Edward the First, an act was passed by which every man possessing an estate of twenty pounds a year was bound to send up his eldest son to be knighted; but it was a just complaint against Charles the First that he enforced this act for the sake of the fees when, from the altered value of money, this sum was a slender revenue. Now, Padua was a twenty-pound estate.

The extravagant length, however, to which the College carried their system of exclusion, and the law-suits to which it gave rise, would be a painful subject for commentary, were not every feeling of this kind dissipated by their liberal concessions of late years. They have justly thought that it is difficult to balance the claims of contending universities, and, rejecting all parchment testimonials, bestow their honours upon the living merits of the candidate. While it would be preposterous to make the titles of the easiest university a ground for admission, it would be equally wrong to consider them as an excluding brand; and the College have, therefore, taken that middle course, which will ensure the approbation of all thinking men, when the temporary heats of party are forgotten.

Professor Kidd informs us that there are nineteen sources for medical degrees or licenses, of which seventeen are in constant operation. He gives the smaller list at length, but we will mention two only, which might be likely to escape our readers' recollection; these are the Faculty of Physic and Surgery of Glasgow (besides the University), and the University of Durham. The list is certainly an awfully long one ; and there would be no harm if one or two of its minor stars could be persuaded to extinguish themselves; but we doubt much whether the profession would feel eventually gratified by the forcible substitution of a bran-new board or boards for the old examining bodies; it is among the possibilities, that the fresh examiners might play such fantastic tricks, that even zealous re-

formers would like the new *sumpsimus* less than the old *mumpsimus*.

The change would be less striking, however, if Dr. Kidd's proposition were adopted, of representing each existing body by one or more of its members in the new board, in addition to the members chosen from the profession at large. He farther proposes that the existing institutions should continue to live on as independent scientific societies, each with its own library, museum, and lectures. If we had a vote on the subject, we should propose that the new boards be rather added to those already existing, than placed as extinguishers over them; for we have lived long enough in the world to hear with but little expectation of the ideal perfections of non-existing institutions. The New Boards (one in each of our three capitals) are to grant licenses " to practice in any and in all the three branches, into which the profession is actually and always must be divided," and the examination is to be such as to shew the candidate to be duly qualified to practise either as a physician, surgeon, or general practitioner. As to the scheme of the boards giving titles as well as licenses, which Dr. Kidd attributes to some of the advocates of medical reform, he thinks it useless; for, provided the board gives the general license to practice, " it would appear that the essential point is gained, as far as individuals are concerned." Not so, Dr. Kidd. An open-handed board is wanted, to bestow the title of M.D. on every comer, and to make the degree very respectable besides. The Irishman in the story is not the only person that ever wished an apple-pie to be made all of quinces.

Another point touched on by the Professor, is the want of legal protection, which, he says, scarcely one of the seventeen licensing bodies can afford

its members. By legal protection he means exclusive privilege, which is, of course, given by the Army and Navy Medical Boards to those who have passed their examinations. The only other body in the list which attempts it, is the Worshipful Society. Their Act is stringent enough, and if they do not always succeed in their prosecutions, it is rather from the force of public opinion than from any loop-hole in the statute. It would require, indeed, several decisions of the Queen's Bench to settle what is meant by " practising as an apothecary." A friend on whom Dr. Kidd relies, supposes the protecting power of the society to be " limited to mere pharmacy, *i. e.* the preparation and sale of medicines." This is, assuredly, a mistake. Any one may either sell physic, or practice physic, without infringing the Act. It is the junction of the two which explodes the galvanic battery of the law.

The " Provincial Physician," whose learned and eccentric pen we immediately recognised*, desires no alteration. Far from sympathizing with those headstrong and headlong reformers or upsetters, who would change our very names, and cannot abide the style of physician or apothecary, he is for retaining all our present institutions. Our three great English corporations, with the druggists, those humble allies who close the rear, all come in for a share of his praise. The College of Physicians he esteems, for having been a model to the profession which it has ennobled. The College of Surgeons he admires as a body

---

* In speaking of the Apothecaries' Society, he says, " It is, with all its faults, a national blessing. I know the complaint that is uttered against it. That it has *not* protected its members. Not extinguished the quack. Not brought the druggist to his bearings. But this is not the fault of the society. Rather of the complainants. The Society has done what it could. But this corporation is not a spirit. It does not possess ubiquity."
The force of *stopping* could no farther go!

of volunteers. Ambition, not the painful compulsion of law, urges on the crowds who yearly obtain its diploma. The Apothecaries he praises, too, but does not agree with them when they lament the existence of practising druggists. "The Apothecaries are they who bewail their lot : or lend themselves to mischief-makers, which ululate in their abused name. These deluded gentlemen complain of the druggists; that they prescribe ; that they practise. That they abstract unfairly the patients of the apothecary."

The plain fact is, that the apothecaries, by their rise in society, have left a gap which has been filled up by the druggists. Sixpenny fees have no attractions to those who can get half-crown ones ; and poor men do not like to thrust them on those who take them grudgingly ; or, in the quaint language of the "provincial physician," they "are loath to knock at the repulsive door of the belackeyed surgeon." However we may regret that so difficult an art as physic should be practised by men of such slender acquirements as the majority of druggists, it is not easy to propose a remedy for the anomaly, which shall be at once agreeable to the profession and the public. The conservative physician proposes to allow the druggist to practise in his own house, but to enforce the law if he attempts to visit. "Drive back the delinquent to his counter." We fear that most of the profession would object to the first half of his proposal, and many of the public to the second.

As another exasperating topic he cites the salaries of the Union surgeons, and recommends them to be refused, as the proper remedy. The Cornish Association has resolved not to admit as a member any one who is sent down by the Poor-Law Commissioners. This looks well, certainly ; and we gladly accept it as an earnest of better times

SIR ASTLEY COOPER.

WE regret to state that Sir Astley Cooper has for some time suffered from an alarming attack on the chest, for which he has been attended by Dr. Bright, with whom Dr. Chambers has been more recently associated. The account of to-day (Thursday) is that he has had an indifferent night, and is not otherwise improved.

REFORM OF THE MEDICAL CORPORATIONS.

A DEPUTATION, consisting of various gentlemen from the Colleges of Physicians and Surgeons, and Society of Apothecaries, waited upon Lord Normandy on Monday the 1st, on the subject of medical reform, more particularly with reference to certain conferences which have recently been held between the bodies whom they severally represented. The following is given in the Lancet of last week as the recommendations contained in the report of the Committee appointed by the College of Physicians ; it will be found to contain some of those concessions which we dwelt upon in a recent article.

"The Committee appointed by the College of Physicians to confer with the deputation from the College of Surgeons, and the Society of Apothecaries, having carefully investigated the various grievances complained of in the several petitions to Parliament for Medical Reform, and having considered the communications from different fellows ' of their views, as to any or what changes in the present constitution of the College can be effected with safety to the great objects of the College,' submits the following report :—

The grievances alleged in the petitions for reform may be stated as follows :

1. The want of a general registration of licensed practitioners.

2. The absence of uniformity of education and qualifications in England, Ireland, and Scotland, and that licences to practise obtained in one country are invalid in the others.

3. Self-election to the fellowship of the College of Physicians, to the Council of the College of Surgeons, and to the Court of Assistants and Examiners of the Society of Apothecaries.

4. Tae exclusion of the licentiates of the College of Physicians from the use of the library and museum of the College.

5. The want of some legislative enactment respecting the licensing of duly qualified persons as chemists and druggists.

6. The want of some body or board to whom all questions of medical police, public health, &c., should be referred.

7. The absence of some restriction upon quacks and venders of quack medicines.

With respect to the last complaint, the necessity for some restrictions upon quacks or quack medicines, the Committee is of opinion, that any future legislative enactments upon that subject, if such were deemed adviseable, should be entirely irrespective of the College of Physicians, and should demand only the interference of the civil magistrate.

As regards the other allegations contained in the petitions, the Committee think that certain changes may be effected with safety, and, in its judgment, with advantage to the College of Physicians; and which will remedy the evils complained of, as far as they relate to the College.

The Committee, fully appreciating the difficulty of the task confided to it, begs to submit to the College the following statement of the alterations which it believes to be desirable at the present time.

RESOLUTIONS OF THE COMMITTEE.

1. That it is expedient that all physicians now practising throughout England and Wales, with a diploma of M.D. obtained from any British University, and who have attained the age of twenty-six years, should be entitled to admission into the order of licentiates of the College, without any examination, but upon the payment of fees hereafter to be determined.

2. In order to do away with the principle of self-election, the licentiates of the College shall henceforth nominate, annually, a certain number from their own body, for election into the fellowship, and from whom the fellows shall select one-half. The nomination to be conducted by ballot, a balloting-paper having been transmitted, on a given day, to each licentiate, whose address appears on the College list. The number of licentiates to be nominated in each year to be determined by the college.

3. That henceforth the licentiates shall, under certain regulations, have access to the library and museum of the College.

4. That the University of London having required for the degree of M.D. a high standard of education, which is, to a great extent, in accordance with the views of the College of Physicians, the College will be ready to admit into the order of licentiates the doctors in medicine of that university, provided that they shall respectively have attained the age of twenty-six years, and that the censors shall have assisted at their medical examinations.

5. That similar or equivalent privileges shall be accorded to the graduates in medi-

cine of Oxford and Cambridge, who have obtained their license to practise, provided those universities shall have adopted a curriculum of medical study equal to that which the College requires.

6. That it is desirable that uniform medical qualifications should be demanded of all candidates for the degree of M.D. in England, Ireland, and Scotland, and that the degree of M.D. so obtained in either country should henceforth confer a right to practise in all, provided the graduate shall have enrolled himself in the College of Physicians of the country where he resides.

7. That doctors in medicine from foreign universities, or from such British universities as shall not assimilate their qualifications for the degree of M.D. to those contemplated in the foregoing resolution, shall be admitted into the order of licentiates upon producing testimonials of having fulfilled the course of medical study now enjoined by the college, and after having undergone the usual examinations by the censors.

8. That the College of Physicians should have only one Board of Examiners and a uniform system of examination for all candidates for their license, and that the order of extra-licentiates should be abolished.

9. That in any new legislative enactments that might be necessary to carry the foregoing resolutions into effect, powers might be vested in visitors appointed by the Crown (or in some other controlling body), to whom all new by-laws of the College of Physicians should be submitted for their approbation.

Lastly, the Committee is of opinion that if the Fellows of the College of Physicians should express their willingness to modify their statutes to meet the wishes of physicians throughout the country, and to facilitate the admission into their body of all duly-educated persons by the altering the mode of election into the fellowship, they would be authorised to claim from the Legislature a confirmation and extension of the jurisdiction of the College, so as to render it effective for the protection of the interests of their branch of the profession throughout England and Wales.

BIOGRAPHICAL SKETCH OF ESQUIROL.

JOHN STEPHEN DOMINIC ESQUIROL was born at Toulouse, in 1772, of a family much esteemed in the town, as well for their private virtues as for the services which they had rendered their fellow-citizens. At the beginning of the Revolution there was a frightful scarcity in France, and the mob of Toulouse was just going to call for the heads

of the engrossers, when Esquirol's father, being informed that there was a stock of corn at some distance from the town, ordered it to be brought immediately, and pledged his fortune for the payment. Though he was rich, his fortune was hardly equal to so enormous an expense, and he would have been ruined, to save the lives of his fellow-citizens, if the town had not discharged the debt so nobly contracted by one of its representatives. Such actions could not fail to make a lively impression on the mind of Esquirol, who, though quite young then, already possessed the high moral qualities of which his life was the continued expansion

Esquirol began his studies at the College de l'Esquille, at Toulouse. He then went to the Seminary of St. Sulpice, to attend a course of philosophy; but the government having ordered this establishment to be closed, he returned to Toulouse, where he commenced his medical studies; less, perhaps, in consequence of a decided vocation for the art of healing, than with the view of obtaining the place of officier de santé in the army, an employment quite in harmony with the mildness of his character and the habits of his mind. After having served as surgeon in the army of the Pyrenees, he returned to Paris with the intention of continuing his medical studies. Two men, equally celebrated, and equally worthy of their celebrity, filled with ardour for science, and rather competitors for fame than professional rivals, were then lecturing on clinical medicine, and divided between them the pupils of the Parisian school: these were Corvisart and Pinel.

Corvisart, an acute observer, as well as a bold, eloquent, and enthusiastic professor, drew an immense concourse of auditors to the Charité. Pinel, hesitating and timid, not knowing how to lecture formally, but only to chat good-humouredly, was followed in his visits to the Salpêtrière by a number of pupils, who, in zeal and knowledge, were nowise inferior to those who thronged the wards of the Charité. What made Pinel followed were two most valuable qualities; namely, great penetration as a practical physician, and great clearness as a professor. When you heard him discuss a disease, you would have thought that he was reading out of the book of nature. A few clear and simple propositions formed the subject of his lectures, and they were set forth in such a manner, that each hearer comprehended them without difficulty, and retained them with ease. From Corvisart one learned quickly; from Pinel, with accuracy. (Chez Corvisart on savait vite; chez Pinel, on savait bien.)

Esquirol attached himself to Pinel. There was such a conformity of character and tastes between the master and the scholar, that their acquaintance once formed, soon changed, on the part of Pinel, into paternal affection; on that of Esquirol, into filial love.

Pinel had struck the fetters off the lunatics in the Bicêtre; he had published his immortal Traité de la Manie, and, with the aid of Pussin, who was placed under him as superintendent, he had effected cures, which were the more surprising, as he had to treat none but lunatics supposed to be incurable, and who had already undergone, in vain, the treatment of the Hôtel-Dieu. This was merely physical; and, with the exception of a few modifications, such as is still employed in some of our establishments. The Noso-graphie Philosophique had also appeared; and this work, which has gone through fifteen editions, had immediately become the classic book of students, and even of physicians. Whether Esquirol thought less of the Nosographie Philosophique than of the Traité de la Manie (in which case he anticipated the judgment which has since been passed on the two works), or whether a secret inclination carried him to the study of mental diseases, he chose the latter subject, and dedicated his whole life to it. Every one knows the rough usage of lunatics before Pinel's time: they were purged, bled, loaded with chains, and confined in dungeons; while others were sent to the gallies, hung, or burned, according to the nature of their delirium, and the countries in which they lived.

In order to cure the mad, Pinel undertook to enlighten persons in their senses, and wrote his treatise on madness. The road being opened, Esquirol entered on it: he attached himself to Pinel, and followed him in his clinique among the lunatics at the Salpêtrière, where he collected his first cases. He admired his master's science, but was not dazzled by it. Being gifted with great penetration, a clear judgment, and wonderful activity of mind, Esquirol thought that Pinel's method might be improved, and undertook to do it. To venture to do more and better than Pinel was a great piece of boldness; yet he had this boldness, and Pinel himself applauded it.

Esquirol began by a thesis published in 1810, on "The Passions considered as Causes, Symptoms, and Curative Means of Mental Alienation." This thesis is not less remarkable for the justness of its thoughts than for the propriety and elevation of its style. Esquirol had been struck, not, as a modern says, by the analogies between madness and reason, for they are contraries, but by the points of similarity between the condition of some lunatics and that of persons agitated by strong passions; and from the cases which he had collected on this subject,

he had concluded, that madness is often a purely moral disease, and curable chiefly by moral means.

" Do you see," he said, " that man with an inflamed face, convulsed features, eyes red and sparkling? He is meditating some act of vengeance. He is uttering the sharpest and most insulting words: his voice is harsh and threatening; his phrases short, quick, and interrupted. It would seem that the organ of speech is not sufficiently moveable to express the ideas which arise in a disorderly crowd in his imagination, quickened by his wrath."

And in another place :—" Do you see that young man near the woman whom he adores? His eyes are fixed; his face turns pale and red; his respiration is frequent, his words interrupted. Do not his deep sighs, and the irregular and tumultuous pulsations of his heart, betray his passion? The image of her whom he loves pursues him; he no longer sleeps; he forgets to eat, and grows thin. Do not directly oppose his passion, for he is capable of attempting anything to obtain the hand of the woman whom it would be in vain to refuse him. The opposition which he encounters makes his desires more energetic; he knows not the voice of his relations, and misapprehends the counsels of his friends. Wait and hope; time and absence will do what neither advice, authority, nor reason could effect."

" A young Italian woman had gone mad in consequence of extreme vexation. A female friend sang some Italian airs before her, and the patient, who was much agitated and convulsed, became quiet and silent, and seemed to listen. The physician seized on this indication; he caused music to be played in the room next to the patient's, and she recovered her health."

Esquirol always recognized and proclaimed the efficacy of moral agents; and in the whole course of his long practice he employed pharmaceutical remedies only when the aberration of thought was accompanied by a material injury, characterized by some bodily symptom.

Some time after having published his thesis, Esquirol became the assistant of Pinel at the Salpêtrière; at the death of his master he succeeded him, and remained at that establishment until 1825, when he was appointed first physician at Charenton.

During his residence at the Salpêtrière, (I say his residence, because he really lived amidst his patients,) Esquirol became a writer for the great *Dictionnaire des Sciences Médicales*, in which he inserted long and really original articles on idiocy, mania, melancholy, monomania, dementia, delirium, hallucinations, and demonomania. The

words *idiotie* and *monomanie* are his own, and have become classical.

To undertake to analyse Esquirol's works on madness, would be to undertake the entire history of the disease; as there is not one of the forms which it puts on that Esquirol did not observe and describe. He pointed out first to physicians, and then to magistrates, the existence of homicidal monomania, and thus saved some unfortunates from death and the infamy of the scaffold. The memoirs written by Esquirol on legal medicine are very numerous. They were chiefly on homicidal monomania and moral liberty, and were inserted in the *Annales d'Hygiène Publique et de Médecine Légale*, of which he was one of the founders and most eminent writers.

While he was chief physician to the lunatic and epileptic patients at the Salpêtrière, Esquirol gave clinical lectures on madness, which yearly attracted a great concourse of native and foreign auditors. This instruction, where the cleverness and delicate tact of the professor were mingled with his profound knowledge, formed those physicians, who subsequently, and after having distinguished themselves by their labours in this branch of the art of healing, were placed, (thanks to the credit which Esquirol justly enjoyed,) at the head of great lunatic establishments. In Germany, in Italy, and even in England, the majority of special physicians, those who have made madness the chief object of their studies, consider themselves fortunate in having attended the lectures at the Salpêtrière, and in being called Esquirol's pupils. They are really so, for they have read and reflected on his works, which they have translated into their language, and made the guide of their practice.

Esquirol several times visited all the lunatic asylums in France at his own expense; he described them, had plans of them engraved, and intended to publish them some day, and to set forth in detail what he has but slightly touched on, namely, the best mode of constructing and managing a lunatic asylum. This work we shall never have, as Esquirol did not leave materials sufficiently worked out, to make us certain, when we collect them together, that we have his entire scheme. Yet the asylum which was built under his direction at Ivry-sur-Seine, may make up for his silence to a certain point, for he combined there, as far as he could, all that he judged capable of contributing to the cure of lunatics. The great establishments in France destined for the treatment of lunacy, have been partly constructed in accordance with the advice and plans of Esquirol; and abroad, where his counsels and name were not less venerated

than at home, we have seen a sovereign—
the King of Sardinia—order a large building,
originally constructed as a lunatic asylum,
to be turned into barracks, and a new edifice
on the plan of the French physician to be
built in its stead.   Esquirol formed the
finest collection in existence of ancient and
modern works, French and foreign, on the
subject of madness ; and he also collected
several hundred skulls and casts of heads to
assist the study of this disease.   It was not
for himself, but rather for the advancement
of science, that he had collected these valua-
ble materials, for they were at the service of
every one who wished to profit by them.
To obtain this favour from him, and to be
allowed to examine his MSS., it was by no
means necessary to adopt his doctrines, or
see as he saw.   With him, every one enjoyed
perfect liberty ; and, if he esteemed your
character, whether you were his pupil or not,
obliged to him or not, you might, without
fear of displeasing him, discuss a question
with him, oppose your ideas to his, and if
you were in the right, he yielded with a good
grace, for his self-love did not suffer in the
least by it.

Though religious by nature, and a devoted
partisan of the old monarchical creed, he
was far from requiring any one to approve
of his principles, far less to conform to his
opinions.   All that he asked from others
was tolerance, and he every day afforded the
example of this virtue.   Some of his old
friends spoke and thought like him ; the
younger ones all belonged to a party con-
trary to him, and yet he loved them all with
the tenderness of a father.   He had himself
made the remark, that those in whom he had
been most interested, whom he had invited
to his house and admitted to his intimacy,
far from sharing his opinions, had almost
always attacked them.   Thus he was never
surrounded by flatterers, a very rare circum-
stance in the high position which he occu-
pied, and which of itself would suffice for his
panegyric.

Too timid to make his way in the world,
as the phrase is, he owed his success to his
merit alone.   He neither intrigued nor
caballed, he felt no jealous rivalry, nor was
he in the least wretched, when some com-
petitor gained the day over him.   He some-
times saw enemies attack him with animosity,
and he pardoned them; he saw pupils whom
he had loved turn against him, and he did
not love them the less.   One day when I
was complaining to him of the attacks
against me, and let him see how much I
suffered from the whispered and printed
calumnies to which I was exposed, he smiled,
and consoled me by reminding me of his own
history.   When he published his first works,
he had been violently attacked ; improper

and abusive appellations had been addressed
to him ; he bore them without saying a
word, and if he remembered them, it was
not to accuse their authors, but to give me
an example useful to my repose.

The timidity of Esquirol never degenerated
into weakness, and he showed courage when
duty or honour required it.   At one time
he defended a man suspected of aristocratic
principles, and on his trial before the revo-
lutionary tribunal at Narbonne.   He spoke
from his heart, his voice was warm, his look
animated, and he astonished by his bold-
ness.   The audience was moved, and the
relenting judges consented to be just for the
nonce.   At another time, when he had become
a man of influence, he prevented the sup-
pression of the college of Sorèze ; it was
tainted with liberalism, and he was quite
monarchical ; but he was tolerant, and desired
to convince, not to force.   On another occa-
sion he opposed the dismissal of a Mont-
pellier professor accused of imparting revo-
lutionary principles to his pupils, and wished
the matter to be left to the cognizance of the
ordinary tribunals.   During the revolution
of July, his house was the asylum of M. de
Montbel, who was then a minister.

When Esquirol came to Paris, he was
without fortune or patronage, and he lived for
several years in a state approaching to dis-
tress.   He liked to recal this epoch of his
life to those pupils who were in a similar
situation, in order to give them courage and
the hope of better times.

A week before his death, and when
already labouring under a pulmonary gan-
grene which had hindered him from seeing
his patients at Charenton that day, he chose
to be present at a sitting of the Council of
Health, of which he was vice-president.   He
returned very ill, feverish, and spitting blood.
He went to bed, and the pulmonary affection
was of itself not serious; but he felt so weak,
that from that moment, MM. Louis and
Cayol, who were called in, thought his life
in danger.   Esquirol thought so too, and
whatever trouble was taken to deceive him
on this point, he prepared to die.   Without
having experienced any but physical suffer-
ings, as calm in mind as when in his best
health, he foresaw the day and hour of his
death, prepared for it with the faith of a
Christian, and expired tranquilly and without
a struggle, on the 12th of December 1840,
in the 68th year of his age.   Esquirol was
one of the most eminent physicians of our
era.   Henceforth his name belongs to his-
tory, and it will not perish.*

* Abridged from a life by M. Leuret, in the
Gazette Médicale, Jan. 2, 1841.

ROYAL MEDICAL AND CHIRUR-
GICAL SOCIETY.
Jan. 26, 1841.

Sir B. C. Brodie, Bart., in the Chair.

*Observations on Vaccination and Small-pox,
more especially with reference to the
Theory of Vaccine Influence, and the re-
lation subsisting between the cicatrix and
the character of the consecutive variola.*
By Geo. Gregory, M.D., Fellow of the
Royal College of Physicians, and Physi-
cian to the Small-pox and Vaccination
Hospital, St. Pancras.   Communicated
by Mr. Arnott.

The observations of the author, in the
present paper, are intended to point out,
first, the alarming increase of small-pox in
the metropolis, as shewn by the books of the
Small-pox Hospital ; and, secondly, the in-
sufficiency of the appearance of the cicatrix
of the former vaccination as a test of the
degree of protection afforded by the process.
Upon the first point he adduces the fact, that
the admissions in the first three-quarters of
1840 only amounted to 142, being at the
rate of 16 *per mensem ;* while in the twenty-
five days immediately preceding the reading
of the paper, they amounted to 93, being
nearly at the rate of 4 *per diem*—a greater
number than was ever admitted in one month
since the establishment of the hospital in
1746. Of 316 cases admitted in 1840, 194
had not been vaccinated ; of whom 87 died
of 45 per cent. ; 120 had been vaccinated,
of whom only 8 died, being at the rate of 7 per
cent. The remaining two had had the small-pox
previously. Of the 316 patients, 47 were
under five years of age, of whom 28 died ;
45 between 5 and 15, of whom 9 died ; 224
were adults, of whom 58 died. The total
mortality 95, or 30 per cent. on the pass
admissions.

With reference to the second point, the
author entered at some length into an ex-
planation of the causes by which the many
observed varieties in the appearance of the
cicatrices may be explained, and presented
the society with two series of well-marked
cases, in the first of which severe small-pox
occurred in cases presenting perfectly normal
cicatrices ; whilst in the second the opposite
anomaly presented itself, the lightest and
truly varicelloid eruptions co-existing with
small and very imperfect cicatrices. In the
conclusion of his paper the author expresses
doubt of the conclusion, seemingly derived
from the late experiments of Mr. Ceely, of
Aylesbury, of the identity of the vaccine and
variolous poisons.

Dr. Webster said he thought it might be
doubted, notwithstanding what Dr. Gregory
had adduced, whether the small-pox of the

present epidemic was really more general or
more fatal than that of 1838. He believed
it was not so much so ; for, on referring to
the Registrar - General's Report and the
weekly list of deaths, he found that the
number of deaths from small-pox in 1838
was considerably greater than any that had
occurred since.   He thought there were
circumstances that might render the results
of the statistics of the Small Pox Hospital
different from those of the metropolis at
large ; and that, however great the number
received into the hospital, the epidemic was
now generally on the decline, and not so
severe as that of 1838.

Dr. Gregory said that the number of cases
of small-pox now occurring and proving
fatal, ought not, in any comparison of this
epidemic and that of 1838, to be compared
with the numbers for the whole of that
epidemic, but with those for the early part
of it. The epidemic of 1838 commenced in
the autumn of 1837, just as the present did
in October, 1840 ; the former reached its
extreme height in May, 1838, in accordance
with the general law according to which
epidemics of small-pox take about from four
to six months to attain their acmé, and then
about the same time again in declining. He
therefore anticipated, and others agreed
with him in the calculation, that the present
epidemic would go on increasing till May or
June, and then again begin to decline. His
conclusion as to its severity was drawn from
the fact that the numbers admitted into the
hospital were increasing weekly, and that in
the last week they had exceeded the greatest
number admitted for very many years.

The President asked whether any compa-
rison had been made of the number of cases
of small-pox that occurred in the three last
months of last year, and in the three cor-
responding months of the year 1837.

Dr. Gregory replied that he had unfortu-
nately been too much occupied at the hospital
during the last month to make the researches
necessary to establish this point ; but his
impression from memory was, that the
number during the last year was somewhat
less than in 1837.

Dr. Webster said that the weekly returns
proved that the number was less : there was
but one week in the last year in which the
deaths from small-pox were more numerous
than in 1837, and that was the last week in
the year—a circumstance which might fairly
be attributed to deaths which had been
omitted in previous weeks, being put down
to this week, in closing the year's accounts.
That there was some error of this kind was
rendered the more probable by the apparently
increased mortality of the last week of the
year being not confined to small-pox, but
extending over many other diseases, so that
the total mortality in that week was stated to

be considerably greater than in either the preceding or the succeeding week. The weekly bills now published showed a decreasing mortality from small-pox, and he could not help thinking that these statistics were more to be relied on than the fact of the increasing number of admissions into the Small-Pox Hospital. It was very probable that the admirable arrangement of that institution, and the zeal and ability with which it was superintended by Dr. Gregory, would have a great effect in attracting patients thither; every one seized with small-pox would be anxious to obtain admission there, where he was sure to receive the best care and attention that could be afforded him.

Mr. Arnott begged to ask Dr. Gregory his opinion as to the age at which vaccination being performed was most likely to secure permanent protection. It was stated in the paper that only one case had been met with in which small-pox occurred after vaccination before the seventh year, and that was in a child that had been vaccinated at two months old. He had himself lately witnessed a case where small-pox occurred in a still younger child, vaccinated in the second month. He was, therefore, anxious to know whether it was likely that vaccination, performed at so young an age, afforded a less chance of success than that done at a later period. It was well known that children at the breast were not so liable to the reception of morbid poisons, such as those of measles, scarlet fever, &c. as older children; and in general the younger the child was, the less likely was it to be infected by these diseases. Did this peculiarity extend also to the vaccine disease?

Dr. Gregory said, that he believed the disposition to receive the vaccine virus did not depend on any peculiarity in the constitution of the young child, but on the condition of its tissues, which rendered it difficult to insert the virus fairly. In the first month or two, before the child becomes plump, it is extremely difficult to insert the virus so that its full effect should be produced; but, after this time, the operation was much more easy, and, in the majority of children, could scarcely fail of success. He should be glad to hear whether the experience of those around him agreed in this respect with his; in particular he would ask Mr. Ceely, of Aylesbury, what his opinion was as to the best time for performing vaccination.

Mr. Ceely said his experience agreed with the whole with that of Dr. Gregory. He did not think there was any thing peculiar in the constitution of the very young child that would prevent the vaccine disease going through its regular course. The condition of the skin in the first two months was an obstacle only to that mode of vaccination which is effected by the insertion of points;

he believed that if a few slight scratches were made carefully with the lancet, the operation would succeed as well, and the disease would pass through as regular a course, in children of a week or two old, as in those of older growth.

The President asked whether, in the cases of small-pox that had occurred after vaccination at the Small-Pox Hospital, it had been determined at what age the persons so affected had been vaccinated.

Mr. Arnott said that that was the pith of the question which he had wished to have answered. It was not asked whether a child two months old, being vaccinated, would have the vaccine disease fully developed and carried through its usual course, but whether, having gone through that course, its protective influence would be as great as it would have been if performed at a later period.

Dr. Gregory replied, it was impossible to answer the question. The greater number of patients admitted into the hospital were adults, whose parents were dead, or absent; these, therefore, could only know what their parents had told them, namely, that they were vaccinated when they were young; they could not be expected to tell the exact month of the operation: and even when the parents were still alive, he had found it impossible to arrive at any accurate information. He had over and over again asked them—when was this child vaccinated? Oh! they would say, when he was very young. But how young? two, six, or twelve months? Well, they commonly answered, somewhere about that age, sir. He could never meet with parents who could tell the age at which each particular child was vaccinated. He had lately lost a case at the hospital; it was that of one of a family of ten children, who had all been vaccinated at Aylesbury by the same practitioner. But the parents could not, even upon careful questioning, remember the age at which this particular child had been vaccinated; they only knew that they were all regularly sent, and that the sum of one pound one (not eighteenpence, but one pound one) was regularly paid. He had, therefore, been quite unable to make out what was the relative value of the operation performed in different months of early life. He believed that its success was best secured by choosing that period when the course of the disease was least likely to be interfered with. Of all causes of interference that which was most to be avoided was teething; and it was, therefore, advisable that the operation should be done before the sixth month, or (as in some children this process commenced very early) before the fifth month. And again, as in the early months the tissues were not in the state best adapted for the

reception of the virus, he thought that the fourth month was that which offered the best prospect of permanent success, and which should be generally adopted. Difficult as it was to arrive at any positive conclusions, yet he thought he had of late been able to make out that, when vaccination was performed later than the end of the second year, or, perhaps, he might say, in adults, the pro- bability of permanent security was not so great as when it was done in the earlier periods of life. He could, however, only throw this out as a suggestion requiring many more facts for its full establishment.

Dr. Webster said he should be glad to hear from Dr. Gregory whether his faith in the power of vaccination had at all decreased. It was evident that a considerable number of cases of small-pox after vaccination had occurred at the hospital, and among them many deaths ; he could not, for his own part, but suspect that, in these cases, the patients were mistaken as to the operation having been performed, or else that it had been ill performed.

Dr. Gregory said the best evidence he could give of his faith in the power of vac- cination was the fact stated in the paper, that of those who had small-pox, without being vaccinated, forty-five in one hundred died ; while of those who had it after vac- cination, with all the doubts and chances connected with the mode in which the operation was performed, only seven per cent. died. He would take this opportunity of asking the members of the Society, and especially Mr. Ceely, what had been the result of their experience in the use of the variolo-vaccine matter; he meant the fluid which had been obtained by that gentleman by inoculating the cow with variolous matter, and thus generating, as was supposed— though, he thought, on evidence not yet sufficient—the true vaccine matter. His own experience of it had of late been rendered extensive by his having had to attend to the vaccination of the patients during the illness of the surgeon. He believed that the variolo- vaccine produced effects by which it might always be distinguished from the old vaccine; the areola was always of a remarkably full red, and in the centre of the vesicle there was always a small green point. Mr. Ceely had described it as like the emerald set in the pearl ; the old vaccine vesicle was likened to the pearl set in the rose ; but this resembled the emerald in the pearl with the rose around it. By these characters he was sure he could always tell the effects of the variolo- vaccine ; and, in addition to these, he had observed that its effects, both locally, in the extent and intensity of the areola, and on the constitution, were more severe than those of the old lymph. He thought, therefore, that we ought to hesitate before admitting the

exact identity of the variolo-vaccine and the vaccine.

Mr. Ceely said that, in his own practice, he had found no constant difference between the effects of the variolo-vaccine and the old vaccine matter ; nor did he believe that the differences, when they did occur, depended on any thing but the characters of the patients. He had been amused by the different accounts sent to him by the various practitioners whom he had supplied with his new lymph : some wrote to him that they could discern no difference whatever between the effects of the new and old matter ; others, that they found the new lymph more active and violent in its effects ; while others again thought its action even milder. He had no doubt that all were right ; and that the differences each had met with depended on the peculiarity of the circumstances in which they had used it, and of the soil in which they had planted it. He believed that if a diversity of patients were vaccinated with it, no constant peculiarity would be observed. Dr. Gregory's patients were generally all of one class, and all placed in nearly similar circumstances ; and hence the regularity of the effects of the virus upon them. The popular opinion in his neigh- bourhood, where he had used the new lymph for the last two years, was, that it was rather more active than that which had been used for many years ; and probably this was, to some extent, true. But the difference was not to be attributed to any other peculiarity in the lymph than its being new ; for it was constantly found that the more recently lymph has been taken from the cow the more energetic is its action, and this whether it be the common vaccine or the variolo- vaccine.

A member having asked Dr. Gregory his opinion respecting the value of revaccination, and the age at which the second operation had better be performed, he replied that it was only within the last few years that he had had much experience in the practice ; for that till lately it had been carried on only in the higher ranks of society, and was scarcely ever resorted to among the class from whom the patients of the Small-Pox Hospital were drawn. In late years, how- ever, he had seen much of it, and had seen several cases (some of which were related in his paper) in which small-pox had occurred after revaccination. The case to which he had already alluded presented some points of interest in reference to revaccination. Ten children in the same family had all been vaccinated in their infancy by the same surgeon, and as nearly as possible under the same circumstances. One of them had lately died of small-pox. Eight of the remaining nine were at once revaccinated : in half, the vaccine disorder passed through all its stages as regularly and fully as if the ope-

ration had never been performed before ; in the other half nothing but an irritating pimple was produced. There was no difference referable to age and distance of time from the former vaccinations in these cases. Some of the youngest children had the disease strongly marked, and some of the eldest ; in others of each class it produced scarcely any effect. He thought there was something yet to be made out respecting that condition which renders an individual incapable of receiving the benefit of vaccination ; and till this was done he could only say, in reference to the operation of revaccination, that it should be done empirically. It was not improbable that by it the individual obtained a better chance of immunity from small-pox, but, whether he really did so or not, it was impossible at present to decide unequivocally. With reference to what had fallen from Mr. Ceely concerning the irregularity of the effects of the variolo vaccine, he would point out this fact as an evidence of its not being identical with the old vaccine. In the latter there was no irregularity ; in the patients vaccinated with it at the Hospital on Mondays and Tuesdays, he always felt sure of the kind of vesicles which they would return with on the Mondays and Tuesdays following ; but in those vaccinated on Thursdays with the variolo-vaccine, there was no such regularity ; matter used on Thursday, the 1st, would produce, perhaps, a severe form ; the matter taken from this on the 8th, would generate a mild disease ; and this last again, on the 15th, would be followed by a severe one. In all this the variolo-vaccine differed from vaccine, and resembled variolous matter, of which it was well known that there was no certainty whether the matter from a case of mild disease would produce a disease of like degree. Only lately he had seen a case in which inoculation from the mildest varioloid vesicles had produced the most severe confluent variola. From all this, therefore, he could not but repeat that it would be unwise to assume the identity of the variolo-vaccine and the vaccine before it had been more completely established by a number of carefully ascertained facts.

On Gouty Concretions ; with a New Method of Treatment. By ALEXANDER URE, Esq. ; communicated by the President.

The author's intention, in the few remarks contained in this paper, is to introduce to the profession a remedy which he believes to be likely to prevent the formation of tophous concretions in gouty subjects. The remedy in question is benzoic acid, administered in doses of one scruple an hour after a meal. " In the course of a couple of hours (as the author has found by frequent experiments made upon himself and others), the urine

voided, amounting to five or six ounces, will be found, on adding a small quantity of muriatic acid, to yield a copious precipitate of beautiful rose-pink acicular crystals, which weigh, after being allowed to settle for a day, about fifteen grains." The body thus produced by the agency of vital chemistry is hippuric acid, and is found to have taken the place of uric acid in the urine, more of the latter being discoverable. By thus substituting hippurate of soda, a salt of easy solubility, for the very sparingly soluble urate of that alkali, the author conceives that the formation of the tophous concretions may be altogether prevented.

The brief discussion which followed the reading of this paper elicited nothing of interest. The meeting, which was a very full one, adjourned at half-past ten o'clock.

CASES OF
DISLOCATIONS AND FRACTURES
IN THE CERVICAL PART OF THE VERTEBRAL COLUMN.
BY DR. SCHUH, OF VIENNA.

CASE I.—F. A., æt. 24, of a strong constitution, was sitting one evening at his work, when a companion sitting behind suddenly called out so as to frighten him ; he looked round quickly, and at the same instant felt a crack in his neck, and could not move his head back again. On the next day when he was brought to the hospital, he presented the following symptoms :—The face was turgid ; the head twisted to the right side, and approximated to the right shoulder ; the left side of the neck somewhat cracked, the right rather hollowed ; pain increased by pressure at the left side of the neck, in the part corresponding to the third, fourth, and fifth vertebræ. Every attempt to give the head and neck another direction was useless and painful : the direction of the upper spinous process could not be accurately followed by the finger ; the muscles of the neck were by no means morbidly tense ; the patient complained of weakness of the right upper extremity, and could raise it only with difficulty ; he could also not press with the fingers of his right hand nearly so forcibly as he could with those of the left. The other functions were normal.

I at once made an attempt at reduction, by drawing the head straight upwards by the chin and the occiput, and by fixing the patient's shoulder as he sat on the ground ; but in vain. In the evening the same attempt was repeated, but again without success : neither this nor the first gave him any pain. Leeches and cold lotions were applied.

On the second day after the accident the patient complained of an increase of weak-

ness in the right arm, and a sensation as if it were asleep. To exert more force, I now in some measure altered my mode of attempting reduction. I made the patient lie on his back in bed ; his shoulders were fixed by two linen towels passed round them, an extension was made with a handkerchief, passed under the chin, while an assistant held up the occiput in both his hands. After a gradually increased, and at last considerable extension had been made, both the patient and the assistant felt a crack or snip in the neck; and when the extension was gradually remitted and had ceased, the head and neck stood in their right position, and could be moved to either side, though not without some pain on the left side of the neck. The weakness of the right arm remained.

The day after the right arm was still of but little use. On the next day giddiness and confusion of the senses came on, with a frequent pulse and a tendency to sleep. Ten ounces of blood were drawn : the patient during the operation became faint and was convulsed ; but afterwards lost the giddiness and rapidity of pulse, and gained more power over his arm. On the following days he continued to improve, and on the ninth day from the accident was perfectly recovered.

This case, the author remarks, seemed to merit publication, because, like those of Desault *(Boyer,* T. iv. 103.) and of Suffert *(Rust's Magazin,* Bd. xxxiv. S. 442) it was produced merely by the sudden rotation of the head, and thus had its symptoms uncomplicated, so as to shew clearly what are the signs of a simple dislocation of an oblique articular process, and whether the stretching of the spinal cord in an attempt at reduction be a matter of indifference or not.—*Oesterreich. Jahrb.* Bd. xxx. St. iv.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXI.

*Diseases of the Brain and nervous system.
Difficulties of the subject. Short review
of some points in the physiology of the
brain and nerves. Peculiarity of the
cerebral circulation. Pressure.*

Diseases of the brain and nerves.—Having
considered some of the most important dis-
orders of the eye, because they afforded me
the means of illustrating many of the doc-
trines and principles which I had previously
endeavoured to lay before you, of *general
pathology,* I go next to the diseases of that
portion of the body, which, though it in-
cludes many distinct parts, is called, collec-
tively, the head. I pass over the maladies
to which the integuments of the head are
liable, because they will be treated of more
naturally and conveniently among the cuta-
neous disorders; and I come at once upon one
of the most interesting, and at the same time
most difficult and obscure subjects of special
pathology—that which embraces the diseases
of the brain and nerves. Though it will be
a slight departure from the plan I have pro-
posed of taking diseases as they affect diffe-
rent parts of the body from the head down-
wards in succession, I shall speak of the
diseases of the spinal cord, and of the ner-
vous system generally, in connexion with
those of the brain. To disunite them would
neither be easy nor useful.

Difficulties of the subject.—The study of
the maladies and disordered conditions of the
brain and nervous system, is surrounded

with peculiar difficulties: and, accordingly,
our knowledge of these diseases is less pre-
cise than of the diseases of most other parts
of the body.

1. One source of difficulty lies in the
circumstance that the structure of the ner-
vous system has no perceptible or understood
connexion with its functions. We do not
discover in the mechanism of this system
that adaptation of means to an end which is
so conspicuous in many other parts of the
body: and consequently, though such adap-
tation doubtless exists, we are not able to trace
the reason or the manner of its interruption.
We find in the lungs an apparatus of tubes
and cells fitted for the reception of air, upon
the expansion of the chest by the contraction
of certain muscles; of which muscles also
we can see and understand the action. If
we meet with any obstruction of those tubes,
or any obvious impediment to the play of
those muscles, we perceive at once how
and why the function of respiration is de-
ranged. But no alterations that become
visible, after death, in the brain or spinal
marrow, afford us any explanation of the
interruption of their proper functions; which
are, in three words, *sensation, thought,* and
voluntary motion. An apoplectic cell has
no relation, direct or inverse, that we are
capable of appreciating, with a sentiment;
nor a distended lateral ventricle with the
exercise of the will. The morbid anatomy
does not in any degree elucidate the disorder,
simply because the natural structure throws
no light upon the healthy office of the parts
concerned.

2. It is a farther source of difficulty, that
physiologists have not yet been able to deter-
mine, with any thing like precision or cer-
tainty, what share the several parts of the
brain and spinal cord have in regulating,
respectively, the functions which all physio-
logists acknowledge to belong to the nervous
system in the aggregate. There are many
and convincing reasons, for believing that the

brain is a complex organ ; but we can seldom put our finger upon this or that portion of the nervous matter which composes it, and say, *here* resides the influence that governs this or that particular function.

3. Again, the brain and cranio-spinal axis are so encased by their bony coverings, that, in the living body, we are unable to ascertain their physical conditions by means of any of our senses. Of many parts of the frame we ascertain the state by the sense of sight ; and of many parts that we cannot see, we still may recognize the changes by the faculty of touch, or by the ear. The brain and spinal cord we can neither see, nor hear, nor handle.

4. Besides these obstacles to the acquisition of information, by the exercise of our senses, concerning the organs affected ; the very disturbance of the functions of the brain cuts us off, in many cases, from that kind of information which we might otherwise derive from the statements of the patient himself.

5. There is a still greater cause of perplexity, with which we have to contend. The very same symptoms accompany alterations of the brain apparently of a very different, nay of the most opposite kind : and on the other hand, changes of structure, which, as far as we can perceive, are absolutely identical in their nature, are associated, in different cases, with totally different symptoms : and more frequently than not, nervous diseases are attended with *no* alterations of structure, appreciable by our senses.

6. And lastly, we are perpetually asking ourselves, when we find the proper functions of the nervous system disordered,—is this disorder the result of disease in the nervous matter itself ? or is it merely sympathetic of disease in other parts ? for there are few diseases of any kind which do not, in some degree, modify or disturb the due exercise of the offices of the brain and nerves : and it is very difficult often, and sometimes it is impossible, to determine whether and how far the disturbance is primary or secondary.

With all its difficulties, however, the pathology of the brain and nerves is always full of interest. How can it be otherwise, when we reflect that the nervous system is the medium through which we hold communion with the world around us ; the stage upon which all the phenomena of animal life are transacted ; the instrument of the mind ?

And with all its difficulties, there is also a good deal, in the pathology of the brain and nerves, that is fairly made out, and well understood; and we are at present in the right way for advancing our knowledge of this intricate and mysterious subject, by that careful collection of facts, and rigid induction of particulars, that will lead, at length, to a safe and useful generalization.

I shall endeavour to point out to you what is *known* of the morbid conditions of the nervous system ; I shall also state the conjectures and probabilities by which our judgment and practice must be guided, when absolute certainty is unattainable. With mere speculative questions, that have no practical bearing, I shall meddle as little as I can.

Physiology of the subject.—Our knowledge, I say, of the exact functions of the different parts of the nervous apparatus, is scanty. Some certainties, however, we possess ; and some strong probabilities which almost amount to certainties. Without first expounding my creed upon these matters, it would be impossible for me to explain, as it would be for you to understand, the notions I entertain respecting many of the diseases of the brain and nerves.

Omitting the sympathetic nerve and its ramifications, (for we know but little of its office, and still less of its disorders), the nervous system is made up of certain masses of nervous matter, called the *nervous centres ;* and of *nerves* therewith connected.

The nervous centres consist of the cerebrum and cerebellum, the medulla oblongata and the medulla spinalis. I shall include the cerebral hemispheres, and the lobes of the cerebellum, under the common term, the *brain*. So I shall speak of the oblong and of the spinal marrow, in the single phrase, the *spinal cord*, or the *cranio-spinal axis ;* their endowments appearing to differ more in degree than in kind.

I adopt the belief that the grey (which are much the more vascular) portions of these nervous centres, form the part in which their peculiar powers reside, or are generated ; and that their white or fibrous portions are, like the white and fibrous nerves, mere conductors of the nervous influence.

I incline also to the opinion (recollect, if you please, that I do not press these opinions of mine upon you as being necessarily correct), that the influence which originates in the grey matter, and is transmitted by the white, will at last be found to consist in, or to be closely connected with, some modification of electricity. We know that some of the effects of this influence may be very exactly imitated, in animals recently dead, by galvanism.

The functions of the brain and nerves are sensation, thought, volition, and the power of originating motion. There may be others ; but these four are all that we need, at present, concern ourselves with.

Now it is a part of my creed that the faculties of sensation, of thought, and of the will, belong to the brain : perhaps to the cerebrum alone. The precise office of the cerebellum is involved in much obscurity and dispute. Some of the opinions that

have been formed respecting it, I shall notice hereafter.

The chief grounds for believing that the brain proper is, exclusively, the instrument of the mind, are these :—

1. Because this portion of the nervous centres is superadded to the cranio-spinal axis, in the greatest bulk and most complicated form, in man : and after him, in those of the inferior animals which shew the largest share of reason.

2. Because, in inferior animals which evince a certain amount of mental endowment, all manifestation of intellect ceases upon the gentle and gradual removal of the cerebrum and cerebellum : the animals continuing to live, for a long time, notwithstanding this mutilation.

Again, it forms a part of my creed on these subjects that the motive power resides in the spinal cord.

The muscles furnish the instruments of motion.

Now there is a certain class of muscles which contract without our willing their contraction ; and generally without our being conscious that they are contracting. Such are the heart, the muscular fibres of the alimentary canal, and of the bladder. These are, therefore, called involuntary muscles.

There is another large class of muscles, which obey the bidding of the will, and serve the purposes of prehension, locomotion, and bodily effort. These are considered and called voluntary muscles.

There is still another distinct set of muscles, of which the habitual action is involuntary, yet which submit also to the interposing control of the will. You will call to mind at once the muscles of respiration, which act while we are asleep, or otherwise unconscious ; and the sphincters, which regulate the entrances and outlets of the body. Here, I say, the habit is involuntary, but the occasional action is prompted and governed by volition. But sometimes the involuntary action rebels against the willed action, and overcomes it. The muscle contracts in spite of the will.

Nay, those muscles which, ordinarily, move only in obedience to volition, do sometimes, under the influence of strong emotion, or of disease, contract independently of any effort of the will, and even in opposition to, and defiance of, the voluntary power.

Under certain circumstances the limbs move with much briskness and force in decapitated animals, in which sensation and volition are extinct. Some physiologists hold, indeed, that sensation and volition are properties of the spinal cord ; and they would object to these cases, that no one is warranted in affirming the movements in question to be independent of the will. The

animal has no means of informing us whether it feels or not, any more than the human head that has been severed by the axe or the guillotine.

This point, however, has been settled by certain phænomena which are observed to occur, in the human body, under disease. Limbs completely palsied as to voluntary motion, and quite dead as to sensation, do yet, under certain conditions, contract and move when the integuments are pinched ; the rational patient not feeling the pinch, and not being conscious of the movements.

Whence does the impulse that leads to motion in these cases proceed—how is the motive power awakened ?

The answer to this physiological question has a most important bearing upon the pathology of the nervous system.

It is no part of my purpose to enter into any history of the steps by which this curious problem has been worked out. Its solution is an achievement of our own time ; and I may add, of our own country. I profess no more than to sketch, in mere outline, the leading facts that have been ascertained ; yet I must, in passing, pay the tribute due to one indefatigable labourer in this department of science, whose sagacity has enabled him to seize the clue, and in a great measure to unfold the mazes, of the labyrinth in which this part of the physiology of the nervous system was so long entangled. Dim and uncertain glimmerings of the truth appear in the writings of bygone authors, but it was never clearly discerned, and plainly stated, and successfully applied to the elucidation of a large class of disorders, until the publication, in 1832 or 1833, of Dr. Marshall Hall's ingenious and most interesting researches into " the functions of the medulla oblongata and spinal cord." Similar views appear to have suggested themselves, about the same time, to Professor Müller of Berlin. I must recommend you to study the works of these authors ; and I may also point out, as fit writings for your perusal (since the doctrines I am now speaking of are comparatively new), Dr. Grainger's *Observations on the Structure and Functions of the Spinal Cord ;* Dr. Carpenter's *Inaugural Dissertation on the Physiological Inferences to be deduced from the Structure of the Nervous System in the invertebrated classes of animals ;* and a very able paper on the Pathology of the Spinal Cord, by Dr. William Budd, in the 22d volume of the *Medico-Chirurgical Transactions.*

If, on the other hand, you wish to see how nearly the idea, which has been so happily simplified into an intelligible principle by Dr. Hall, was reached by earlier observers, you may consult the writings of Dr. Whytt, upon nervous diseases.

740 DR. WATSON ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

What, then, are the main facts and doctrines, respecting this intricate subject, which modern research has made clearer?

It seems ascertained, that movements of those muscles which acknowledge the empire of the will, depend essentially upon some momentary change in the condition of the spinal cord. This change (whatever may be its nature) is capable of being affected in three several ways.

First, volition, originating in the brain, may send down an influence, which travels with electrical rapidity to the spinal cord; whence, the requisite change having been instantly produced, the motive influence passes, with proportional speed, along the nerves which connect the cord with the muscles to be moved.

Secondly, the change productive of motion may be wrought in the cord, whether the brain be attached to it or not, by mechanical, chemical, or electrical agencies, operating directly upon the cord itself.

Thirdly, the change productive of motion may be wrought in the cord, by an influence carried to the cord, not from the brain, but from the extremities of nerves distributed upon the internal and external surfaces of the body.

The action of this nervous circle, whereby, I say, an influence is first carried from the surfaces of the body, along nerves, to the spinal cord—whence again an influence is transmitted, or *reflected*, as it were, to certain muscles along certain other nerves—has been called by Dr. Hall the *reflex function* of the spinal cord. The apparatus subservient to this function is named by him the *excito-motory system*: the nerves which carry the impression *to* the cord are *incident* or *excitor* nerves; those which convey the motive impulse *from* the cord, *reflex* or *motor* nerves. Mr. Carpenter's terms (which I like better, except for their similarity in sound) are *afferent* and *efferent* nerves.

Dr. Grainger believes that physiology indicates, and anatomy can exhibit, *four* sets of fibres belonging to the nerves and the nervous centres. *Sensiferous*, and *volition* nerves, connected with the grey substance of the cerebrum, and subordinate to the exercise of feeling and the will; and *incident* and *reflex* nerves, connected with the grey matter of the cord, and belonging to the excito-motory system.

Whether this be the true state of the case, or whether the efferent fibres be the same, while the afferent fibres are different; the latter coming to the spinal marrow both from the brain and from the various surfaces, just as two trains may arrive at Euston Square ultimately by the same rail, although the one starts at Derby and the other at Birmingham; or (which is perhaps the better illustration) as, in some houses, the same bell is made to ring in the servants' hall by pulling,

indifferently, the dining room or the drawing room rope:—which of these two hypotheses is the more correct, I am not competent to determine.

This reflex action, independent of the will, and although attended often by consciousness and sensation, yet often also exercised when there is neither, governs the orifices by which air and food are introduced, and excrements are voided. The infant breathes and sucks by it; the adult uses his will for bringing nutriment into his mouth; in both, the act of deglutition, after the food has reached a certain point, is involuntary. The expulsion of the fæces, the urine, the semen, and the fœtus, is regulated by the same function. Nevertheless, most of these muscular acts are capable of being moderated and directed by volition. The reflex power, on the other hand, extends, both in health and in disease, to the entire system of the strictly voluntary muscles; during health it is manifested only in the maintenance of what is called their *tone*, their natural tension and firmness: in disease, as we shall hereafter see, it sometimes acts upon them with terrific energy.

Some of the difficulties which I enumerated in the beginning of the lecture, as impeding our researches into the diseases of the nervous centres, are insurmountable. One or two of them, however, appear to call for a more attentive consideration.

I say we often fail to discover *any* deviation from the natural condition of these nervous centres, or of their appendages; even when the disorder of their functions has been strongly pronounced.

We are not to infer, from this, that no change has taken place in these parts. The only legitimate conclusion is, that the nervous functions are liable to be deranged, impaired, or suspended, by altered conditions, not traceable by our senses, or at least not yet discovered by us, of the organs which minister to those functions.

There may be only one such undiscovered disturbing cause, variable in degree in different cases; or (what is more probable) there may be several such conditions differing in kind. A blow or fall, which *jars* the brain; a sudden mental emotion; an electric shock; a tea-spoonful of prussic acid; any one of these causes may destroy life, yet leave no vestige of its action in the nervous substance upon which it operates. It is probable that the fatal condition is not, in each case, the same.

We may even form a reasonable conjecture of the manner in which the invisible changes are sometimes brought about. We can conceive, for example, that *undue pressure* upon the nervous pulp on the one hand, or *insufficient pressure*—the other, may con-

stitute conditions of the kind we are in search of; and I shall be able, I think, to convince you that such is sometimes the case. Again, we can conceive that such conditions may be furnished by the varying state of the cerebral circulation. In point of fact, we *know* of some changes in the circulation through the brain which have the effect, invariably, first of modifying, and at length, if they are continued, of arresting, the cerebral functions. If *no* blood be sent through the arteries of the brain, death in the way of *syncope* ensues; if *venous* blood circulates in those vessels, it leads to death by *coma.*

But whatever may be the nature of the unknown, and perhaps fugitive, physical conditions of the nervous centres, thus capable of disturbing or abolishing their functions, it is useful to keep in our minds a distinct and clear conception of the fact that there must be some such physical conditions. By steadily retaining this idea of their real existence, we may hope, at length, to get some insight into their nature; which we are the less likely to obtain, if we dwell only on the obvious and visible injuries effected in the nervous substance; associated, as they are apt to be, with so perplexing a diversity of symptoms. Indeed, by the help of this distinct conception, we are at once enabled to reconcile some of the seeming anomalies and inconsistencies to which I before adverted. The same symptoms, I repeat, have been found to accompany physical lesions of the nervous centres, apparently different in kind, place, and degree: and, on the contrary, physical lesions, apparently identical in their nature, extent, and situation, are attended by different and contradictory symptoms. We must not attribute the symptoms, in such cases, to the visible physical lesions, but to some unperceived condition of the nervous centres, concomitant with those lesions. The *proximate cause* of the *symptoms* escapes our notice. The obvious physical changes may be remoter causes of the symptoms—causes of this proximate cause: but they may also be merely contemporaneous effects of some other remote agency.

Peculiarity of the cerebral circulation.—
I have adverted to deviations from the natural and healthy circulation of the blood through the brain, as being capable of modifying the nervous functions. But there is a very remarkable peculiarity in the circumstances under which the cerebral circulation is carried on *at all times*, which it is very necessary that you should know, or be reminded of. There is nothing like it in any other part of the body. The brain is the only organ which, under the ordinary state of the parts, contains at all times the same

quantity, or very nearly the same quantity of blood. This depends upon the mechanical construction of the head, and is capable of explanation upon the known principles of hydraulics. The brain is closely shut up in an unyielding case of bone, and is therefore exempt from the influence of atmospheric pressure: so that, supposing the solid parts unaltered, you cannot empty the blood-vessels of the brain. The cavity being completely full, the blood which circulates in the vessels cannot be materially increased, unless something is displaced or compressed, to make room for the addition. Nor, as it would seem, can the quantity be materially diminished, without the entrance of something to supply the place of the blood subtracted. We should arrive at these conclusion by *à priori* reasoning; and we find that they are confirmed by certain very curious facts, which I will briefly mention, because they suggest considerations of much practical interest and importance.

Dr. Kellie, of Leith, performed, with reference to this subject, a series of experiments upon animals. He bled the animals to death, under various circumstances: and he found, as might naturally have been expected, that all the other organs of the body were blanched and emptied of their blood. But, (what would have been very surprising to him, if he had not been aware of the hydraulic principle just adverted to), the *brain,* in these cases, presented its ordinary appearance; or even seemed to contain more blood, in its superficial vessels, than usual. In one instance, he describes the sinuses as being loaded with dark blood, and the vessels of the pia mater as being delicately filled with florid blood. In another, the sinuses were charged with blood, the veins of the pia mater were filled, and the choroid plexus remarkably turgid. In a very few cases only did he remark that the vessels of the brain contained sensibly less red blood than in the others; and in all of these few, some serous effusion was observed. Having satisfied himself, by repeated trials, upon these points, he varied the experiment. He first made a small opening in the skull by means of the trephining instrument, taking away a little circular piece of bone, and *then* he bled the animals until they died; and in *all these* cases he found that the brain was as completely drained of red blood as any other part of the body. He did *that* with respect to the blood contained in the brain, which housekeepers do when they tap a barrel of beer. You know that if the barrel is quite full, you may introduce a faucet at its lower part, but no beer will run out through it. The pressure of the atmosphere operates upon that portion only of the fluid which is now exposed to the air, and its effect is to keep the beer in. But if you

bore a small hole with a gimlet through the top of the cask, and so admit air into the barrel, the beer will then flow readily through the lower outlet. Dr. Kellie imitated this process of making what I believe is called a *rent-hole*, when he trepanned the skulls of the sheep, upon which he made his experiments, and admitted air to the yielding membranes of the brain.

He availed himself also in these researches of what may be considered the converse experiment. He desired to ascertain whether, under circumstances calculated to gorge the vessels of the *head*, those of the *brain* were or were not made really more full than usual. He examined the brains of two men who had been hanged. When the scalp in these cases was divided, a great quantity of blood escaped, marking plainly enough the congestion of the vesssels *exterior to the cranium :* but there was no such congestion observable within ; "the sinuses contained blood, but in no extraordinary quantity ; the larger vessels on the surface, and between the convolutions, were but moderately filled; and the pia mater was, upon the whole, *paler* and less vascular than we often find it in ordinary cases." I can corroborate the accuracy of Dr. Kellie's observations in these last instances by what I have noticed myself. I paid particular attention to the condition of the head, when the body of Bishop, the murderer of the Italian boy, was examined below stairs. When he was brought here after the execution, the eyes were bloodshotten, and the lips and countenance turgid and livid. The inner surface of the scalp, when it was turned back, and the exposed surface of the skull, were very red and bloody, and in one part, on the right side of the head, there was some blood *extravasated :* but when the bone had been sawn through, and the skull-cap removed, the large veins of the brain did *not* appear unnaturally full.

In the year 1826, 1 was present in St. Bartholomew's Hospital, at the opening of the head of a woman who had been hanged, the day before, for murder. I find the following statement in a note which I made at the time :— "The scalp was bloody ; but the brain was of a very natural texture and appearance, and not more than usually full of blood."

In France, you know, they execute criminals by means of the guillotine ; and some curious speculations have been raised as to whether the head, after decapitation, remains for a short space of time sensible of what is going on or not. These speculations have led to a closer observation of the phaenomena that immediately succeed this mode of punishment ; and it has been noticed that, although much blood is effused as soon as the head is severed from the body, it comes from the vessels of the *trunk ;* and that the arteries

and veins of the *head* do not discharge themselves of their contents for some little time. All these facts go, you see, to the same conclusion ; viz. that so long as the solid contents of the cranium remain entire, the quantity of blood contained in the vessels does not, and cannot, vary much.

But although the actual quantity of blood in the cerebral vessels may continue the same, it does not follow that the relative quantities contained in the arteries and veins should remain unaltered. The healthy state of the cerebral circulation consists, in all probability, in the nice balance and adjustment of the blood in these two sets of vessels. I have already sufficiently explained to you the consequences of the circulation of venous blood through the arteries of the brain, shewing that without any change of texture in the cerebral matter itself, a mere alteration in the nature of the fluid circulating in its vessels may have fatal results. And the altered ratio of the arterial and venous blood in the organ may, and most probably does, disturb its functions very seriously.

In a very plethoric condition of the body, the arteries which go towards the head partaking of the general fulness, it is not difficult to conceive that there will be an impulse, or effort, *tending* to the propulsion of an undue quantity of blood into the arteries *within the cranium ;* and, under certain circumstances, actually producing a fuller state of those arteries, at the expense of the cerebral veins. On the other hand, any sensible interruption of the return of the blood through the veins will virtually augment that impulse upon the arterial current, which arises from the force of the general circulation. It is true that we cannot measure or weigh, so as to compare them together, the actual quantities of arterial and venous blood circulating at any period in the cerebral vessels. We never, therefore, can have any demonstrative proof that the kind of derangement, the alteration of balance, that has just been supposed, does really occur : but, as it evidently, in the nature of things, may occur, so many physiologists believe that it actually does take place, under various circumstances of disease. And taking for granted not only the possibility, but the positive existence of such a derangement, we are enabled to explain many remarkable circumstances connected with the pathology of the brain, which might otherwise be altogether mysterious and inexplicable, we can understand how it may happen that a person shall fall down insensible, become completely comatose, and perish ; and yet, on the examination of his brain, there shall be found no trace of inflammation, or of softening ; neither extravasated blood, nor effused serum, nor any change that our senses are capable of estimating.

Again, supposing such a derangement as has been alluded to really to exist, and to be attended with disordered functions of the brain, (giddiness, or headache, or drowsiness, or delirium), there would also exist (by the supposition) a tendency in the force of the general circulation to introduce more blood into the arteries of the brain than they could receive. And one consequence of this would be, an increased flow of blood into the *external* vessels of the *head:* and we know that in apoplectic attacks, with such symptoms as were just mentioned, there often are marks of what is called a determination of blood towards the head, of external plethora of the head; such as redness and turgidity of the face and neck, throbbing of the temporal arteries, a loaded condition of the conjunctiva, and so on. Now we see, in this state of things, how it is that we are able to relieve that condition upon which the symptoms and danger depend. We cannot, by blood-letting or other evacuations, diminish the quantity of blood in the cerebral vessels, but we can take off from those vessels the excessive impulse and stress arising from the general circulation, and even reduce it below what would naturally constitute a healthy impulse ; and so leave the vessels of the brain in a state favourable for recovering their proper balance. And that we *have* taken off this unnatural stress, we learn from the disappearance of the *external* redness and turgescence.

We may explain, by the help of this same theory, a very singular phænomenon observed in certain forms of cerebral disease, I mean, the *occasional* recurrence only of the symptoms, although the organic disease itself be *permanent*. For example, we see continually persons who are epileptic: that is, they have fits of convulsion and stupor *now and then*, and appear perfectly well in the intervals. After the death of such patients we sometimes find organic disease of the brain : a piece of bone perhaps projecting from the cranium, or a tumor, or a cyst : and this we are apt to consider as a sufficient explanation of the preceding disease ; but we are always pressed with this difficulty : if the tumor or piece of bone was the cause of the paroxysms, why had the paroxysms any cessation ?

It seems probable, or not improbable, that in such cases as these, and in many others, the permanent morbid condition does not interrupt the circulation in the brain, except when there is some increased impulse given to the circulation. The paroxysms are frequently accompanied by outward signs of plethora, or brought on by circumstances that are known to give a temporary increase to the force of the general circulation ; such as intemperance, bodily exertion, mental emotion, a costive state of bowels, straining,

and the like. A healthy brain might bear the variation thus induced in the pressure with which the blood from the heart seeks to enter the cerebral arteries ; in the diseased brain the balance is more easily destroyed.

There is a totally opposite condition of the system to those which I have hitherto spoken of ; marked, however, by symptoms of a like kind. And this also may be explained, upon the principle that the functions of the brain require, for their due manifestation, a certain equilibrium of the arterial and venous circulation.

Suppose we have anemia instead of plethora ; suppose that the whole mass of blood in the body is diminished : the effect of this upon each artery, (and therefore upon the arteries of the brain), is that the calibre of the vessel will lessen, and consequently a less quantity of blood will be transmitted towards and into the cerebral arteries ; but the whole volume of blood in the brain remains the same ; therefore blood will accumulate more in the veins ; and upon this increased mass of blood in the veins, the volume in the arteries will now act with a proportionally diminished and inadequate impulse. The balance of the circulation will be deranged, but in the *opposite direction* to that in which the former derangement was effected. It is probably in this way that the appearance of congestion in the superficial veins of the brain is brought about in animals that are bled to death.

Now disturbances in the functions of the brain, very much resembling those produced by the contrary derangement, will follow from this predominance of the blood in the cerebral veins also. Take one short case, very much to the point, narrated by Dr. Abercrombie, of whose full and clear statement respecting the peculiarity of the cerebral circulation I have made a free use : " A lady, aged 25, had been bled on account of head symptoms, which had supervened upon an injury. Considerable relief had followed each bleeding ; but the symptoms had soon returned, so as to lead to a repetition of the bleeding at short intervals; and this had been going on for several months. When Dr. Abercrombie saw her, she was stretched upon a couch ; her face of the most death-like paleness, or rather of the paleness of a stucco figure ; her pulse very rapid, and as small as a thread ; her general weakness extreme. The mass of blood appeared to be reduced to the lowest point that was compatible with life ; but she still complained of frequent headache, violent throbbing in the head, confusion, and giddiness. It was evident that evacuations could be carried no farther ; and, as a last experiment, trial was made of an opposite system of treatment : nourishing diet and tonics were prescribed. *In a fortnight* she was restored to very tolerable health.''

We see scores of cases resembling this, every day, in chlorotic girls; in children with head affections ; in women who have lost much blood in parturition; and in various other sick persons. These considerations are pregnant with the deepest interest. Dr. Marshall Hall, and the late Dr. Gooch, have deserved well of the profession and of the public, in having solicited attention to these cases, in which symptoms like those produced by plethora or inflammation are presented, and in which the treatment proper for plethora or inflammation has, for that reason, been too often adopted, with well-meant, but fatal energy. I do not pretend to tell you that our knowledge on these subjects is yet complete : for the points I have been adverting to are comparatively new to our contemplation : but I wish you to bear them steadfastly in mind in your future observation of disease. I am confident that you will often find in them the key to correct and successful treatment. I showed you, in the last lecture, how amaurosis might result from a comparative emptiness of the arteries of the eye : I am tempted here (as it illustrates also what I am at present speaking of) to cite an analogous affection, from a similar cause, of the sense of hearing. A gentleman, thirty years old, was reduced to a state of extreme weakness and emaciation by some complaint of his stomach. As the debility advanced he became very deaf; and this symptom varied in the following instructive manner. He was very deaf while sitting erect, or standing ; but when he lay horizontally, with his head very low, he heard perfectly. If, when standing, he stooped forwards, so as to produce flushing of the face, his hearing was perfect; and upon raising himself again into the erect posture, he continued to hear distinctly as long as the flushing continued : as this went off the deafness returned. *(Abercrombie.)* An old clergyman, who is sometimes my patient, is troubled by two grievances ; deafness, and an intermitting pulse. They are both always benefitted by quina.

Pressure.—I have thought it right to lay before you this view of the peculiar predicament in which the circulation of blood through the cerebral vessels is placed, and the probability thence arising that a disturbance of the equilibrium between the arterial and venous blood in that organ may be a frequent cause of certain derangements of its functions. But there is another principle by which many of the same derangements, that leave no vestige behind them in the corpse, may, with *at least equal probability*, be explained. I mean the principle of *varying pressure* upon the nervous substance. Physiologists say that the cerebral matter is incompressible : I know not on

what grounds this opinion rests; but whether it be compressible or not, whether, that is it be or be not reducible by pressure into a smaller compass, it is clearly capable of having different degress of pressure applied to it, and of being pressed out of its ordinary form. We shall see, hereafter, that by pressure exercised from within, by the distension of what are called the ventricles of the brain, the convolutions on its surface are sometimes flattened, and the natural furrows between them nearly effaced. Pressure there certainly is in what I shall have to describe to you as *hypertrophy* of the brain. There must be considerable pressure on the nervous pulp when blood is poured out within it from a ruptured artery in cerebral hæmorrhage. But the phænomena noticeable when a portion of the skull has been removed by the trephine, show very clearly that the encephalon sustains pressure from varying states of the circulation during perfect health. The surface of the brain, seen through the circular opening in the bone, is observed to pulsate ; and to pulsate with a twofold motion. With every systole of the heart, the surface protrudes a little ; and it again subsides with the succeeding diastole. This shows that the tension of the arteries, produced by every contraction of the ventricles of the heart, exerts a degree of pressure upon the contents of the cranium. But the brain has an alternate movement also, corresponding with the movements of the thorax in breathing ; rising with every act of expiration, and sinking with every act of inspiration. Now, during expiration, the blood escapes less freely from the head through the veins ; and thus again vascular fulness is found connected with evidence of pressure on the parts within the head. In further proof of this, if any were needed, I may again refer to Dr. Kellie's experiments. He removed a portion of the cranium of a dog by the trephine. The brain was observed to rise and fall alternately, but so as always to fill the cranium ; so that the rise was a sort of protrusion through the opening that had been made. One of the carotid arteries was now opened, and in a minute or two afterwards there was an evident gradual sinking and receding of the brain from the margin of the opening.

It is certain then that, whether the cerebral pulp yields to it or not, there is a constant alternation of a greater and a less compressing force, exerted upon it, during life. It is not improbable that this continual variation of the compressing force may be essential to the performance of the cerebral functions. May not the brain be thus incessantly *charged*, if indeed it be (as has been suggested by no less a philosopher than Sir John Herschel) " an electric pile, constantly in action," discharging itself by the

nerves, at brief intervals, " when the tension of the electricity developed reaches a certain point ?" However this may be, it is equally certain that the compressing force may transgress its natural limits, in either direction ; may be too great or too little. The functions of the nervous centres may be perverted, or lost, when the pressure becomes excessive ; or, on the other hand, when the pressure is insufficient. And this hypothesis of pressure being at the bottom of many nervous disorders, will explain equally well the obscure cases to which reference has been made. The pressure may cause fatal coma, and yet no evidence of its operation be left in the dead brain ; in cases of *permanent* disease with *occasional* symptoms, accidental circumstances may from time to time determine an undue amount of compressing force, or a deficient amount : and I think Dr. Abercrombie has gone too far when he says " we may safely assert that the brain is not compressible by any such force as can be conveyed to it from the heart through the carotid and vertebral arteries." Dr. Kellie narrates the following curious circumstance : — " Mr. G., with a numerous train of distressing symptoms, which too well marked the existence of enlargement of the heart, and of the violent propulsive energy of that viscus, had only one, characteristic of any disturbance within the head. On looking upwards to the whitened ceiling of a room, he saw a darkened spectrum, which vanished and reappeared with great regularity. It was soon discovered that the appearance of this umbra was synchronous with the systole of the heart, so that he used often, in my presence, to count his pulse with the utmost precision, by keeping his eye fixed on the ceiling, and numbering every appearance of the spectrum."

Objections, I should tell you, have been raised against this theory of pressure affecting the functions of the nervous centres ; but I think the objections are susceptible of a satisfactory answer. I must content myself, however, for the present, with having pointed out the main grounds upon which the theory rests. The difficulties that attend it, and the considerations which diminish the force of those difficulties, will come necessarily before us on a future occasion.

The two principles which I have here touched upon, as relating to derangements of the nervous functions — namely, an altered proportion of venous and arterial blood in the cerebral vessels ; and the agency of pressure ;—may perhaps both run up into one and the same principle. Pressure may act by disturbing the balance of the circulation : or the disturbed balance may act by inducing a variation or shifting of pressure. The evidence in favour of the operation of pressure is, to my mind, the more certain

and satisfactory of the two. To the one principle or the other I shall frequently be obliged to refer, in endeavouring to account for the phenomena of cerebral diseases : some of which I shall proceed to consider in the next lecture.

LECTURES
ON
MORTIFICATION,

Delivered at the Medical Theatre of St. George's Hospital.

By Sir Benjamin C. Brodie, Bart.
F.R.S. &c.

Lecture VI.—Jan. 20, 1841.

Mortification of the integuments of the leg.

There are cases of mortification of the integuments of the legs which appear to correspond very nearly to those of mortification of the toes, of which I treated in the last lecture. There is, however, sufficient difference between these two classes of cases to justify me in noticing them separately. Mortification of the integuments of the legs is of more frequent occurrence than mortification of the toes. We meet with it earlier in life, and in those who have less distinct marks of old age upon them ; at the same time that the chances of recovery are greater in the former than they are in the latter. Undoubtedly mortification of the leg (as well as mortification of the toes) frequently has its origin in organic disease of the vascular system. But then I find reason to believe that it takes place in many cases independently of organic disease of any kind—as in persons who are merely lowered and exhausted by previous illness ; whose heart does not act with sufficient power, because it partakes of the general debility. Such persons may and do recover perfectly, living for years afterwards without any symptoms of organic disease shewing themselves.

Let me not, however, run the risk of misleading you ; as the more fortunate cases, of which I have just spoken, do not include the whole of those which you will meet with in practice. So when you are first called to a case of this kind you must always look at it, in the first instance, with anxiety and suspicion.

A person comes to you with a vesication on the leg, and when the cuticle has given way you find a little slough at the bottom. The slough may go on spreading, probably very slowly, perhaps with little or no suffering. By and by there is an attack of severe pain, with surrounding inflammation, and perhaps shivering. In a day or two after this the mortification is found to be making greater progress. In bad cases the mortification spreads with frightful rapidity, with

much constitutional disturbance. The pulse becomes irregular, feeble, intermittent; the tongue is dry and brown; the patient wanders in his mind, then becomes comatose, sinks, and dies. Such is the history of one of the worst cases of mortification of the skin of the leg; corresponding, you will perceive, a good deal, in the symptoms, to those of senile mortification of the toes. There is a chronic attack of the disease at first, with little constitutional disturbance; the mortification spreading slowly; the disease afterwards assuming an acute form, and in a short time terminating life. But in other more fortunate cases the mortification goes on spreading slowly, with little or no suffering, with no great constitutional disturbance, and at last under proper treatment stops; the slough coming away, the sore granulating and healing. As I told you before, a patient who has suffered in this manner may live for many years afterwards, and have no return of the disease.

Sometimes the disease appears in a somewhat different shape. There is a simple varicose or other ulcer of the leg : by and by the surface of the ulcer assumes a dark colour, the granulations die, the mortification extends to the skin at the margin, and spreads slowly or rapidly, according to circumstances. Perhaps the slough may come away, the sore begin to heal, and actually heal to a certain point; then mortification may begin again, and go on to a certain extent, and then stop a second time. In this way I have known the disease to linger on for a year or more, sometimes terminating well at last, and at other times terminating unfavourably.

The treatment of these cases is very similar to that of the cases which I noticed in the last lecture, and, therefore, I need not occupy your time long with this part of the subject. The patient ought to be kept in the recumbent posture in the uniform warmth of bed. This I conceive to be a most essential part of the treatment, though it may sometimes require a considerable effort of your persuasive powers to carry it into execution. Not feeling himself ill, and suffering little or no pain, he may wish to lie on a sofa, or even to walk about. I have known patients thus afflicted walk to my house to see me, and have had great difficulty in persuading them that they must go home and go to bed.

With respect to the local treatment : in the greater number of cases I find none to answer so well as this—applying some simple dressing (calamine cerate, for example) to protect the part, and then wrap up the limb in carded wool, in the way which I explained in the last lecture. This should be left undisturbed, in the first instance, for several days; the period varying afterwards according to the quantity of discharge. There are a few

cases to which this treatment is not at first applicable : I allude to those in which there is a good deal of surrounding inflammation, and great heat of the limb. Under these circumstances the sufferings of the patient may be aggravated by keeping the limb wrapped up in wool. The part requires to be kept cool, and you may apply a piece of lint dipped in water, and kept constantly moist, or a simple poultice. Water dressing, however, is the simplest application, causing the least trouble to the patient, and is, at any rate, as effectual as the poultice. But when the heat and pain have in some degree subsided, then you may have recourse to the other treatment. When the slough has separated a broad ulcer is left, seldom very deep, and often quite superficial, and for the treatment of this no specific rule can be laid down. Usually the sore does not require any very stimulating application. I have found, on the whole, the Barbadoes naphtha (if it be genuine) a better remedy for the ulcers left after the slough has separated than any thing else. It is a mild and soothing application, yet it has a great tendency to clean what we commonly call a foul ulcerated surface. It is applied thus :—You dip lint in it, lay it upon the surface of the sore, place a piece of oiled silk over it, and then apply a bandage not very tight. This may be changed once, and, under certain circumstances, twice daily. If the limb be cold, and the circulation in it feeble, you may continue to apply the carded wool, or a thick fleecy hosiery stocking after the slough has separated; and in general it will be prudent for the patient to wear a warm stocking ever afterwards.

With regard to the constitutional treatment, your first attention must be directed to the state of the digestive organs. Generally in these cases the patient requires an occasional mercurial purgative once in four or five days, or once in a week, according to circumstances. I have given bark and other tonics, ammonia, and so on; but I cannot say that my experience leads me to place much faith in any of these remedies. I may refer you here to the observations on this subject which I offered when speaking of mortification of the toes. It is most essential that the patient's stomach should be able to digest food, and you should take care not to overload it with medicine if it interferes with his food; for food is much better than medicine. Wine is generally required, except just at the period when there is much inflammation and pain in the leg : but the quantity of wine administered must depend on circumstances. Here also I may recal to your minds what I said on the use of wine in the last lecture. Opium in these cases is, according to my experience, very

serviceable, just as it is in cases of mortification of the toes, but subject to the same restrictions as in the last mentioned cases. If it makes the tongue dry, if it interferes with digestion, it does harm ; but if it does not make the tongue dry, nor interfere with digestion, it does great good. You may exhibit it at first in moderate doses, increasing them according to circumstances ; but always bear in mind that when you have occasion to exhibit opium, mercurial purgatives will be especially required, as opium always has a tendency to stop the secretion of the liver, and nothing counteracts this ill effect of it to the same extent as mercury. When the sore has become quite clean and healthy, you may apply diachylon or soap plaster in stripes in a circular manner round the limb, with a bandage from the toes to the knee, treating it as you would treat other sores of the leg.

Peculiar species of dry gangrene of the skin. —The wax model that you see on the table exhibits the appearances of a very peculiar sort of mortification, which is not well described, so far as 1 know, by surgical writers. If I recollect right, however, there is a brief notice of a case of this kind in M. Quesnay's book on gangrene—a very excellent work, published by an eminent French surgeon about the middle of the last century.

I have extracted from one of my old notebooks the history of the first case of the kind that I met with ; and I shall read it as it stands here, believing that I can adopt no better method than this for conveying to you a knowledge of this disease.

" Susan Orange, a girl fourteen years of age, was an out-patient of the hospital, under my care, so long ago as October, 1812, on account of some kind of eruption of the skin of the left arm. She appeared full grown, but had never menstruated. She had a pale sallow complexion, with a very feeble pulse ; altogether exhibiting marks of a very languid state of the system. About the end of February, 1813, the eruptions became very much relieved. (Now of this early part of her case I have only some short notes ; and it is not even stated what was the exact character of the eruption. Whatever they were they did not exist to any very great extent.) Almost immediately after the eruptions in the arm had disappeared, in the beginning of March, 1813, she was seized with pain, confined to a single spot on the left forearm. The pain lasted three hours, and then subsided ; but that part of the skin of the forearm to which the pain had been referred, and which was of about the extent of a shilling, was left with a white and shrivelled appearance ; it was, in fact, dead, and in a short time the dried skin became hard and horny, of a straw colour, somewhat resem

bling a piece of parchment in appearance. As it dried, the small vessels in the skin became apparent, injected with red blood in a coagulated state. In a few days the slough separated, leaving a superficial sore, which granulated and healed under some very simple treatment. But before this sore was well closed, the patient had a second attack of pain referred to the margin of the cicatrix, and this was followed by a second slough very similar in appearance to the first. There was, however, this peculiarity in it—that while it formed a complete zone or circle round the cicatrix it was at some little distance from it, there being a narrow band of sound skin left between them. This second slough gradually separated, and the sore which it left healed ; but before this process was completed there was a third attack of pain at the margin of the second cicatrix. A third slough formed, nearly similar to the last — that is, presenting the appearance of a zone, with an intermediate zone of sound skin between it and the last formed cicatrix. The sore left by the third slough healed like all the others. On the 9th of May there was another attack of pain referred to another spot on the inside of the left forearm. It lasted a day and a night, was more severe than on the former occasions, and was followed by the destruction of a piece of the skin two inches in diameter. The slough presented the same appearances as the former ones, and came away at the end of a fortnight, being of the thickness of a crown piece. It left a sore which healed but slowly. About the middle of May she began to experience a slight pain upon one instep, which continued, and on the fourth of June this pain became very intense, entirely preventing sleep on the following night. On the morning of the 5th of June the pain had subsided, but a slough was formed as large as the palm of a man's hand, covering the greater part of the instep, which presented the same appearances, and ran the same course, as those on the forearm, except that the separation of the slough, and the healing of the sore, were more tedious than had been the case in the upper extremity. After this no fresh sloughs formed for a considerable time, though the patient continued in the same feeble state of health. She left the hospital, and I lost sight of her until October in the same year, when she was admitted into the physicians' ward, under Dr. Warren. She remained there for a considerable time in very weak health, with occasional formations of the same white cutaneous sloughs in different parts of the body. At last she quitted the hospital, and I lost sight of her altogether. But Mr. Hammerton, of Piccadilly, who was apothecary of the hospital at the time, informed

me that she went to stay with some friends who lived near Windsor. He has since heard that she died there, and that there was no post-mortem examination.

The model that you see on the table was taken from a patient of Mr. Keate's, and it very accurately represents the peculiar appearance which the sloughs assumed in the case of which I have given you the history. You see the disease in its various stages: some of the sloughs are recently formed, and in other places they have separated, and there is a clean granulating ulcer. The only circumstance that I remember different in the case of Susan Orange is, that there the vessels injected with red blood in a coagulated state, and ramifying through the white slough, were much more distinct than they are in this model. Mr. Keate's patient became a great deal better, and it is supposed that she ultimately recovered under the continued use of tonics. Tonics, and especially steel, were administered to the first patient whose case I have mentioned, without any advantage.

I had a patient in the hospital who laboured under a disease very similar. This also was a woman with irregular menstruation, who was liable to attacks of pain in the leg, which ended in the formation of thin sloughs. The only difference between this and the other cases was, that each slough was preceded by a vesication. The slough itself had the appearance which I have just described. This patient improved very much under the long-continued use of small doses of sulphate of copper; but at last she left the hospital, and I lost sight of her; and, indeed, you know that it must be very difficult to get the whole history of one of these cases; or of other cases, in which the disease is protracted for a great length of time.

Mortification from the Ergot of Rye.— Cases of mortification of the limbs are described as arising from the use of certain deleterious articles of food, especially from the eating of bread made with blighted rye, or rye containing ergot. It is said that people who eat bread of this unwholesome kind are liable to mortification of the extremities; and that whole families become affected with mortification under these circumstances. I have never seen any of these cases myself, and I cannot obtain from books any satisfactory information as to their pathology. I am not aware that there is any account extant of the appearances which they exhibit on dissection. I think it right to notice the subject, but as I can tell you nothing more of it than you can find in books I shall not dwell upon it.

Mortification of the extremities from unknown causes.— In one of the earlier volumes of the Annual Register you will

find a very curious account of a whole family becoming affected with mortification of the extremities, though it is not stated that they had been living on any deleterious articles of food. The account is given by a physician in Suffolk of a family in that county, and nothing is stated which throws light upon the cause of the mysterious disease. The father, mother, and five children, if I remember right, were all affected. The lower extremities mortified in all except the father, in whom the fingers only mortified. Mr. Solly, in the two last volumes of the Medico-Chirurgical Transactions, has given the history of a child in whom one extremity after another, without any evident reason, mortified. The disease went on for twelvemonths before it terminated fatally. The limbs had all mortified, and the sloughs had separated, a sort of natural amputation having taken place. The child died, and the body was examined after death, but the examination threw little light on the pathology; and the cause of the disease is quite mysterious.

In practice, you will every now and then find other forms of mortification, which it is impossible to notice in lectures.

Anthrax or Carbuncle.—There is, however, one other form of this disease which I think deserves your especial consideration, and with an account of which I shall finish this division of my course of lectures. The disease to which I allude is what is commonly called anthrax or carbuncle. There is something more to be said on this subject than upon ordinary cases of inflammation terminating in gangrene, and it is for this reason that, although I have referred to it already in one of my former lectures, I shall again call your attention to it.

Persons who become affected with carbuncle are most frequently those belonging to the affluent classes of society; and those especially who have eaten and drunk a good deal, and lived freely, and who have apparently enjoyed robust health, are liable to this disease, after they have passed the middle period of life. Dr. Prout has observed a very peculiar circumstance connected with this carbuncle, namely, that it frequently exists in combination with that form of diabetes in which there is sugar in the urine. The patient is generally in a state of ill health before the carbuncle appears; often he feels ill, though he hardly knows how to explain in what respect he is so, and then the carbuncle shews itself.

Carbuncle, in its commencement, does not always present itself just in the same manner. Sometimes there is a red cutaneous tubercle, or a pimple, which becomes exceedingly painful, resembling a boil, but which, instead of soon terminating like a

boil, goes on increasing in size, becoming more and more painful, with much induration at the base. Supposing the disease to be left to run its course, it will proceed thus:—the induration goes on increasing in degree as well as in extent, the skin becoming hard and brawny, and of a dark crimson colour, especially at the centre of the induration. I have known the induration at last to occupy a space not less in size than that of a soup-plate. The patient all this time suffers exceedingly from a burning pain, with a sense of weight, constriction, and stiffness. His health is otherwise deranged; his pulse is frequent; his tongue furred; sometimes he is sick, and perhaps he nauseates his food. In cases that terminate ill, you will find, after a certain time, when the induration is very extensive, the pulse becoming weak, irregular, and intermittent; there is great prostration of strength, a hurried manner, delirium, coma, and this last symptom precedes death. But the disease may terminate more favourably, even without the aid of surgery. The central part of the hardness becomes softer; you can feel an imperfect fluctuation under the fingers; the skin ulcerates in one small point, then in another, till you find it perforated in a great number of points, and a white slough is seen through the perforations. By and by the intermediate portions of the skin between these points perish, and a slough of the skin comes away. There is a discharge of a small quantity of thin matter, and a large slough of the cellular membrane is seen underneath. Some time afterwards the slough comes away, consisting partly of dead cellular membrane, partly of lymph, and partly of pus, which is infiltrated into it. Then the exposed surface granulates and heals.

But in other cases the disease, in its origin, is somewhat different, shewing itself not in the skin, but in the subcutaneous texture. There is a hard lump in the cellular membrane under the skin, which is excessively painful; this goes on increasing till it adheres to the skin, then the skin becomes discoloured, and the disease runs the same course as in the other cases, in which it begun with a red pimple.

The disease occurs in men more frequently than in women, perhaps because they live on the whole more intemperately. It occurs more frequently on the back, between the shoulders, than any where else; sometimes on the back of the neck, and sometimes on the occiput. I have observed that when it is on the back of the neck, and especially when it is on the occiput, the disease is very dangerous; but by far the greater number of patients recover in whom the disease is situated elsewhere, and in whom a proper

treatment is adopted. The disease is not very common on other parts of the body; I have, however, known it to occur on the nates and thighs, and once upon the face. I was sent for to see a gentleman who I was told was very ill, and when I visited him I could not at first conceive what complaint he had. I never saw such a man's face before. It took me some time to understand what it was. There was a carbuncle on the nose, and you may conceive, better than I can describe, the strange appearance of the human face under such circumstances.

This disease, I have said, occurs in those who have lived very freely, and, like most diseases to which such persons are liable, requires to be treated not by lowering the patient, but by giving him nourishment and wine—nourishment, as far as his stomach can digest it; wine, as far as he can take it without being heated, and rendered feverish and irritable. Where there is excessive pain you must administer opium. It is better, generally, when the patient is suffering a great deal of pain, to give a good dose of opium at night; but, if possible, to avoid giving it in the day-time. There is always a great objection to the exhibition of opium, as it will interfere with digestion and confine the bowels; but there is a still greater objection to the want of sleep, and you must give it as the least of two evils. If you administer medicine besides, bark, quinine, and other tonics, may be given. But I do not think that in general, during the active stage of the disease at least, you will find much good from any thing but nourishment, wine, and opium, with an occasional purgative. The purging, however, should not be carried to an excess. Moderate purgatives, administered at intervals, may be useful, and indeed necessary; but a repetition of drastic purgatives will be injurious.

But the principal remedy in these cases belongs to the local treatment. I described to you the disease, supposing it to be left to run its course, and it is always desirable to know what a disease will be if you let it alone; but I do not advise you to let this alone, nevertheless. Until there is an opening in the skin, until the pus begins to escape and the slough is exposed, the brawny hardness of the skin continues to spread. The slough and matter require an exit, and you must give them an exit by making a free crucial incision through the carbuncle. Make, not a small partial incision in the middle, but one which extends completely through the whole brawny tumor, from one side to the other, and then another at right angles to the first, also completely through the tumor and to the bottom of it. If this be done effectually, and not too early, you will generally

find that the progress of the induration is stopped. If it should, however, continue to extend, youmust follow it with an incision on another day. Where this incision is made at the proper period, it is generally effectual ; and with good medical treatment the patient recovers. In making the incision, you will find that you divide a thick slough of the cellular membrane, and it has a peculiar appearance, as I have already explained, in consequence of its being infiltrated with lymph and pus, so that when it comes away it is more than the mere destruction of the living parts will account for. After you have made the incisions you may apply a poultice to the part, and change it three or four times a day. It is not un-common to apply some digestive ointment, such as used to be called *basilicon*, or the *unguentum elemi compositum* ; it being supposed that this favours the separation of the slough. I do not know whether such applications have this effect or not ; perhaps they may : at any rate they can do no harm. When the sloughs are separated, the patient's system will be relieved ; but he will require support, both from food and medicine. If they were not useful before, he will now derive benefit from tonics, especially from bark. Although I much doubt the efficacy of tonic medicines in the early stage of the disease, I have no doubt they are very effi-cient and very useful at this period, when the sloughs have separated.

M. Dupuytren says, that there are elon-gations of the subcutaneous cellular mem-brane which extend into the skin, and that when one of these becomes inflamed it forms a boil, but if several be inflamed they form a carbuncle. It may be so : the disease may begin in these elongations of the cellular membrane of which he speaks, as far as I know; I cannot contradict this opinion. But there is something more than this : I do not believe a carbuncle to be a mere local affec-tion ; it is a constitutional disease, and is always preceded by something wrong in the general health. It seems to me as if there were something like a poison in the circula-tion, which is thrown out of it into the cellular membrane in cases of carbuncle ; so that we might be justified in classing this disease with small-pox and other exanthemata. In a case of small-pox, there is first an attack of fever, which is relieved as soon as the pustules appear ; and as these contain the variolous poison, there is little reason to doubt that it is the expulsion of the poison from the cir-culation that relieves the fever. The case which I am about to relate seems to indicate that something like this happens in cases of carbuncle. A gentleman, an old acquaint-ance of mine, formerly a surgeon of emi-nence in a provincial town, but who has

retired from his profession, about sixty-three or sixty-four years of age, called upon me some years ago, at my own house, in the morning, and said there was some complaint in his back, and that he suffered a great deal of pain. On examination I found that there was a carbuncle. I sent him home, and told him to poultice it. Two or three days afterwards, it being, as I supposed, in a proper state for the operation, I made a crucial incision through it. He was very much relieved, and was going on very well indeed, when there appeared another carbuncle, but on a smaller scale than the first. It was not a pimple in the skin, but the subcutaneous form of the disease which I have already mentioned. I told him what I believed to be the case. He said that it did not give him a great deal of pain, and I therefore thought it would be better to let it ad-vance a little further before I opened it. It went on increasing, the skin over it became purple, and the whole assuming the ordinary form of carbuncle. In the mean-time he continued well, and appeared to have hardly any thing the matter with him except the local complaint. But two or three days afterwards, on calling upon him, I found him in bed. On inquiring the cause, he said, in a faint voice, " O ! my dear friend, I am dying." I expressed a hope that that was not the case. " O ! yes," said he, " I am dying." I found that indeed his words were true. His skin was cold and clammy, and the pulse scarcely perceptible. I asked him how long he had been in that state ? His answer was, " During the night, all the pain subsided, and at the same time I became ill. I believe that the carbuncle itself has disappeared." And so it was : when I examined the back I could find scarcely a vestige of it. He died in less than twenty-four hours after this change had taken place.

Another circumstance is worthy of notice, as confirming the view which I have taken of the pathology of this disease. It fre-quently happens, when a patient has recover-ed from a large carbuncle, that other smaller ones, like boils, appear on different parts of his body ; and a succession of these, gradually becoming smaller and smaller, may continue for many months, or even for one or two years.

AN ACCOUNT

OF SOME

CASES OF UNNATURAL NARROW-NESS OF THE AORTA,

AND OF THE CONSEQUENCES OF THIS
MALFORMATION ;

*With Observations on the Causes which
produce the Communications between
the two sides of the Heart.*

BY T. WILKINSON KING,

Lecturer on Pathology at Guy's Hospital.

[Continued from p. 689*.]

Of the cause of the communication of the ventricles of the heart.

I SHOULD in the next place attempt to shew that the narrow aorta is one among many causes of the communication of the two auricles, but it will scarcely be out of place to make a few remarks on the communication of the ventricles, and these may lead to a readier comprehension of the opinion which I shall then take up.

It is scarcely a modern remark that in a very large majority of the cases in which the ventricles communicate, the pulmonary artery is at the same time obstructed seriously, though in various degrees. I do not suppose the case is different when the artery is in all points perfect, but takes its origin from a little third ventricle, through which the true right ventricle has the same kind of difficulty in expelling its contents towards the lungs.

I am not aware that any one has explained† the above coincidence ; and, indeed, until a corresponding elucidation of certain exceptions occurred to me, it seemed very difficult to prove any necessary relation between the two states ; but now probably the explanation adduced below will only require to be understood to obtain credence.

If the diagram above represent the state of the septum of the ventricles during the second month of fœtal life, and we suppose an impediment in the pulmonary artery, it is easy to conceive that delay and accumulation in the
Diagram of the two ventricles of the heart and their great arteries, with the septum of the ventricles incomplete, about the fifth week of fœtal life. The dotted line is in the situation of the common communication* of the two cavities.

right ventricle may keep up a current and a passage into the left cavity in the situation of the dotted line ; and thus, on the other hand, impediment in the aorta should also lead to the persistence of the ventricular communications by the pressure of the blood towards the right side. This last case is comparatively rare.

The common instance is that in which the aorta is said to arise from or communicate with the two ventricles, the pulmonary artery being too narrow, and sometimes completely obstructed ; in which case the aorta receives all the blood, and supplies the pulmonary arteries through the persistent ductus arteriosus.

The rarer cases are those in which the pulmonary artery arises from both ventricles, the aorta being too small, and the ductus arteriosus furnishes the descending aorta, or the chief part of it. Here I suppose it must be evident that the left ventricle will impel its residual current into the pulmonary artery, and thus maintain the opening in the septum.

The facts on which the above opinions are based must be too well known to need even a reference.

At present I do not know if there be certainly any other than the two kinds of cases here given. The following instance, however, may be thought to offer some difficulty in the way of the conclusion :—

No. 1380.—In the collection at Guy's

† A seemingly erroneous interpretation of Louis by Dr. Joy may appear to contradict this conclusion.

---

* Notwithstanding a contrary statement which has run through a succession of books, I very much doubt that the perforation of the septum ventriculorum ever occurs at any other part.

is a "heart with an aperture in the upper part of the septum of the ventricles. It was taken from a young woman, age 120, of loose life, but who had enjoyed good health till two years before her admission. Her principal symptoms were lividity of countenance, orthopnœa, and great physical weakness. The heart is not enlarged." The aorta seems pretty natural. The pulmonary artery can only be said to be small, and to have rather scanty and weak valves. The circumference of the perforation betrays a degree of thickening, roughness, opacity, and induration, that cannot well be accounted for, without inferring the existence of inflammation at some early period. My opinion is, notwithstanding, that the small pulmonary artery was probably concerned in the origin of this affection.

It may happen that the obstruction in the pulmonary artery or aorta is not quite sufficient to obviate the closing up of the septum, and we may find it, therefore, completed, though scantily ; thin, membranous, broad, and semitransparent : a fossa ovalis in the septum of the ventricles, situated beneath and between the posterior aortic crescent and the right anterior one ; and this is not a very uncommon appearance.

We have next to trace the consequences of congenital obstructions in the foramen ovale.

Of the communications of the two auricles.

Although the kind of impediment we have been considering may be inadequate to maintaining the ventricular communication of the young fœtus, it may still exert a mischievous influence on the foramen ovale of the auricles, by creating an undue distension in one auricle or in both. The parts being weaker, and the opening continuing naturally till birth, may render the effect of distension more considerable as well as more frequent.

If obstructions in the respiration and pulmonary circulation arise in the young child, (and sometimes doubtless at any age), the right auricle of the heart being distended by the delay in the pulmonary artery, and consequent accumulation and reflux in the right side of the heart, the valve of Botal may still be unclosed or very ready to yield, whilst

the support of fulness in the left auricle is unnaturally deficient. So long, however, as the foramen ovale is truly valvular (opening only when the chief pressure is from right to left) we must suppose that it transmits no blood when the two auricles are equally filled ; that is to say, when the pulmonary circulation is easy, and allows the left auricle to be well filled from the right ventricle.

M. Bizot has shewn that in two-sevenths of the cases he has examined there was more or less communication between the auricles ; but I do not believe the communication is to be considered as important in more than a quarter of the cases in which it exists. A narrow and oblique passage can avail little in any case.

It is only when the opening is free, and the pulmonary obstruction material, that the circumstance is to have weight in physiological and pathological reasoning ; and these instances are probably not equal to one-fiftieth of all fatal cases.

Of course, as a matter of theory, it is true, with respect to the communication of the auricles and of the ventricles, that the power being greater on either side will determine the course of the stream ; but other important circumstances must also be weighed along with the power, in considering the direction of the currents and their peculiar effects. The quantity of influx, the degree of distension, the relation between the capacity and thickness of the cavity, and the freedom of the outlets— all these, and probably more, are to be considered, and comparison made between them on the two opposite sides of the heart.

I shall now speak of a few marked cases in which, the foramen ovale being closed, pressure on one side has deepened the fossa into a pouch or cul-de-sac—a state which I shall call sacciform depression of the fossa ovalis. The only importance which I would here attach to the knowledge of this change relates to its illustrating still progressive alterations, such as by absorption, of which I shall afterwards speak.

The sacciform depression of the oval fossa is scarcely, I think, very uncommon. I do not know that it is ever produced but from undue pressure in the right auricle.

No. 1418 in the Museum is a "heart somewhat dilated, with large excrescences or vegetations about the aortic valves, which are somewhat contracted. There are likewise some adherent coagula within the left ventricle attached to the thickened curtains and cords of the mitral valve. The patient laboured under rheumatism about four years before death, but only complained of palpitation of the heart for the last twelve months. There are traces of slight pericarditis." Here is also a wide unequal fossa ovalis, with a concave depression; the ascending aorta appears narrow; the descending wider: the dilatation of the heart is considerable.

A drawing in the collection at Guy's represents a somewhat early stage of this sacciform depression of the fossa ovalis. The cavity would lodge the larger half of a filbert. In this case the foramen was open, but strictly valvular: it would easily have admitted a black lead pencil (vide No. 39-40).

The following is a somewhat more remarkable case (14th 8th mo. 1838):— A man, æt. 32, was affected with renal dropsies, and severe pulmonary engorgements. The cavities of the heart were dilated. The left ventricle was a little thickened; the left auricle was less dilated than the right, and the fossa ovalis formed a wide and deep depression, quite entire, but much and unequally thinned. A laminated cystiform clot was found in the right auricular appendix, and a similar body occupied one cup of the aortic valves.

No. 1396, in the Guy's Museum, is a specimen of an "enlarged heart, the parietes of which are remarkably attenuated near the apex of the left ventricle; the carneæ columnæ appear to be ruptured, and there is a considerable coagulum formed at this part (aneurism of the heart). From a gentleman, rather above the middle age, who died very suddenly in a state of syncope, of which he had had two or three previous attacks." This is an instance of general dilatation of the heart, and the auricles have equally participated in the yielding. The foramen ovale has a slight and valvular opening, but the membrane of the valve is elongated into the left auricle like the top of the finger of a glove, nearly an inch in length, and with very little appearance of wasting.

These examples are, at least, curious;

and I do not know that they have been before adverted to, yet possibly, when looked for, they will not prove extremely rare*. They result from undue pressure on the right side, together with defective support on the left. The main importance of the observation of them, after all, may be, that they illustrate the state of the auricles as to tension, which is still too little understood. It is needless to repeat that they are adduced here for a different object.

Many pathologists have dwelt on the possibility of the foramen ovale being opened by rupture, or a kind of ulceration; and I think I have some facts in illustration of these opinions, or rather of the latter process; for, although sudden violence, regarded by itself, may affect any part of the body, I conceive that, apart from an ulcerative or absorbing process, the laceration of the septum of the auricles must be exceedingly uncommon, and still more difficult to establish in the way of demonstration. The reflection is reduced almost to an absurdity, when we try to suppose the kind of external violence which an experimentalist might resort to, in order to rupture the fossa ovalis in an ox or a sheep alive and in health

Independently of the common valvular opening in the fossa ovalis of the adult heart, I think I could adduce a good variety of partial wastings and perforations arising in company with general dilatation, and some of these combined with undue openness of the proper foramen, which is likewise, I presume, mainly attributable to distension. It is, however, most probable that almost all the remarkable recorded instances of wasting of the valve have been connected with obstructions in the circulation in early life.

The following examples will not fail to establish two distinct circumstances. First, the valve perforated by absorption; and, secondly, the valve being incompletely closed in consequence of expansion of the auricular septum. I have not thought it necessary to advert to the simple congenital scantiness of the valve, which is well known.

I have by me a sketch from a prepa-

* Since writing the above I have again met with the like appearance. An expanded aneurismal fossa, completely cup-shaped, with slight partial thinning, but without any valvular or other opening. The patient was sixty-six years of age, and had aneurism of the aorta and carotid.

ration in the Boston Museum *, in which the diameter of the whole fossa ovalis is considerably more than an inch, but it is principally occupied by two nearly equal oval perforations, which are only separated towards the centre of the fossa by a thin narrow fibrous band. This band widens towards its connections with the edges of the fossa, and I conclude that it is progressively wasting in the middle. I need not tell those who reflect on these states, that, if the part were in a permanent state, it would be in the form of a rounded cord in the middle. My opinion is, that the disturbance continuing (*i. e.* the dilatation of the auricles), this band would become divided; for it is evident that a defective nutrition, as well as absorption, are predominant.

The following example occurred to Mr. T. Iliffe, of Newington :—A lady, about twenty-six years old, of delicate but not bad health, who had sometimes had bluish lips, became pregnant for the first time, and, towards the end of gestation, had dyspnœa and anasarca, a feeble and intermitting pulse, and a slight cough, with frothy expectoration. After an easy delivery, her health seemed to improve for a few days, but a rapid return and aggravation of symptoms, with somewhat coagulable urine, carried her off in a fortnight.

The heart presented some general dilatation and hypertrophy. The right ventricle was the most affected, and the pulmonary artery was disproportionately large. The foramen ovale formed a circular aperture of full three inches in circumference. Some strong reticular threads, situated posteriorly, or rather inferiorly (where the trace of the valve is to be sought) were the only remains of valvular membrane—sufficient indices of so many perforations in their interstices. The aorta was evidently too small. The kidneys were a little granular.

The following are exemplifications of the influence of distension in producing the wasting and retraction of the valve of Botal, without perforation : yet the wasting and perforation will be thought almost identical in some cases, as regards their origin and progress, since both are equally indicative that the absorbent action predominates over the nutritive power.

In the first case I presume that the narrow aorta has given rise to the free communication of the auricles.

In the second, that the same cause must explain the communication both of the ventricles and auricles.

The third case has a wide foramen ovale, which is probably referable to distension, which has arisen from undue narrowness both of pulmonary artery and aorta ; and here it is observable that no inequality of fulness has existed to obstruct the growing up of the septum ventriculorum.

The concluding example is one in which both pulmonary artery and aorta are narrow, but the chief consequences belong to dilatation of the heart.

In the collection at Fort Pitt, and in the Section of the circulating organs, No. 7, is a "Heart much enlarged, the foramen ovale open : diameter of opening an inch and a half.

From Michael Cooney, æt. 37, 45th Regiment, who, having suffered much in Ceylon from dyspnœa and other distressing pectoral affections, was invalided. On arrival he was admitted into hospital, and died in ten days. On dissection, the lining membrane of the trachea and bronchiæ was observed to be highly inflamed, and the heart much enlarged, particularly on the right side. There was no vestige of septum between the auricles ; the pulmonary veins were much enlarged."

I have examined this specimen several times. The pulmonary artery is very wide, and the aorta is decidedly small; and I presume it had an important share in the production of this man's disorders.

No. 5810. In the Comparative Anatomy Museum of Guy's is the heart of a sheep, seemingly nearly full grown. The right ventricle seems nearly as strong as the left, both the cavities being dilated. The valves appear healthy, but the safety valve is perhaps too close. There is a communication between the ventricles, in the usual situation, wider than a goose's quill. The foramen ovale is as large in diameter as the aorta itself, with a trace only of valvular membrane posteriorly. The auricles have been dilated ; the aorta is manifestly too small; the pulmonary artery is healthy and large. This is, I think, an interesting example of the consequences of a moderate permanent obstruction

in the main outlet of the heart, existing from birth, and all the appearances which are anormal are fully explained by the view proposed.

In the end of March, 1838, a boy, aged eleven, who had always been a little odd in his manner, and was certainly not quick in intelligence, and who had only been considered unwell for a few days, went into the water-closet, cried out, put his hand to his heart, and died. During the preceding few days his lips had been observed to be bluish.

On the second day, or later, the heart was examined by Mr. Key. It was much distended, and particularly the right side.

Five days after its removal from the body I noted that it was a good deal enlarged, the muscular substance good, and the auricles then pretty natural. A recess on the right involved a little piece of white firm fibrous clot.

The foramen ovale was a circular opening, half an inch wide, with scarcely a trace of valvular structure; it readily admitted my thumb. The right ventricle was a little too capacious, but firm and greatly thickened; the moderator bands, two, oblique and thick; the first column of distension nearly double, large and confined. There was a second column, and two considerable accessory (or fixed) columns, inclined full half way to the yielding wall. A clot, involving the tricuspid, which Mr. Key regarded as the cause of death, had been torn away. When I saw it it was a ragged mass, as large as a walnut, mostly pale, and uniformly solid and firm. At one or two parts it was dark and more grumous. It seemed altogether without traces of layers or gradual formation.

The circumference of the pulmonary artery varied a little, about one inch and three quarters.

The left auricle was certainly less developed than the right.

The left ventricle, without being small and contracted, was less capacious, and scarcely thicker, than the right.

The circumference of the aorta varied a little, about one inch and a half.*

In the above example the pulmonary artery and aorta appear pretty plainly to have been too small, and the state of

the heart seems to me to be sufficiently accounted for by this fact. Notwithstanding the impediment there had been no partial distension of either ventricle to prevent the septum closing up. Delay in the auricles had led to the wasting of their valvular partition.

19th, 12th mo., 1840.—E. L., a female servant, æt. 21, who has menstruated pretty naturally since her fifteenth year, has had some slight general pains occasionally for two years. She has had very severe palpitations, more or less, for nearly a year, decidedly relieved, however, during the summer. She has been troubled with cough during the last two months. Dyspnœa, pain between the shoulders, heats and perspirations, feebleness, wasting and sickness, have successively accumulated upon the first symptoms, The frost, and the cold ward, seem to me to have repeatedly aggravated the disorders to the last.

On inspection, the body was of very moderate size, and slight, but pretty fully developed. There were no very evident marks of wasting or œdema.

The expanded pericardium was thin, and of great extent; it seemed very little, if at all, less in circumference than the crown of a hat.

The right auricle was moderately dilated and thickened in proportion to the rest.

The right ventricle was large and thick; the pulmonary artery was two inches and three-eighths in circumference above the valves.

The left auricle was most excessively dilated; its walls but moderately thickened, and its lining thick and rugous.

The fossa ovalis closed.

The mitral opening was very wide; the curtains opaque, and with the cords somewhat thick; the posterior curtain, more particularly, seemed also contracted.

The left bronchus was compressed into a very flat oval tube by the dilated auricle.

The left ventricle was about large enough to contain the girl's fist, and rather thin than thick.

The aorta was thick, and its lining much rippled for the age; its circumference above the valves was two inches and one-eighth. In this case it was evident to the finger, before opening the aorta, that it was narrow, as several were invited to feel.

The lungs were of a light colour,

---

* These measurements were carefully taken among a considerable series, by Dr. Guy, of King's College, and Dr. Rankin, of Bury St. Edmonds.

considerably emphysematous, and no-
where devoid of air. Some small masses
of lobules, chiefly in the right lung,
were more red and watery; other parts,
besides being watery, seemed spotted as
with small ecchymoses : this was seen
in sections.

The liver was large and indurated,
and partially like nutmeg.

The spleen very small and firm.

The kidneys were much indurated,
and their tunics thick and too adherent.

The ovaries were small, thick coated,
and fissured, and speckled with little
yellowish grains.

It can hardly be questioned that the
last is a case of anormal narrowness of
both pulmonary artery and aorta, and
of the proper consequences of such
obstruction, although somewhat dif-
ferent from the case preceding it.

By the general references which have
been introduced to the principal morbid
alterations found in connection with
the disordered passages of the heart, it
may be seen that whilst I regard the
last as serious states, I do not mean
that every thing ought not to be taken
into the account in reasoning on the
complicated processes which bring dis-
ease to its final termination. To those
who are accustomed to reflect on the
mutual dependence of every part of
the circulation on the rest (even merely
in a physical sense) these facts may
serve as a means of judging of the par-
ticular importance of the states which
I have mainly endeavoured to illustrate.

In conclusion it may be well to re-
peat, that these cases are brought for-
ward in illustration of

1st. Narrowness of the aorta, and of
the pulmonary artery.

2d. The communication of the ven-
tricles.

3d. The sacciform depression   or
elongation of the fossa ovalis.

4th. The ulcerative perforation of
the fossa ovalis.

The connection which may appear
often to subsist between these several
morbid states will suffice to draw atten-
tion to the physical state of the circu-
lation in analogous cases. To compre-
hend fairly the relation of different
parts of the circulation can alone help
us surely in the indispensable treatment
of its disturbances or disorganizations;
and I venture to hope that the pre-
ceding statement, however defective,
will assist to render the topics consi-
dered more correctly appreciated.

ON HIP DISEASE AND LUMBAR ABSCESS.

By Wm. Oliver Chalk, Esq.

Resident Surgeon to the Royal Sea-Bathing
Infirmary, Margate.

(For the Medical Gazette.)

I had held my present situation for a
short time only, before my attention was
attracted to the numerous cases of
diseased hip joint received at this infir-
mary; nor could I fail to observe that,
although the symptoms and general
appearances of these disorders seemed
to differ but slightly, yet their termi-
nation was often entirely dissimilar :
some, after years of protracted suffer-
ing, recovering the entire use of the
limb and articulation, with no further
traces of a once formidable disease, ex-
cept, perhaps, slight contraction of the
hip and knee joints, and the cicatrices
of ulcers which at one time had formed
the outlet to a large and deeply-seated
abscess; others remaining crippled for
life, or too frequently sinking under the
severity of the constitutional and local
symptoms.

It was scarcely possible in many in-
stances to avoid questioning the diag-
nosis, for it was extremely difficult to
conceive that perfect recovery could
take place if disease had really existed
within the cavity of the joint for a suf-
ficient time to terminate in suppuration;
for in that case structural changes must
have occurred which would ever render
the motion of the joint defective, and
give rise to more or less irremediable
deformity.

The complications which presented
themselves in the latter stages of these
disorders rendered the diagnosis ex-
ceedingly difficult, if not impossible. I
was therefore obliged to study primary
symptoms with great attention. Unfor-
tunately, incipient disease was compara-
tively rare among in-door patients,
whose cases naturally afforded the best
opportunities for observation. With
those out of the house it was more fre-
quent; but it sometimes happened that
their poverty obliged them to return
home before due time had been allowed
for a sufficient investigation of their
symptoms. In this way I was often
obliged to retrace my steps, and wait for
further opportunities. The numerous
cases, however, that were admitted each

ensuing season from the London and provincial hospitals (chiefly from the former), and from private sources, afforded ample scope for further observation ; and it soon became sufficiently obvious that the diagnosis of hip disease was more than questionable. I felt assured that a vast majority * of these cases were of lumbar origin; but the proportion was so large, that I determined to withhold my conviction until such time as I could confirm it through the medium of post-mortem inspections. This became absolutely necessary when I considered that many of these patients had been under the guidance and treatment of some of our most eminent surgeons.

It was not until the year 1833 that an opportunity offered of a post-mortem inspection, in the case of William Hopkins, ætat. 40, admitted May 14th, from the Oxford Infirmary, said to be labouring under diseased hip joint. On examination, I found several sinuses in the vicinity of the articulation and the upper and external part of the thigh, from whence proceeded a profuse and extremely offensive discharge of ill-conditioned pus. The limb was extended, rigid, and apparently shortened, and slightly turned inwards. Any attempt at movement gave severe pain. The integuments around the articulation were covered with numerous scars of cuppings, leeches, blisters, &c. which were highly sensitive, and materially aggravated the condition of the soft parts, already tense, swollen, and painful, from extensive subjacent disease. These symptoms were accompanied by great constitutional disturbance, viz. hectic fever, constant diarrhœa, great tenderness over the whole abdomen, more especially in the region of the liver, which was enlarged ; pulse feeble and rapid ; profuse perspiration. It was evident that he was fast sinking under the influence of accumulated and protracted disease. He died fourteen days after his admission.

On examination, the following appear-

ances were observed * : the under surface of the gluteus maximus, and the subjacent layers of muscles connected with the joint, had lost all traces of normal structure, presenting a blackened appearance, and so softened as to be readily broken down by the fingers, or handle of the scalpel ; their interspaces were occupied by a profusion of pus, similar to that which had been discharged during life. The capsular ligament was entire, and of a healthy appearance ; on its inner surface the cavity of the joint was entirely free from disease. It was evident that the matter was issuing from a remoter source, namely, the loins ; and I regret very much that, from unavoidable circumstances, time did not permit us to examine the state of the viscera, or to trace the abscess to this source. There could be little doubt of the fact, however, as I could, during life, produce a copious flow of pus through the external openings, by pressing on the abdomen in the lumbar region : at all events the diagnosis was confirmed, as far as concerned the state of the articulation itself†.

Having thus more fully succeeded in clearing up my doubts, I proceeded in my investigation of these diseases without delay. The apparent similitude of the symptoms, however, for a long time baffled my endeavours ; and I was often on the point of yielding to the difficulties which seemed to beset the inquiry. Sir Charles Bell is the only surgeon, so far as I have been able to ascertain, who alludes to the difficulties of the diagnosis ‡ ; and I am happy to avail myself of such distinguished authority by transcribing his remarks :—

" The diagnosis is the grand difficulty, and I would require no better proof to give to any person of the interest I take in you, and the desire I feel of being useful to you, than that I should return to the subject of the hip joint, for be assured that there is none that you will find more difficult to investigate, or a greater source of anxiety." Again, he says, " I will not dwell on the next point, which is psoas abscess ; you must take care, however,

* With reference to this assertion, however incredible it may appear, I will take as example the season of 1836, when thirty-six cases of hip disease are reported (in a work already alluded to) to have been received at the infirmary. Out of the whole number at that time in the house, there were not more than eight cases of primary disease of the articulation ; the rest were of lumbar origin, most of which had been treated as hip disease. I regret to observe that this statement has found its way into one of our standard works, Cooper's Surgical Dictionary, last edition.

* I was assisted in the dissection by my friend, Mr. G. H. Hoffman, of Margate.
† When speaking hereafter more particularly of psoas abscess, I shall have occasion to relate various dissections wherein the disease had been treated for an affection of the articulation.
‡ Vide Clinical Lecture, as published in this Gazette, vol. 14.

to distinguish psoas abscess from disease of the hip joint ; and you have the more difficulty, because both diseases belong to the same condition of the general system, a strumous habit. You have visited several cases with me, when I have not concealed the difficulty I have had in saying whether the disease existed in the hip or in the loins, and the course of the psoas muscle."

In a subsequent article, the case of S. A. Hoffmeister, admitted into the Middlesex Hospital, supposed to be labouring under hip disease, is related, together with the appearances after death : both femora were found an-chylosed in their sockets, and it was further ascertained that this state was consequent on psoas abscess. Mons. le Baron Boyer, when treating of spon-taneous consecutive dislocations of the femur, thus describes a dissection :—" Les muscles de la fesse et de l'aine étoient disséqués par le pus, le capsule orbiculaire étoit detruite, et conservoit à peine quelques traces de sa structure fibreuse; toute la surface du col du femur étoit denudée, la couche cartila-gineuse detruite, la cavité cotyloide fort aggrandie par une érosion qui en avoit emporté le fond et surtout la partie interne de sa circonference, sur laquelle la tête du femur étoit placée, le pus avoit détruit le muscle releveur de l'anus, et fusée le long du muscle psoas jusqu'aux lombes, il sortoit du bassin avec ce dernier pour communiquer avec les foyers exterieurs, ceux-ci s'éten-doient par une fusée jusqu'au genou." It is evident that the appearances here described originated in psoas abscess, for it cannot be imagined that the pus should have ascended from the hip joint along the course of the psoas muscle.

Before entering on a description of the respective local symptoms which characterize these disorders, I am anxious to make some observations on the diathesis with which they are com-monly associated, viz., the scrofulous, tubercular, or phthisical. Whenever tubercular matter was localized in other structures than the lungs, M. Laennec used the term " irregular phthisis ;" seeming to imply that he restricted that of phthisis to a tubercular disease of these organs only ; but the brilliant researches of later writers, Louis, An-dral, Carswell, and others, prove beyond dispute that a tubercular disease of the lungs is frequently associated with a similar state of other organs of the body, as well as with a more or less morbid condition of the digestive and nutritive, viz., the stomach, liver, small intestines, &c. From the state of the latter viscera alone, M. Louis could with certainty infer the pre-sence of tubercles in the lungs.

It is not my intention to enter on a discussion of phthisis any further than is necessary to my present subject, with which it is unavoidably connected, lest I should lay myself open to the charge of presumption, since it has for so long a time occupied the pens of the most distinguished writers in this and other countries, and of whose labours I can only profess myself the humble admirer.

The term latent phthisis, it would ap-pear, has been used by writers to denote that state of the system which existed prior to the sudden development of phthisical symptoms, upon any acci-dental and existing cause, such as bronchitis, common catarrh, febrile attacks, &c., thereby admitting the presence of tubercular depositions prior to the invasion of these accidental diseases. A singular instance of this description came under my observation whilst following the clinique of Mons. Le Baron Dupuytren, at the Hôtel Dieu, in the winter of 1828 and 29, which made a forcible impression on my mind at that period. A fine look-ing youth, between 16 and 17 years of age, presented himself one morning for examination. He stated that he had been suffering from a withered state of the right lower extremity from his in-fancy, that his health was excellent, yet he and his friends were desirous that he should undergo amputation of the limb, giving as a reason that it was in his way. M. D. hesitated, observing that these affections were commonly associated with " un vice constitu-tionel," which he feared in this instance might render the operation abortive. The boy and his friends persisted. He was received a day or two after, placed in bed, and was subjected by Mons. D. to a most careful examination of the abdominal and thoracic viscera. The result seemed favourable, and the opera-tion was performed on the following day, with the usual dexterity of that accomplished surgeon : great care was taken to avoid any unnecessary loss of

blood. The night previous to the second dressing of the stump, the patient suffered from an accession of fever, and complained that the dressings caused pain: on the following morning (being the fourth from the operation) they were removed: no attempt at union had taken place; the wound was ash-coloured and gaping, exhaling a profuse and fœtid sanies; symptoms of phthisis rapidly ensued, and the patient died about 14 days after the operation.

[To be continued]

MR. COULSON'S REPLY TO MR. CHALK.

To the Editor of the Medical Gazette.

Sir,

I have read in your last number a communication from Mr. Chalk, in which he has alluded, in a tone and spirit that I shall not imitate, to my works on the Diseases of the Hip-Joint.

Mr. Chalk complains that many of the alterations and additions in the second edition of my work consist in observations and allusions to the practice pursued by him in these disorders at the Royal Sea-bathing Infirmary, without acknowledgment of the source from whence they were derived.

Except the letter from Mr. Childs, which I shall presently refer to, it so happens that all the allusions to the practice in the Infirmary in question, in my last edition, are contained in the previous edition; and it may be inferred from the silence of a person of Mr. Chalk's temper for five years, that no injury was done him by that previous edition. Why there was no acknowledgment to Mr. Chalk is sufficiently explained by his own statement, that, in reply to written inquiries (some of them such as may be reasonably required in courtesy to be answered by the paid surgeon of a public institution) concerning the results of cases in the Infirmary, he declined to give me any information. A reference to my work will shew, which has not been questioned by any one but Mr. Chalk, that I have acknowledged the sources of my information with more than ordinary care.

Mr. Chalk has introduced several passages from my edition of 1841, to show, as he expresses it, that "I have picked up a respectable stock of information;" manifestly wishing it to be inferred that it can only have been derived from his quarry. It so happens that all the passages referred to by Mr. Chalk will be found in substance, and for the most part in the very words, in my former edition, which was published towards the end of 1836. For example, the passages quoted by Mr. Chalk are:

Second Edit. 1841.	First Edit.* 1837.
Page 5 ———	Vide page 74.
—— 34 ———	——— 72-73.
—— 57 ———	——— 11.
—— 75 ———	——— 86.
—— 89 ———	——— 94.

My letter, dated April 22d, 1836, which Mr. Chalk has published, contains several interrogatories respecting the disease of the hip, and on this account Mr. Chalk very sagaciously assumes that I was then ignorant of the disease, and that I had no views or opinions of my own upon the subject of my questions. This scarcely needs a remark; but I may tell Mr. Chalk, that, six years and a half before I sent my interrogatories to him, I had published on the disease of the hip; and at the time of sending my letter the materials for another work were then in a state of forwardness for the press.

The residue of Mr. Chalk's letter consists in great part of a complaint against Mr. Childs for having communicated to me respecting the practice of the Infirmary, which I have acknowledged and printed, and against me, I presume, for having published it. With the personal accusation against Mr. Childs I have nothing to do; but I have yet to learn that it is in any degree improper for a gentleman connected with a charitable institution to publish the result of any mode of treatment which he may consider beneficial.

If I were to give Mr. Chalk any advice, it would be, that, instead of complaining of Mr. Childs or myself for publishing information which we think valuable, he should at once contribute what he can to the common stock of information, and trust his claims to reputation to the judgment of the profession.—I am, sir,

Your obedient servant,

WILLIAM COULSON.

Frederic Place, Feb. 8, 1841.

* The preface to this edition is dated October 8th, 1836.

MEDICAL GAZETTE.

Friday, February 12, 1841.

MEDICAL DEGREES.

MARISCHAL COLLEGE, ABERDEEN.

AMIDST the numerous projects for change in the medical institutions of the country, brought forward within the last few years, it is satisfactory to observe the many valuable improvements which these institutions have themselves seen fit to introduce. Nor is this change for the better any where more conspicuous than in Scotland.

There, until very recently, the ease with which medical degrees could be obtained was proverbial ; and it must be confessed that they frequently were bestowed, at least in some of the seats of learning, in such a manner as to give too much countenance to the vulgar belief, that the bodies conferring them had an eye mainly to the fee derived from their diploma, or, as it was illiberally expressed, were bent on bartering their LL. D. for L. S. D. Edinburgh, indeed, was an exception, and, we may add, not the only exception, to the general rule ; and the many distinguished names to be found among its graduates at once evince and account for the higher value attached to its degrees.

But those who look into the matter, as it at present stands, will find a very different order of things. The Edinburgh degree has less weight than of old, not from the standard of qualifications having been lowered, but owing to the higher scale of attainments demanded from candidates by other institutions. The alterations alluded to have not been hastily engrafted on the former system, nor have all been equally prompt to carry them into effect. But the " Regulations of the Marischal College and University of Aberdeen," inserted elsewhere *, complete the series of change, if not of unqualified improvement. To some of these provisions, as bearing upon Scotch degrees in general, we would briefly invite the attention of our readers :—

In the first place it will be observed, that, of the four years to be spent in medical study, " three, at least, must be passed in a University, including one, at least, in this University." Now Marischal College is not singular in imposing, or rather continuing the imposition of this, as we must term it, illiberal restriction. But we had hoped to see, in a newly revised set of Regulations, some relaxation in this important point ; considering, as we do, that whatever may be deemed necessary in the way of preliminary general education, yet, if certificates of attendance on all the prescribed courses of medical lectures are produced from any of the acknowledged metropolitan or provincial schools, one year might very safely be made the whole period of University attendance exacted. The one year of attendance in Aberdeen is, however, to be all that is required of those who possess a diploma from any licensing body in the kingdom. What reception, then, awaits these gentlemen, thus comparatively mature in years and knowledge ? A catalogue (*crediti posteri !*) is to be called over at the beginning of each lecture† ; at the end of every month the number of times each student has been absent is to be hung up in the class room : and at the end of the course the total number of absences is to be notified by the Professor on the back of each certificate. Imagine a member of the Royal College of Sur-

---

† This is mentioned in a minor paper of regulations of detail, which we have not room to print.

geons, who hopes to be M.D. within a few months,

"Creeping, like snail, unwillingly to school."

It is not thus that lecture-rooms can be filled; even the junior medical students are of an age to which such treatment is wholly inapplicable.

Another point in which the case before us agrees but too closely with that of some other learned bodies, is the very short period of attendance on hospital practice which it requires. If the time to be dedicated to the acquisition of medical knowledge were considerably extended, eighteen months' hospital attendance (which includes both medical and surgical practice) might be deemed sufficient; because the probability of the student's having had opportunities of seeing the practical part of his profession elsewhere would in that case be proportionably increased. But where only four years of study altogether are required, it should be made imperative, in every case, to adduce positive testimony of a considerably longer attendance: and we tremble for the limbs and lives of those who shall be dealt with by persons so inadequately prepared.

Another point seems very objectionable. The number of subjects, on which the candidate is to be examined, shews a wish to establish a high standard for degrees; yet some of the rules must wholly defeat this object. In the first place, direct encouragement is held out to students to begin their attendance on medical classes before they have completed the usual course of College education—a practice what has crept in of late years, and with very unfortunate consequences. The general education of the student is interrupted just at the age when, if good for any thing, he is making the most rapid progress in liberal knowledge ; and he is induced to make this grave sacrifice without any suitable return. Besides, this inter-

feres with medical education itself ; for if we require only four years' study altogether, we cannot assuredly expect to find men highly qualified, if one or two of these four are divided between medicine, and the important subjects which the last two winters at College present to the consideration of the student.

Again, the plan of having three separate examinations for the degree, and allowing to such as choose to avail themselves of it an interval of eighteen months between each, is most objectionable. The consequence will inevitably be, that students will *cram* for the first examination to the neglect of every thing else ; then *grind* for the second ; and both *cram* and *grind* for the third. The number of subjects on which they are to undergo at each stage a very lengthened examination, will infallibly lead to this most pernicious result. The effect of the whole will be, that, at the time they take their bachelor's degree, they will be acquainted only with the subjects to which their attention was last directed, while the others will have been in great measure dismissed from their memory. Are these anticipations groundless ? No. Cramming is found to be an almost universal practice, in spite of all precautions.

It is a rule to which we know no exception, that the candidate must at least possess, at the time he receives his diploma, that which his diploma declares him to *have*, not to *have had*, a competent acquaintance with all the leading branches of professional knowledge ; whereas this system will enable the examiners to certify rather how much he has forgotten than how much he knows.

But what strikes us most of all in these regulations is, the extraordinary and novel circumstance, that the degrees are to be given *gratis ;* that is, the degree of M.D. for £11, being £10 for the stamp, and £1 for the expense

of preparing the diploma ; and the de-
gree of M.B. for £1, the mere expense
of the diploma, no government stamp
being required.

At all other places where degrees,
licenses, or diplomas are granted, the
labourer is deemed worthy of his hire :
the honour is not so obtruded on the
public as to make it seem that the
granter, not the receiver, is the person
obliged in the transaction. These are
important passports for professional
men, and imply the assumption of a
very grave responsibility by the learned
body which pledges itself for their
competence. The fees are generally
on such a scale as not to subject such
learned bodies to the imputation of
voluntarily courting this responsibility,
and going out of their way to vouch
for the acquirements of all comers.
Why, then, should *this* institution de-
part from the common practice ? It
may be said that Marischal College,
Aberdeen, looking back with little sa-
tisfaction to its former indiscriminate
issue of degrees, and wishing in vain
to erase from its list Drs Solomon and
Brodum—the least favourably known
of its graduates—

> " Sed revocare gradum,
> Hoc opus, hic labor est ;"

has adopted a scale of payment " which
may serve altogether to remove every
suspicion of there being any thing like
self-interest in their motives*." But
this is not so; for every candidate for
a degree must have passed one year at
least in the medical school of the Col-
lege ; so that the whole resolves itself
into an expedient for drawing students
away from the medical school of the
University and King's College (which,
like other universities, charges fees
upon degrees, and which does not
make attendance at its own medical
school an indispensable preliminary)—

by offering gratuitous degrees at the
end of the course.

There is, however, another pecu-
liarity about these degrees, which it
nearly concerns the honour of the pro-
fession to notice, especially at a time
when it is proposed to confer certain
privileges on all graduates of British
universities. We have grievously
wronged Marischal College in saying
that her degrees are gratuitous. They
are not so; they are too dear by £10,
being the amount of the government
stamp, *for they are not degrees at all,*
and are worth no more than the parch-
ment and wax of the diploma.

We speak advisedly. We have now
lying before us all the charters, acts,
and muniments of Marischal College,
printed by the Royal Commissioners
for visiting the Scottish Universities,
from returns made by Marischal Col-
lege itself. We write on the autho-
rity of these documents, and of the
acts of the Scottish Parliament.

Soon after the Reformation, a Col-
lege was founded in Aberdeen by the
Earl Marischal, and its foundation was
ratified by Parliament, over and over
again, as a free College, consisting of
a faculty of arts, without any faculty
of theology, of law, or of medicine, and
it was empowered to confer degrees in
arts, but it never was created a Uni-
versity, and never received any shadow
of authority to confer any degree ex-
cept in arts ; and no wonder, since the
University and King's College had
already flourished in the neighbour-
hood for a century, with all the fa-
culties complete, and the fullest powers
to confer degrees in each.

It is believed to have been about the
year 1728 that Marischal College,
crowning itself — like Napoleon at
Nôtre Dame—was pleased to confer on
itself the power of conferring on others
the degree of Doctor in theology, law,
or medicine. The degree of B.M. is

of new coinage, and has not, so far as we are informed, been yet conferred.

It is well known that any privilege which can only emanate from the crown, must be exercised either by virtue of an actual charter, or by immemorial prescription; that is, custom of which the commencement cannot be traced, and which is therefore attributed by law to an ancient grant from the crown. Marischal College has been created far within the period of prescription; it can point out no such grant, and can show no such custom. But, it is said, others have acquiesced. Now it is very difficult and invidious, and is no man's business in particular, to pluck off such borrowed plumes. People at this end of the island, aware of the fact of there being a University at Aberdeen, took it for granted that an Aberdeen degree was a degree conferred by the University, but it is merely absurd to say that the acquiescence of neighbours, or of the public, (supposing it to be true that there has been acquiescence) can confer so important a right. If Marischal College had created baronets as well as doctors, a step equally justified by their charter, would the contemptuous silence of the public erect this usurpation into a right? Any ten gentlemen who choose to seat themselves round a table have exactly the same power. The College then, in its new scale of fees, has unconsciously estimated its degrees at their real value—*nothing*.

MR. BACOT ON MEDICAL REFORM.

To the Editor of the Medical Gazette.

Sir,

So much has lately been written on the subject of Medical Reform, that even members of the profession itself may probably be wearied with the discussion; yet, perhaps, your readers may be disposed to bear patiently with *one* more labourer in the same field, who promises to be concise.

Having for many years been actively engaged in considering the details of medical education and examination, I trust that the few observations I shall venture to offer regarding this *vexata questio* will at least be favoured with an attentive perusal.

In considering the subject of medical reform, the first party to be satisfied is the public; they should have the fullest assurance that the practitioner in each branch of the profession is a competent person, not only from his medical qualifications, but from his general education, which can alone entitle him to hold the station in society which is his due, and that will give to the public something like a security that he will practise his profession, not merely for lucre, but upon those high and honourable principles that should actuate the members of all the liberal professions.

To maintain this high moral tone in the profession, subordination in its different departments is, in my opinion, requisite: giving to the lower grade a fair object of ambition, by leaving the road to his advancement entirely open, and inducing the higher grade to maintain his rank by superiority of attainments as well as by the integrity and purity of his character and conduct. It therefore appears to me extremely objectionable to propose the adoption of any plan which shall amalgamate the different orders of the profession into one faculty, and still more so to create elective bodies of any large amount in point of number; keeping the profession in a state of perpetual agitation, increasing the acrimony and ill feeling which professional rivalry always tends to engender, and probably, as a result, bestowing the official appointments of the profession upon the most obstinate, or, it may be, upon the most impudent candidate.

It is true that the number of institutions in the three kingdoms, now authorised to grant diplomas or licenses to practise in the different departments of the profession, is considerable, and that the most absurd restrictions exist to prevent the person licensed in one part of the empire from practising in any other part. The first step in reform would be to assimilate the education and examination in the three kingdoms to one uniform standard; that is, let

there be one system for the physician every where throughout the empire ; one for the surgeon and one for the apothecary ; and then let no impediment exist to prevent the practitioner (wherever licensed) from pursuing his calling in whatever part of the empire he choose, only providing that he shall be duly registered as a licensed practitioner in the country in which he practises. Then, as a consequence of this arrangement, all prosecutions of unqualified practitioners should cease, and nothing would be necessary but to ascertain that the party was duly registered before he was allowed to undertake the office of physician, surgeon, or apothecary, to any public institution, or before the latter class of practitioners could obtain a remuneration for his services in any court of law.

If these great preliminaries were assented to (and I believe the three corporations in England are perfectly agreed on these points) nothing would be easier than to settle the minor details, and all reasonable men would, I conceive, be ready to admit that the present medical institutions of the country are competent to undertake the duties of their respective departments, and need not be destroyed in order to build up a something which would, at no distant period, assume a political character, and, whether it did so or not, would, at all events, keep a profession requiring contemplation and repose in a continued state of agitation ; exciting those passions which it is the duty of all good men to allay, and retarding, instead of promoting, the interests of humanity and science.

I also contemplate, as a completion of this scheme, the formation of a fourth or controlling body appointed by government (not consisting of medical men) ; to which body the several institutions should communicate their respective bye-laws and regulations for approval, and to which they should also annually report the results of their proceedings— the number of persons admitted to examination in their respective departments, the number rejected, the amount of their receipts, the mode in which the money has been expended, and all other circumstances from which a complete statistical account of the state of the profession might be collected from year to year.

Another subject of complaint in the profession is, the extent to which the chemist and druggist now assumes the duties of the regular practitioner ; and to the apothecary, at least, the evil is very great, who, being obliged to undergo an expensive education, and a strict investigation of his medical qualifications, when he commences his career as a practitioner is met at every turn by the chemist, who, with his collection of prescriptions and his smattering of knowledge, visits and prescribes, with all the authority of an Esculapius : not only does he give advice from behind his counter, but he scruples not in too many instances to assume out of doors all the functions of the medical man ; and yet I doubt the propriety of meeting this abuse by any medical interference. It is quite obvious that one principal point in medical reform would be to keep every man in his place, to confine the practice and business of each man to his own department ; and this, with the aid of government, might easily be done in this case ; providing, however, that the chemist and druggist should give some proof, before he is established in his business, that he knows enough to ensure the safe and accurate composition of remedies prescribed by medical authority. As to any attempt to put down quacks and other pretenders to cure diseases, the notion is absurd : as long as there are complaints that defy all our present curative processes, so long must there be quacks and venders of such remedies. Mankind will never sit down contented with being told they must die of cancer or phthisis ; they will naturally resort to any one, male or female, who offers an infallible remedy ; and why should they not ? Is it wise, or even possible, to extinguish hope by an Act of Parliament? and, after all, the profession itself is, perhaps, the gainer by the system, if so low a motive be permitted to enter into our consideration at all.

With regard to the curricula of study now enjoined by different medical bodies much might be said, but it may be enough for my purpose to intimate my belief that in some instances these curricula are too stringent. Too much time is devoted to lectures, and not enough to reading ; and, to hospital practice, the student is taught rather *jurare in verba magistri* than to work out his own course, and to rely upon the resources

of his own mind. I have no objection to make the examination as strict as possible; the student should be informed accurately of the subjects he is expected to know, as well as the course and general tenor of examination: a certain order of study might also be recommended as most suitable to be pursued; but I doubt the propriety of insisting upon a constant and compulsory application.

One word only respecting the apprenticeship. Every one who has practised pharmacy, especially in the country, must know that the time spent by the apprentice is far from being wasted; it is employed in collecting information which is most valuable to the student in after, life; but a period of five years so employed is much too long, still less should the apprenticeship be compulsory, for if good in itself it will be followed without any legislative enactment, but it should be left at least to the choice of those who still entertain such an opinion: it would be quite sufficient if the pupil was required to receive instruction in practical pharmacy for two years either as an apprentice or not. I shall not pretend at present to enter further into the details of this very extensive subject, being persuaded that if the general outlines I have hinted at are carefully filled up, the expectations of all reasonable men would be satisfied.

I am, sir,
Your obedient servant,
JOHN BACOT.
Portugal Street, Feb. 4, 1841.

ADVANTAGE OF APPRENTICESHIPS.

To the Editor of the Medical Gazette.

SIR,

I HOPE you will spare room, in your valuable periodical, for a few remarks elicited by your able leader on the "Apprenticeship System" in the last GAZETTE, and ere the knell of that system is sounded, allow a feeble note to be raised in its praise. You are doubtless aware, Mr. Editor, that the effect of the late prescribed course of medical education has been to diminish very materially the number of pupils in the country, and the smaller towns; and, if the apprenticeship system be entirely annulled, all the medical students will begin and complete their studies in the metropolis, or the larger provincial towns where the required lectures are given. But would not a serious injury be thus inflicted on the smaller hospitals and country practitioners? The cases occurring in those institutions would not be rendered available for the purposes of medical education, and thus many valuable opportunities of acquiring knowledge would be lost; for it is not, perhaps, too much to say, that the few pupils who act as dressers in a provincial hospital, under the immediate eye of their masters, are as likely to acquire valuable information as those students who, in a crowd, attend the practice of the larger hospitals without an opportunity of exercising surgical manipulation; and the "habit of observing, thinking, and acting for himself," which, by the *Quarterly* is considered so essential to make a good practitioner, is as much encouraged in him who quietly dresses patients from day to day, in a smaller provincial infirmary, as in him who, during the bustle of surgical peregrinations in large hospitals, attends, even more than is customary, to the cases presented to his notice: and I would, moreover, add, the responsibility incurred by visiting and prescribing for the patients who partially come under the care of pupils in the country during their apprenticeship, excites more interest, and enforces habits of attention and reflection more effectually, than where such responsibility does not exist.

But the student who is designed to practise in the country (and many must) will be, in other respects, a loser by the entire abrogation of the apprenticeship system. He will lose all that salutary restraint, and that training of the mind to undergo privations, which are so necessary for youth. He will lose an insight into the management of private patients — the customary charges and book-keeping, and all the drudgery unavoidably connected with the practice of medicine, in country districts. He will be unable to form an estimate of the situation which he must afterwards fill, or of the difference between the study of medicine as a branch of learning, and the practice of it as a profession by which he is to live; so that, when commencing business in the country, after an attendance on lectures and at hospitals alone, where he has been enabled to follow the full bent of his inclinations, he will probably find that he cannot comfortably submit to the necessary constraint on his feelings and actions which would contribute so much to his success; that he cannot well manage the whims and caprices of private patients, and other little practical details; that, in short, he cannot endure, without spending a miserable existence, the inconveniences and ills of a profession which he was not prepared for; while, to his astonishment, his more plodding, but, perhaps, less scientific neighbour, inured to the hardships of an apprentice, bears the midnight watch

and laborious journeys with scarce a murmur, and puts up with those toils and discomforts which, in early life, he was accustomed to, as a matter of course.   There is, indeed, Mr. Editor, something besides medical knowledge necessary for ordinary provincial practice, namely, a mind schooled and trained to submit to that which must be borne ; and if the apprenticeship system must be given up, which, under your auspices, I trust it will not, I much doubt whether the country practitioners of the succeeding generation will be more happy themselves, better suited for their situations, or for the service of the public, than those of the present day. But I am trespassing too much on your kindness ; and therefore, hoping that the attention of pro- vincial practitioners will be awakened to the subject I have touched upon, I leave the matter in abler hands.—I am, sir,

        Your obedient servant,

                A CONSTANT READER.

Gloucester, Feb. 2d, 1841.

PROPOSED RESTRICTIONS ON FOREIGN GRADUATES.

To the Editor of the Medical Gazette.

SIR,

As a constant reader of and occasional con- tributor to your valuable journal, I shall feel much favoured by your giving me a reply to the following question, in which is deeply involved the interest and happiness of many highly talented and respectable practition- ers :—

Will certain restrictions, which are about to be proposed respecting foreign graduates, extend to those in *actual practice ?*

About fifteen years since I attended lec- tures and hospital practice at Paris and Berlin, and ultimately graduated at the ancient and distinguished seat of learning, Giessen, in Germany, having been subjected to a most severe examination. Since this period I have been in very limited practice, but having at length been appointed medical officer to an extensive dispensary, I am led to believe that brighter prospects are opening to me.   I find, however, from the tenour of certain bills, which are immediately to be laid before Parliament, that it is doubtful whether any foreign graduate will be admitted as a mem- ber of the new medical corporation, unless he proves that he has undergone the *pre- scribed* medical education, and submits to an *examination.*   Now I must confess that I have not attended to any particular curri- culum, but obtained my professional educa- tion from those sources, and in that manner which I conceived best calculated to render me acquainted with my profession.   With respect to an examination, I am rather scep- tical as to whether I should be considered

sufficiently versed in minute anatomy and chemistry, which, at the time I was pur- suing my university studies, I was as con- versant with as my own name, but which now, I fear, I have in a great measure lost : my (almost) undivided attention having been bestowed on the *practical* part of my profession. Many years since I was con- sidered a good Latinist, but should now falter at translations which then appeared as easy as A B C ; so little time have I had to cultivate my classical knowledge, amid the many perplexing troubles and anxieties I have had to contend with.   You are doubt- less aware that not *one* in *fifty* physicians now practising in London and the provinces are members of the London College : the majo- rity being licentiates of the Irish, German, and Scotch universities.   It, therefore, ap- pears to me that it would be a decided injus- tice to prevent foreign graduates, more espe- cially those in *actual practice*, from be- coming registered members of the new medical institution.   It would also be bad policy for the medical profession in this country to oppose this principle, for very few natives of foreign countries, who had graduated abroad, whatever might be their qualification and their skill, would be able to overcome the antipathies of the people of this country to employ them in their families, so as to succeed here to any great extent ; on the contrary, there is a great demand for British physicians in foreign countries, both in those cities which are principally fre- quented by British travellers, and, generally speaking, by all classes in the United States ; and the demand presents opportunities of employment to a great number of young graduates and holders of diplomas, who annu- ally swarm off from the British hive.   Now any exclusion of foreign graduates in this coun- try might provoke foreign countries to reta- liate on British subjects practising medicine abroad, and the balance in that case would be greatly to the prejudice of British practi- tioners.   When I commenced practice I legally possessed the same privileges as the licentiate of any college or university ; and these privileges still exist.   Under these circumstances I feel well assured that the educated foreign graduate will find in you an able and unflinching advocate for the *con- tinuance of those rights which they at pre- sent enjoy.*   I doubt not but that in several instances diplomas have been unworthily obtained, both from the Scotch and German universities, but I believe this system has not prevailed to any great extent ; and I cannot but think that it would be unwise to interfere with the *present holders* of even these venal degrees. Let the iniquities of the past be buried in oblivion, but most carefully guarded against in future enact- ments.

These hastily penned observations are sent with the view of directing your attention to the subject, and with the hope of seeing an answer to the foregoing question, which has been submitted to you, with great respect, by

Your obedient servant,
AN M.D.
Of twelve years standing.

Feb. 1, 1841.

[We have inserted the foregoing letter not at all as patronizing foreign degrees, but to direct the attention of those who are about to legislate to the important consideration—what effect will it have on those holding *our* degrees, when they go abroad, if we refuse to acknowledge foreign degrees here? —ED. GAZ.]

MARISCHAL COLLEGE AND UNIVERSITY OF ABERDEEN.

REGULATIONS FOR GRANTING MEDICAL DEGREES.

Curriculum.

1. Four years of attendance on Medical Classes, of which one year may be passed at any recognised Medical School; but three, at least, must be passed in a University, including one, at least, in this University. The attendance, in each year, to embrace not fewer than two medical classes of six months each, or one of six months, with two of three months each. But it will be held equivalent to *one* of four years of such attendance in a University, 1st, in a Master of Arts, to have attended one Medical Class while passing through the Curriculum of Arts: or, 2dly, in any Student, to have attended a Medical Class, in each of two years, along with Classes in the Curriculum of Arts. The University attendance to include the following eight Classes, each for a Course of six months—Anatomy, Practical Anatomy, Chemistry, Materia Medica, Institutes of Medicine, Surgery, Practice of Medicine, Midwifery, and the following three Classes, each for a Course of three months—Botany, Practical Chemistry, Medical Jurisprudence.

2. Eighteen months of attendance on the Medical and Surgical Practice of an Hospital containing not fewer than eighty beds, along with attendance for six months on Lectures on Clinical Medicine, and for three months on Lectures on Clinical Surgery.

3. Six months of compounding and dispensing of medicines in the laboratory of an hospital, or of a public dispensary, or of a licensed general practitioner, or of a regular dispensing druggist.

Exemption to Practitioners.

4. It will be held equivalent to the Curriculum prescribed in the three Regulations foregoing, to have obtained, upon examination, a Diploma or a License, in Medicine or in Surgery, from a University or other authority established by law within the United Kingdom, and to have subsequently attended Medical Classes in this University for one year.

Examinations.

5. The Examination Terms to be two in each year—the *first* to commence on the 20th of April, if a Wednesday, but if not, on the first Wednesday thereafter; the *second* on the 13th of October, if a Wednesday, but if not, on the first Wednesday thereafter.

6. Every candidate to undergo at least three separate professional examinations—the first Pharmaceutical, the second Surgical, the third Medical—to be conducted partly in writing, as well as *vivâ voce*, and partly by demonstration.

The *first* to include chemistry, botany, materia medica, pharmacy, and the doctrines of physics relating to specific gravities, to gases and vapours, and to climate.

The *second* to include anatomy, institutes of medicine, surgery, and the doctrines of chemistry and physics illustrative of animal structure and function.

The *third* to include the practice of medicine, midwifery, and medical jurisprudence.

7. Every candidate, not a Master of Arts, must undergo a preliminary examination on the Latin language (the book to be used being *Celsus de Medicinâ*), and on the etymology of such terms in the Medical Sciences as are derived from the Latin and the Greek.

8. Any candidate that so desires shall be admitted to each one, or to any two, of his three professional examinations at different terms; but not to the first examination, until the beginning of his third year of medical classes; nor to the second, until the end of his third year; nor to the third, until the end of his fourth year, and until he be twenty-one years of age; nor shall a greater interval than eighteen months be allowed between two successive professional examinations, without a full renewal of the previous one or two. The preliminary examination must be passed at the same term as the first professional examination.

9. In order to be received for examination, certificates must have been lodged with the professor of medicine, on the first day of the month of the examination term, shewing that the candidate is of the required age, that he is of good moral character, and that he has passed through the requisite course of professional education. Along with such certificates, must be lodged a schedule, filled up in his own hand-writing, containing a list of them, and specifying such additional

branches of education, professional and general, as he may have studied.

Conferring of Degrees.

10. Medical degrees to be conferred at the close of each examination term.

11. The degree of bachelor of medicine may be conferred on any candidate who has passed the foregoing examinations.

12. The degree of Doctor of Medicine may be conferred on any candidate, after passing the foregoing examinations, if not under twenty-two years of age, or on any candidate who has been at least six months a bachelor of medicine of this University. The candidate, if a bachelor, shall state in a written application, what opportunities of professional improvement he has enjoyed since he was made bachelor.

FEES.

For the Degree of Bachelor of Medicine.
Expense of Diploma   .   .   £1

For the Degree of Doctor of Medicine.
Expense of Diploma   .   . £ 1
Government Stamp   .   . 10—£11

There are no Examiners' Fees.

SIR ASTLEY COOPER.

We lament to say that we cannot report any improvement in Sir Astley Cooper's health. We understand that the symptoms shew no disposition to amend.

REFORM DEPUTATIONS.

Deputations from the "British Medical," the "Provincial Medical and Surgical," and the "North of England Medical" Associations, waited on Lord John Russell on Saturday (6th). They were accompanied by Mr. Serjeant Talfourd, Mr. Wakley, Dr. Webster, Messrs. Evans, Farr, Carter, and Eales. Of the result we know nothing, but we shall be surprised if the ministers be not fairly bothered by the contradictory representations made to them by the various parties interested in the question of reform.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, December 31, 1840.
Edmund Hartley.—Duckworth John Nelson, Dublin.—William Fearse, Exeter.

Thursday, Jan. 7, 1841.
R. M. Hiddleston.—J. Honeywood, London.

Thursday, Jan. 14, 1841.
J. Osborn.- M.H. Beaumont.—A. Featherstonhaugh.–J. M. Monteath, London.

Thursday, Jan, 21, 1841.
H. F. Brett, East Garden, Yorkshire. – W. Winship, Newcastle-upon-Tyne.—W. Row, Shaldon, Devon

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the Number of Deaths from all Causes registered in the Week, ending Saturday, the 30th January, 1841.

Small Pox	64
Measles	15
Scarlatina	11
Hooping Cough	49
Croup	8
Thrush	8
Diarrhœa	7
Dysentery	1
Cholera	0
Influenza	2
Typhus	26
Erysipelas	9
Syphilis	0
Hydrophobia	0
Diseases of the Brain, Nerves, and Senses	173
Diseases of the Lungs, and other Organs of Respiration	350
Diseases of the Heart and Blood-vessels	22
Diseases of the Stomach, Liver, and other Organs of Digestion	77
Diseases of the Kidneys, &c.	6
Childbed	18
Ovarian Dropsy	1
Diseases of Uterus, &c.	3
Rheumatism	6
Diseases of Joints, &c.	2
Ulcer	0
Fistula	0
Diseases of Skin, &c.	0
Diseases of Uncertain Seat	114
Old Age or Natural Decay	103
Deaths by Violence, Privation, or Intemperance	30
Causes not specified	2
Deaths from all Causes	1107

BY DR. WATSON.

LECTURE XXII.

Symptoms of cerebral diseases.—Inflammation of the dura mater and arachnoid, from external injury; from disease of the bones of the ear, and of the nose.— Inflammation of the pia mater.

THE functions of the brain, summarily expressed, being sensation, thought, and voluntary motion, we naturally look for disturbances of those functions whenever the organ suffers disorder or disease. And experience has made us familiar with various forms of disturbance to which these same cerebral functions are liable. Let us pass them shortly in review.

1. The faculty of *sensation* may be morbidly keen, or morbidly obtuse; or it may be perverted : in other words, it may deviate in degree, or in kind, from the healthy standard.

The sensations referred to the several surfaces and structures of the body, and to the organs of sense, may (without any fault in those parts and organs) be preternaturally acute. Tenderness ascribed to different parts, their natural sensations being heightened into pain ; a general state of irritability ; intolerance of light, and of noise ; are so many instances of this over-sensitiveness of the percipient organ.

Under the head of diminished or defective sensation may be ranked, numbness in all its degrees, up to total loss of sensibility or *anæsthesia;* dulness of hearing, deafness ; dimness of sight, blindness ; failure, or

690.—XXVII.

absolute extinction, of the senses of taste and of smell.

Perverted sensations, sensations unnatural in kind, are very numerous. To mention a few : giddiness ; nausea ; ringing in the ears ; ocular spectra ; ill smells in the nostrils ; false tastes on the palate ; itching ; and sundry uneasy feelings, many of which are indescribable. Various kinds of pain belong to this class ; spirits violently high ; causeless depression, anxiety, and dread.

2. Innumerable degrees and varieties of disturbance of the faculty of *thought* are met with. Delirium in all its shades ; dulness and confusion of intellect ; sundry defects of memory ; incapacity of judgment ; and every degree of stupor up to complete coma.

Of the function of *voluntary motion* there are also various kinds and gradations of derangement : twitchings of the muscles ; tremors of the limbs ; rigidity from spasm ; irregular and involuntary jactitation ; convulsions ; muscular debility ; palsy.

Now, as I stated before, there is no physical exploration of the living brain. We are limited therefore, in studying its diseases, to the rational symptoms. It becomes our task to interpret the import of the multiform disturbances of function just enumerated, in every case in which more or fewer of them appear ; and when you are told that these symptoms are apt to present themselves in almost every conceivable order and combination, and, moreover, that many of them may be sympathetic of diseases of other parts than the brain, you will scarcely need to be farther informed, that the language they speak is often very hard to construe ; that we frequently fail to reach and discover, by these outward signals, the inward things they denote.

I am about to consider, in the first place, some of the inflammatory affections of the brain, and some which may easily be mistaken for inflammatory affections ; and I

3 D

warn you beforehand, that, in respect to exactness of diagnosis, we are sadly barren of certainties in these matters. Hints, sketches, approximations, are nearly all that I can promise concerning not a few of the many diseased conditions to which the brain and nerves are obnoxious.

In the brain, as in other composite organs, inflammation may be general or partial. It may attack certain tissues only ; it may be seated in the substance of the cerebral mass, or in the membranes that envelope it.

I need not tell any of you that the membranes which invest the brain are three in number ; the fibrous dura mater, the serous arachnoid, and the pia mater, which is composed of blood-vessels held together by a web of cellular tissue.

Speaking generally, inflammation of the cerebral substance alone, is perhaps more common than inflammation of the investing membranes alone. The central parts of the nervous mass may and do suffer inflammation, while the membranes escape. But it seems to me scarcely possible that inflammation of the pia mater should take place without implicating also the surface of the convolutions, with which it has so close a relation, and so intimate a vascular connexion.

Again, with respect to the membranes themselves, the dura mater may be inflamed while the pia mater remains unaffected. I believe also that the arachnoid may suffer inflammation, and leave the subjacent pia mater untouched. Whether the arachnoid ever escapes participating in the inflammation of the dura mater on the one side, or the pia mater on the other, is to be doubted.

Can we separate and distinguish these several inflammations by assigning to each its proper external phænomena ? Seldom ; scarcely ever. Doubtless each has its peculiar symptoms ; and if inflammation was often strictly limited to the one membrane or the other, and if the course and events of the inflammation did not modify the condition of the brain itself, by pressure, or by affecting the circulation of blood through it, then we might expect greater uniformity, and hope by careful and repeated observation to seize upon the desired distinctions. But this simplicity is not exhibited by the inflammatory affections of the parts within the cranium. Inflammation commencing in one membrane is apt to spread readily and rapidly to the rest, and to the cerebral substance ; and the complication of diseased conditions coexisting within the skull at the same time, throws confusion over the whole subject. This uncertainty of exact diagnosis is however of the less consequence, inasmuch as when we have learned that inflammation is going on in any part of the ence-

phalon, we have learned enough to direct us as to the general plan of treatment to be adopted.

After all, certain symptoms do present themselves more frequently when one part is inflamed, and certain other symptoms more frequently when another part is inflamed ; and it will be proper and convenient to contemplate certain forms of meningeal inflammation separately.

Inflammation of the dura mater.—Let us first then consider inflammation as it is confined, occasionally, to the dura mater—or to the dura mater and arachnoid.

This very rarely happens as an idiopathic or spontaneous disease ; but it is not at all uncommon as a result of external injury. And we may advantageously trace its ordinary phænomena and consequences, by attending to these instances of traumatic inflammation of the dura mater. They were excellently well described, many years ago, by Mr. Pott. A man receives a blow on the head ; the blow stuns him perhaps at the time, but he presently recovers himself, and remains, for a certain period, apparently in perfect health. But after some days he begins to complain ; he has pain of the head, is restless, cannot sleep, has a frequent and hard pulse, a hot and dry skin, his countenance becomes flushed, his eyes are red and ferretty; rigors, nausea, and vomiting supervene ; and, towards the end, convulsions and delirium. Meanwhile the part which was struck becomes puffy, tumid, and somewhat tender ; and if this tumid portion of the scalp be cut through, the pericranium beneath it is found to be separated from the bone ; and the bone itself is observed to be altered in colour, whiter and drier than the healthy bone ; and if a piece of this bone be removed, it is also seen that the dura mater on the other side of it is detached from the cranium, and sometimes smeared with lymph or puriform matter. This is a form of disease very often met with by the surgeon. I have watched, with much interest, several such cases under the care of my hospital colleagues. One or two of them I will briefly describe.

In the year 1833, during Christmas time, the coachman of a lady living in my neighbourhood fell, being intoxicated, into a cellar or area, struck in his fall one side of his head, and tore up the scalp over a considerable space. He was carried to the hospital, where the loose flap of integuments was cleansed and replaced. After some days erysipelas came on, and then a much larger portion of the scalp sloughed away, so that the bone was laid bare to a frightful extent, and looked, at a little distance, as he sat up in bed, like the tonsure of a monk. Nevertheless the man seemed wonderfully free from suffering or distress : his pulse, indeed,

was frequent, but it was said to be so during health. His intellect was clear, and he had *no* head symptoms; or rather, no brain symptoms.

In the early part of February, 1834, he had a shivering fit, which was followed by convulsions of the right side of the body, and subsequently by paralysis of the right arm and leg, and by stupor, from which he could easily be roused. He would put out his tongue when desired to do so; but to every question he answered "yes." A portion of the left parietal bone was evidently dead: here the trephine was applied; and a piece of bone being removed, the dura mater was exposed. It looked as if it also had lost its vitality. Some pus lay upon it. No relief followed the operation.

On the 10th of February fluctuation was detected beneath the dura mater, which was slit open. About three drachms of puriform fluid escaped. The patient died soon afterwards, having had no active delirium throughout.

The surface of the dura mater was found to be nearly of its natural appearance, except where the trepanning had been performed. At that spot it was dry and sloughy. Over the whole of the anterior and lateral surface of the left hemisphere lay a thick coating of coagulable lymph, smeared with pus: this extended down the posterior part of the hemisphere also, nearly to its base. There was no other morbid appearance; no fluid in the pia mater, or in the ventricles. The substance of the brain was every where perfectly sound and healthy: it was divided in all directions in search of an abscess, but nothing unnatural could be detected.

Another man came to the hospital to have a small incised wound of the scalp looked at. The injury appeared to be trivial; the cut was dressed, and the man made an out-patient. A few days afterwards he came again, imperfectly paralytic on one side of the body. I saw this man's skull trepanned: he was perfectly calm and collected: that part of the dura mater which corresponded to the wound was found to be inflamed; and there was pus diffused over the arachnoid covering the cerebral convolutions on the same side. He sank quietly into a state of coma, and so died. Not the slightest incoherence or delirium had been manifested, there had been no convulsions, nor was there any other morbid appearance within the cranium.

I mention these cases to show you the grounds of my own opinion that inflammation, beginning in the fibrous membrane, *may* affect the arachnoid, without *necessarily* extending to the pia mater; just as inflammation *may* overspread the pleura, or the pericardium, without touching the lung or heart which those serous membranes re-

spectively invest. Here no sensible traces of inflammation were discovered, deeper than the free surface of the arachnoid; and there had been no disturbance, till towards the end, of the proper functions of the brain. I conclude that the disease did not pass beyond the serous membrane; for I can scarcely conceive inflammation of the pia mater to exist without involving, in some degree, the surface of the brain; nor inflammation of the surface of the brain to exist without some manifest derangement of the cerebral functions. In the instances that I have been relating the final stupor and palsy may reasonably be ascribed to *pressure* resulting from the *events* of the inflammation of the arachnoid; from the effused pus and lymph.

Inflammation of the dura mater is very rare as a simple and idiopathic affection. Dr. Abercrombie relates one instance of it, as the only one he had seen; and even that was not a pure case of inflammation of the dura mater. There was pus upon that membrane; and it adhered to the cranium over a space as big as a crown-piece; and at that spot it was ulcerated. But there was also found an adventitious membrane *beneath the arachnoid* where it covers the brain.

Speaking generally, this complaint is marked by pain of the head, by fever, and by rigors which intermit; and so regular sometimes are the intermissions, that the practitioner may be tempted to believe that he has got an aguish patient, and to administer bark. The intellectual functions, especially at the outset of the disease, are but little affected; which is just what we might expect.

Although inflammation of the dura mater is very uncommon as an idiopathic or primary disorder, we very frequently meet with it as a secondary affection; and then there are few diseases more surely fatal, or less within the reach of remedies. It is as a consequence of what is called *otitis*, that physicians are chiefly accustomed to encounter inflammation of the dura mater. It results from disease of the internal ear, and of the petrous portion of the temporal bone. Sometimes acute inflammation arises within the tympanum, when there has been no previous disease: the patient has severe ear-ache; at length a gush of matter comes from the external meatus, but the pain does not, as it usually does in such cases, cease; it continues, or even increases in intensity: the patient begins to shiver; he becomes dull and drowsy; slight delirium perhaps occurs; and by degrees he sinks into stupor. In some instances no pus issues externally. More commonly symptoms of the same kind supervene upon a *chronic* discharge of purulent matter from the ear. It is scarcely possible to sketch an accurate general picture of this insidious, but most dangerous com-

plaint. Next to seeing and watching actual cases of it, the best way of becoming acquainted with its phænomena is by attending to recorded instances. I will bring before you, therefore, some examples of inflammation of the dura mater, occurring in connexion with disease of the interior of the organ of hearing.

A youth, sixteen years old, applied to the late Dr. Powell (who has related the case in the fifth volume of the *Transactions of the College of Physicians*) on account of an eruption, with an acrid discharge, behind the right ear. He had become deaf five years before, after scarlet fever, but no discharge took place at that time from the ear. In the following year, however, he had the measles, and then an abscess formed in the right ear, and after giving him much pain, it burst. He had again suffered, three days before Dr. Powell first saw him, a sudden attack of very severe pain in the same ear. The pain quite deprived him of rest; but he had no fever, nor delirium, nor coma. He slept, indeed, a great deal, but that was the effect of opiates, which he took to relieve the pain. This symptom was quieted by the opium; but it always returned with severity if the medicine was suspended. A fœtid discharge came from the ear. On the tenth day of this attack, after a most violent paroxysm of pain, his strength rapidly declined, and he died.

"When the head was examined, the structure of the dura mater was healthy and natural, but beneath this membrane the whole superior surface of the right hemisphere was covered with a layer of coagulable lymph and pus. The vessels of the substance of the brain were not more numerous or loaded than usual, and the brain itself was healthy in every part. In the base of the skull the dura mater adhered to the bone, except at one part, of about half an inch diameter, just over the petrous portion of the temporal bone, where it was black and sloughy. The subjacent portion of the bone itself was carious, black, and crumbling; and contained fœtid pus."

In this case, you will observe, there was no symptom to mark the extensive mischief within the head, except the *pain:* the pulse never exceeded 72; the skin was warm and moist; there was neither fever, nor delirium, nor convulsion, nor coma.

A girl, aged nine, (I take this case from Dr. Abercrombie, whose volume on the diseases of the brain is full of practical and instructive *examples*) had been liable to attacks of suppuration of the ear, which were usually preceded by severe pain, and some fever. She suffered one of these attacks in the left ear, in July, 1810, from which she was not relieved, as before, when the discharge of matter took place, but continued to be affected with pain, which ex-

tended over the forehead. When Dr. Abercrombie saw her, he found that, besides the pain, she had some vomiting, and impatience of light. Her look was oppressed; the pulse 84. Blood-letting, purging, blistering, and mercury, were employed without relief. Two days afterwards there was slight and transient delirium, a degree of stupor, and slight convulsions. She lay constantly with both her hands pressed upon her forehead, and moaning from pain, of which there had not been the least alleviation. On the fifth day from the commencement of the discharge, she continued sensible, and died suddenly in the afternoon, without either squinting, blindness, or coma, the pulse having been always under 90. A considerable quantity of colourless fluid was found in the ventricles of the brain, which, in other respects, was healthy. In the left lobe of the *cerebellum* there was an abscess of considerable extent, containing purulent matter of intolerable fœtor. The dura mater, where it covered this part of the cerebellum, was thickened and spongy, and the bone corresponding to this portion was soft, and slightly carious on its inner surface; but there was no communication with the cavity of the ear.

Here again the pain was the most prominent symptom, and probably resulted from the partial inflammation of the dura mater. It is interesting to mark these two points:— that the disease in the bone imparted disease to the dura mater, although no passage was opened from the tympanum; and that this inflammatory state of the external membrane of the brain led (apparently) to deep-seated suppuration in the cerebellum; the parts lying between the abscess and the dura mater escaping.

This last, and somewhat singular circumstance, might have been owing, (so at least I conjecture) to the introduction of pus from the suppurating ear, into some of the cerebral veins, and the consequent formation in the cerebellum of one of those secondary abscesses so commonly noticed in uncircumscribed phlebitis. Two very remarkable instances of diffused inflammation of veins, and of its terrible effects, occurring in connexion with purulent otorrhœa, have fallen under my own observation: one of them in private practice, the other in the hospital. As I am not aware that such consequences as supervened in these cases upon otitis, have received much attention, I will briefly describe them.

The first of these two patients was a boy, eleven years old, whom I attended with Dr. Mac Intyre and Mr. Arnott. He had had a discharge of offensive purulent matter from his ear since the time when, four years before, he had gone through scarlet fever. In August, 1833, he went, for a walk, into Kensington Gardens, and there lay down,

and slept upon the damp grass. The next day he was attacked with headache, shivering, and fever. Strong rigors, followed by heat and perspiration, occurred very regularly for two or three days in succession ; suggesting a suspicion that the complaint might be ague : but then pain and swelling of some of the joints came on, and were, at first, considered rheumatic. However, the true and alarming nature of the case soon became apparent. Abscesses formed in and about the affected joints, and one of these fluctuating swellings was opened, and a considerable quantity of foul, grumous, dark-coloured matter let out. After about a fortnight the child sunk under the continued irritation of the disease. The hip-joint presented a frightful specimen of disorganization ; it was full of unhealthy sanious pus, the ligamentum teres was destroyed, the articular cartilages were gone, and matter had burrowed extensively among the surrounding muscles. The knee and ankle-joints of the same limb were in a similar state. It is curious that the destructive disease of the joints was limited to those of the right lower extremity, while the primary suppuration was in the left ear. Unfortunately the head was not examined ; but that the fatal disorder had penetrated from the ear to the dura mater, I entertain no doubt : in all probability the inflammation had involved the veins and sinuses of the head.

The second case had many points of similarity with this.

William Marriott, aged 19, was admitted under my care into the Middlesex Hospital on the 18th of October, 1834, having pain and tumefaction of the right shoulder, wrist, and foot, with redness of the latter. He complained also of headache, vertigo, drowsiness, and of an occasional feeling of stupor. His skin was hot and dry, his face flushed, his tongue furred, his pulse frequent (112), and his bowels were relaxed. A puriform discharge came from his right ear.

He had been suddenly seized, a week before, with sharp pain in that ear, which lasted twenty-four hours, when the discharge began, and the pain was relieved. He then began also to have headache, which had never left him, and to be sometimes dizzy. Three days previously to his admission the rheumatism (as he supposed it to be) commenced in the foot. When this part was examined, the redness was found to be circumscribed, somewhat livid, and limited to the great toe. It had much the appearance of gout.

He soon began to be troubled with shivering fits, which recurred regularly every morning about the same hour, and were followed by burning heat of the skin, but no sweating. An abscess formed near the toe, and was opened by Mr. Mayo, and some healthy looking pus evacuated. Next a large fluctuating tumor near the shoulder was punctured, and three ounces of pus, mixed with blood, came out. After this incision the rigors ceased ; but the abscesses continued open, and the discharge had an offensive smell. On the 14th of November it was discovered that matter had collected in the left hip : this also was emptied by puncture. On the 1st of December, a very large quantity, not less than three pints, of unhealthy and grumous pus, was let out from a vast abscess which had formed in the loins : and pus was noticed in his stools. The discharge from the shoulder came at last to resemble the lees of port wine.

During all this while the patient remained feverish, with a dry parched tongue, and a rapid and feeble pulse. The diarrhœa continued, more or less, throughout. For some time before his death, which happened about the middle of the month of December, the left leg and thigh had been much enlarged by œdema.

I was not able to be present at the inspection of the body ; and I have to regret that in the report which I received of it, the condition of the brain, of its membranes, and its veins, was not noted.

The right shoulder-joint was extensively diseased ; the cartilages were destroyed by ulceration over a considerable space. Those of the left hip were entire, but the synovial cavity was full of foul matter. The joint of the great toe was implicated also in the abscess which had formed there. The femoral vein, on the left side, was plugged up, throughout its whole extent, by a coagulum, which was firm and of a reddish brown colour at the upper part of the vessel, loose and darker towards the ham. The saphena was pervious : the iliac was free from disease.

The lungs had undergone partial disorganization. Several distinct portions of the pulmonary tissue were nearly solid, while the tissue immediately around them was crepitant and healthy. From the vessels belonging to these solidified portions, purulent matter could be expressed.

The mastoid cells of the right temporal bone were filled with pus, and there was a slit-like opening in the membrana tympani. The small bones of the ear were sound.

I much lament that in these two instances, the direct link of connexion between the disease of the ear and the disorganization of the joints was not demonstrated : for seeing (they say) is believing. Yet the pain of the ear, the discharge of pus from the external meatus, the subsequent pain of the head, coming on with fever and rigors, and followed after a short interval by destructive suppuration in several distant parts, and, in the last case, the actual femoral phlebitis : these circumstances form a chain of presump-

tive evidence, amounting, in my judgment, to moral certainty, that the fatal mischief, in each case, found eatrance through " the porches of the ear ;" and that the dura mater underwent inflammation. The same evidence is scarcely less affirmative of the complication of cerebral phlebitis. The immediate vicinity of some of the sinuses to the diseased bone, and their formation by a dupliature of the dura mater, would seem to render such a complication highly probable*.

Dr. Griffin has published, in the *Dublin Journal of Science*, two cases of otitis attended with symptoms exactly resembling those of intermittent fever. One of them is as follows :—A young man, previously healthy, was attacked with fits of shivering, accompanied by pain in the left side of the head. At first the paroxysms were rather irregular, but they soon assumed the form of *tertian ague ;* coming on every other day, at about the same hour ; the cold fit commencing at noon, and lasting about half an hour, followed by a hot stage of somewhat longer duration, and terminating in profuse perspiration. In the intermissions the pain in the head was trifling : there was no thirst, or heat of skin, but he did not sleep. A tumour formed over the mastoid process of the left side, and was opened, and a quantity of extremely offensive brownish pus sprang out with great force. This gave much relief. The bone was carious over a space as big as a shilling. After about ten days, the pain in the head and in the mastoid process became very severe : the patient had violent shivering fits many times in the day, great thirst. heat of skin, vomiting, and delirium ; his face was flushed, and his pulse hard ; and he died within a few hours after the accession of these last symptoms.

The most remarkable features in this case were the similarity of the fits of shivering to the paroxysms of ague, their regular recurrence at periods of forty-eight hours, and the circumstance that they seemed, for some time, benefited by the treatment proper in ague ; namely, the exhibition of bark. The occurrence of *quotidian* paroxysms of the same kind has been noticed in relating some of the previous cases.

I have related them to shew you what different symptoms may result from inflammation of the dura mater ; and to put you upon your guard against overlooking the cause from which such inflammation does frequently originate. The suppuration of the tympanum, and consequent disease of the bone, are more common in scrofulous persons than in others ; and they are more apt to occur as sequelæ of scarlet fever than in any other way. I conceive that the inflammation of the throat, which belongs to that disorder, and often constitutes all its danger, creeps along the eustachian tube into the interior of the ear. In strumous subjects the fire thus lighted smoulders on, or if it ever goes out, is readily rekindled ; that part of the temporal bone, in which the organ of hearing is principally lodged, becomes carious ; the membrana tympani is perforated ; the little bones of the ear come away ; more or less deafness ensues ; and from time to time, or habitually it may be, there is a discharge of pus from the external orifice. At length the inner surface of the bone participates in the disease ; and then the inflammation is apt to be propagated to the dura mater, in the manner of which I have given you some instances. It is in the first onset of the inflammation in the ear that remedies are most likely to be efficient in preventing this catastrophe. Leeches applied early and repeatedly to the mastoid process, especially when that part becomes tender, as it often does in such cases, and counter-irritation afterwards, are the best means in our possession. If symptoms of inflammation within the head supervene, the complaint requires more vigorous treatment, which I shall describe when I have spoken of inflammation of the other membranes of the brain. After what has been said, it is unnecessary to point out to you that the prognosis in these cases is very unfavourable. But we are not to abandon them in despair. That inflammation of the dura mater may be recovered from, we know, by what happens in certain injuries of the head : and the following would seem to be an instance of recovery when the source of the mischief was situated in the ear :—A young lady, after the usual symptoms in the head, lay for three or four days in a state of perfect coma, and her condition was thought utterly hopeless. Her medical attendants continued to visit her as a matter of form ; and one day they were agreeably surprised to find her sitting up, and free from complaint : a copious discharge of matter had taken place from the ear with immediate relief ; and she *continued* in good health.—*(Abercrombie.)* We cannot be sure in such a case that the matter came from the brain ; but the symptoms made that supposition exceedingly probable. The case shews clearly one of two things ; either that pus may thus escape from

---

* Almost while this lecture was passing through the press, an interesting communication from Dr. Bruce, of Liverpool, upon the very point here discussed, has appeared in the MED. GAZETTE. (pp. 608 and 636 of the present volume.) Dr. Bruce narrates two cases, witnessed by himself, of " Phlebitis of the Cerebral Sinuses as a Result of Purulent Otorrhœa ;" and he refers to several others recorded by different authors. This combination of disease is doubtless more common than has been heretofore supposed ; and the important pathological considerations connected with it will probably receive further illustration, now that the attention of the profession has been called to the subject by Dr. Bruce's paper.—T. W.

the interior of the skull and the patient get well; or that pus shut up in the cavity of the tympanum may produce the urgent symptoms that are known to result from cerebral pressure.

Cases are recorded of analogous disease communicated from the carious *æthmoid* bone to the dura mater; the patients having had pain in the forehead and purulent discharge from the nose, and becoming at last forgetful and delirious, and dying in a state of coma. I have never met with an instance of this kind; nor of inflammation spreading inwards from the socket of the eye: but I make no doubt that both may occasionally happen.

These three then—*idiopathic* inflammation of the dura-mater—very rare; inflammation of the dura mater by extension of disease from the æthmoid bone, or from the orbit—also infrequent; and inflammation of the dura mater by extension of disease from the petrous portion of the temporal bone—very common: constitute those forms of inflammation of the outermost tunic of the brain, which the physician may be called upon to treat. The inflammation is not always—nay, perhaps it is seldom, if ever—restricted to that tunic; but it begins there; and the essence of the disease is inflammation of the *dura mater*.

Acute *arachnitis*—by which I mean active and *uncombined* inflammation of the arachnoid membrane—is, I apprehend, a very uncommon disorder; although that term is of frequent occurrence in medical writings. I have shown you already that inflammation may pass from the fibrous dura mater to the serous membrane reflected over it; and thence (by what is sometimes called contiguous sympathy) to the opposite portion of the same membrane spread over the surface of the brain. So, likewise, inflammation may extend from the pia mater to the arachnoid. If simple arachnitis, of an acute kind, ever happens, it has not been my fortune to see, or recognize it; and I can tell you nothing about it. In truth, the authors who use the term arachnitis do not intend thereby to express unmixed inflammation of the arachnoid; but include under that appellation inflammation of the pia mater also. Some apply the name *meningitis* to that compound affection; and the only objection to this nomenclature is, that the dura mater is as much one of the meninges of the brain as the other two.

Inflammation of the pia mater.—In the few remarks which I have to make upon inflammation of the pia mater (or, if you will, of the pia mater and arachnoid at once) I shall chiefly follow Dr. Abercrombie: because his observations are comparatively recent, and carefully made; because his veracity, and sobriety of judgment, and philosophical turn of mind, are well known; and because his cases (as regards this particular affection) are quite to the point, and his descriptions clear and concise.

But I must premise a word or two respecting the anatomical characters of the disease.

When the upper part of the skull, and the dura mater, have been removed, you may frequently see, on the surface of the exposed brain, what seems to be a thin layer of a clear gelatinous substance; but this appearance is fallacious. Puncture here and there the transparent arachnoid, and a limpid fluid, like water, trickles out; and the jelly-like investment of the convolutions is gone. Now this thin serous liquid, thus collected in the meshes of the pia mater, may be the event of inflammation of that membrane; but it may also be produced, and it very often indeed is produced, by simple congestion and remora in the cerebral veins: we cannot, therefore, with any certainty, infer, merely from seeing this serous effusion, that there has been inflammation: we judge of its import, by noting the coexistence, or the absence, of other traces of inflammation; and by the character of the symptoms that preceded death.

On the other hand, we may be sure that there has been inflammation of one or both of these tunics of the brain when we find *false membranes* between them; layers, *i. e.* of coagulable lymph. In the effusion of this substance I conclude that the vessels of the pia mater play the main part; both because it is always, in such cases, excessively vascular, while the arachnoid is seldom found to be so in any remarkable degree, if at all: and also, because this false membrane commonly, though not always, sends down processes, between those duplicatures of the pia mater which descend into the sulci formed by the convolutions; where, as you know, the arachnoid does not go. In fact, considering the arachnoid as the serous membrane of the brain, we should expect that, when inflamed, it would present the events or products of inflammation on its free surface; and we sometimes find them there; but this is very rare; and for my own part, I look upon those effusions which lie beneath the arachnoid, between it and the pia mater, as being furnished exclusively by the vessels of which the latter membrane is mainly composed.

Now the inflammation of these membranes (taking them together) commences, and declares itself, by no fixed or uniform symptoms. The most common and striking phænomenon is a sudden and long-continued paroxysm of *general convulsions*. Sometimes this is the first thing noticed; sometimes it comes on after a few days of discomfort, and headache; and among the symptoms thus preceding the convulsions, *vomiting* is of frequent occurrence: the convulsions recur, and at length end in coma. Some-

times, again, the first attack of convulsions comes on after violent pain in the head, setting in quite suddenly, and attended with screaming. I do not find in any of the various examples given by Dr. Abercrombie any mention made of violent or continued *delirium;* which is generally set down by authors as marking inflammation of the membranes. He does give cases, indeed, in which there *was much* delirium ; but they were not cases of meningitis of any kind. He relates them as instances " of a very dangerous modification of the disease, which shows only increased vascularity." I venture, with great humility, to question or criticise any opinion of Dr. Abercrombie's : but I entertain no doubt about the nature of the cases which he so describes ; and I hope to convince you by-and-by that they are not examples of inflammation at all: they neither show the anatomical characters of inflammation, nor yield to the remedies of inflammation. Excluding these cases, I do not find delirium marked as a symptom of uncombined meningitis. I shall abridge one or two of the well-marked examples of the disease.

A girl, aged nine, woke suddenly in the middle of the night, screaming from violent headache, and exclaiming that some person had given her a blow on the head : for the next two days she complained of some, but not much pain in her forehead, and did not even remain constantly in bed ; no alarm was felt about her. On the third day she was seized with violent and long-continued convulsions, and immediately after the convulsions she fell into a state of deep coma : she remained in this state, with a natural pulse, till she died, on the sixth day of the disease.

When the dura mater had been removed, the other membranes appeared highly vascular, except where this appearance was concealed by a layer of yellow adventitious membrane, spread out betwixt the arachnoid and the pia mater. This was distributed in irregular patches over various parts of the surface of the brain, but was most abundant on the upper part of the right hemisphere. It was as thick as a wafer, and in some places dipped down between the convolutions. A considerable quantity of it extended over the surface of the cerebellum also.

A child two years old was suddenly attacked one morning with severe and long-continued convulsions. The convulsions recurred many times; in the intervals she was dull and torpid, in a state of partial coma, with occasional starting, and a frequent and feeble pulse. On the fourth day she sunk.

The surface of the brain, when the dura mater was removed, was covered in many places, betwixt the arachnoid and pia mater, by an adventitious membrane. It was chiefly found above the openings between the convolutions, and in some places appeared

to descend a little way between them. The arachnoid when detached seemed to be healthy ; but the pia mater was in the highest state of vascularity throughout; and when the brain was cut vertically, the spaces between the convolutions were most strikingly marked by a bright line of vivid redness, produced by the inflamed membrane. There was no effusion in the ventricles, and no other morbid appearance.

In another example the whole surface of the brain was covered by a continued stratum of yellow false membrane, lying between the arachnoid and pia mater, and in some parts following the course of the pia mater through the whole depth of the convolutions ; the pia mater and arachnoid adhered together every where, very firmly, by means of it : not a trace of it could be found either on the outer surface of the arachnoid, or the inner surface of the pia mater : the arachnoid itself, when separated, presented no unusual appearance, but the pia mater was every where excessively vascular. There was no serous effusion, and the brain and cerebellum were perfectly healthy.

Now in this dissection there was unequivocal evidence of acute and extensive inflammation of these membranes, or, I should say, of the pia mater ; yet the symptoms had been very obscure. The child in whom the disease occurred was convalescent from a mild attack of scarlet fever. One evening he became very feverish, and complained of his belly. Three days afterwards he had frequent *vomiting,* followed by coma, and some convulsive movements of his face and arms, and death took place four days and a half after the feverishness began. We learn from this case, that general and severe inflammation of the innermost membrane may exist, and prove fatal, without giving rise to any violent symptoms at all.

I must trouble you with one more history, because it affords another example of what I have mentioned as being rare ; viz. the effusion of the products of inflammatory action upon the outer surface of the arachnoid, and marking therefore very distinctly the inflammation of that membrane. It was evidently combined, however, with inflammation of the *pia mater* also. A child, eight months old, died after more than three weeks illness ; which began with fever, restlessness, and quick breathing ; afterwards there were frequent convulsive affections, with much oppression; and at last severe convulsions, squinting, and coma. At an early period of the complaint, a remarkable prominence of the anterior fontanelle was noticed ; in the second week this *increased* considerably ; and in the third week, it was elevated into a distinct circumscribed tumour, which was soft and fluctuating, and pressure upon it occasioned convulsions. It was opened by a small puncture, and discharged at first some

purulent matter, afterwards bloody serum. No change took place in the symptoms, and the child died four days after.

A deposition of thick flocculent matter mixed with pus was found covering the surface of the brain to a considerable extent, and lying *upon* the free surface of the arachnoid. There was a similar deposition also between the arachnoid and the pia mater, and considerable effusion into the ventricles.

If the sketches I have been giving you afford a true outline of the phænomena which attend acute inflammation of the pia mater, or of the pia mater and arachnoid jointly, what, you may naturally ask, is the nature of those cases in which there is high excitement, and much fever, and great delirium, and which are sometimes spoken of as *phrenitis*, or as brain-fever? Why these *are* instances of acute inflammation of the whole contents of the cranium; of the brain *and* its membranes; of the encephalon in short; and, therefore, the disease has, not improperly, been called *encephalitis*. Of this formidable malady I shall give you some account to-morrow.

Lecture I.

General View of the Functions of the Nervous System.

The existence of *consciousness*, by which the individual (*le moi*, in the language of French physiologists) becomes *sensible* of impressions made upon its bodily structure,—and the power of *spontaneously* exciting contractions in its tissues, by which evident motions are produced,—may be regarded as the peculiar attributes of the beings composing the Animal kingdom. Although evident motions are exhibited by some plants, they cannot be regarded as indicating the existence of any psychical endowments in the beings included in the vegetable kingdom. These motions are usually to be referred to the direct operation of a stimulus upon a contractile tissue: as when the stamen of the berberry is caused to move by the mechanical irritation of the contractile cells on one side of the base of its filament. In some cases, as in the *Dionæa* and *Mimosa*, the irritation, which is at first produced by a mechanical stimulus, occasions motion in a distant part; but there is not here any necessity to imagine the existence of a nervous system as the recipient of the impression and

the originator of the motion; since the phenomena may be accounted for without any such supposition; and it is a well-known rule in philosophy, which cannot be too steadily kept in view in prosecuting physiological inquiries,—*non fingere hypotheses.*

There are in animals, however, many movements which are equally dependent upon direct stimuli for their production. Such are, even in the highest, the actions of the heart and of the alimentary canal. These, in the lowest tribes, probably bear a much greater proportion to the whole amount of those exhibited by the beings, than they do in the higher; whilst those which we may regard as specially dependent on a nervous system, appear to constitute but a small part of their general vital actions. The life of such beings much more closely resembles that of the vegetable, than that of the higher animal. Their organic functions are performed with scarcely more of sensible movement than is seen in plants; and of the motions which they do exhibit (nearly all of them *immediately* concerned in the maintenance of the organic functions), it is probable that many are the result of the simple contractility of their tissues, called into action by the stimuli directly applied to them. It is scarcely possible to imagine that such beings can enjoy any of those higher mental powers, which man recognizes by observation on himself, and of which he discerns the manifestations in the tribes, which, from their nearer relation to himself, he regards as more elevated in the scale of existence.

If we direct our attention, on the other hand, to the psychical* operations of man, as forming part of his general vital actions, we perceive that the proportion is completely reversed. So far from his organic life exhibiting a predominance, it appears entirely subordinate to his animal functions, and seems destined only to afford the conditions for their performance. If we could imagine his nervous and muscular systems to be isolated from the remainder of his corporeal structure, and endowed in themselves with the power of retaining their integrity and activity, we should have all that is essential to our idea of man. But, as at present constituted, these organs are dependent, for the maintenance of their integrity and functional activity, upon the nutritive apparatus; and the whole object of the latter appears to be the supply of those conditions necessary to the exercise of the peculiarly *animal* functions. That his mental activity should be thus made dependent upon the due supply of his bodily wants, is a part of the general scheme of his probationary existence; and

---

* Here and elsewhere this term will be employed in its most extended sense, to designate *all* the mental operations,—whether intellectual, emotional, instinctive,—of which man's nervous system is the instrument.

the first excitement of his intellectual powers is in a great degree dependent upon this arrangement.

All our positive knowledge of the functions of the nervous system is derived from observation of the movements exhibited by animals, and from our own consciousness of that which passes within us. Except through the movements consequent upon them, we have no means of ascertaining whether or not particular changes in the nervous system are attended with sensation. The cries and struggles of the animal made the subject of experiment, are ordinarily considered as indications of sensation ; but it is not right so to regard them in every instance ; nor are we justified in asserting that consciousness results from any external irritation, merely because movements evidently tending to get rid of it are performed in respondence. We know that the contractions of the heart and alimentary tube are ordinarily excited by a stimulus, without any sensation being involved ; and these movements, like all that are concerned in the maintenance of the organic functions, have an obvious design, when considered either in their immediate effects, or in their more remote consequences. The character of *adaptiveness*, then, in muscular movements excited by external stimuli, is no proof that they are performed in obedience to sensation ; much less, that they have a voluntary character.   In no cases is this adaptiveness more remarkable than in some of those purely instinctive actions, which are not only performed without any effort of the will, but which the will cannot imitate.   This is the case, for example, with the act of deglutition ; the muscles concerned in which cannot be thrown into contraction by a voluntary impulse, being stimulated only by impressions conveyed from the mucous surface of the fauces to the medulla oblongata, and thence reflected along the efferent fibres.   No one can swallow without producing an impression of some kind upon this surface, to which the muscular movements will immediately respond.   Now it is impossible to conceive any movements more perfectly adapted to a given purpose, than those of the parts in question ; and yet they are not only independent of volition, but of sensation, being still performed in cases in which consciousness is completely suspended, or entirely absent.

There is much difficulty, then, in ascertaining the really elementary functions of the nervous system by experiments upon animals ; and it is only when their results are corrected and explained by pathological observation in the only case in which we can obtain satisfactory evidence of the presence or absence of sensation, that they have much value to the physiological inquirer.   From these combined sources, however, a vast amount of knowledge of the functions of the nervous system has recently been gained ; and the general purposes to which it is subservient may be advantageously stated in a systematic form, before we enter upon any detailed examination of them.

1. The nervous system receives impressions, which, being conveyed by its afferent fibres to the sensorium, are there communicated to the conscious mind.   It is subservient in some way to the acts of that mind ; and, as the result of these acts, a motor impulse is transmitted along the efferent trunks to particular muscles, exciting them to contraction.   This motor impulse, however, may be either of an *emotional* or a *voluntary* character.   We shall hereafter see reason to believe that to these functions the brain and the nerves proceeding from it are subservient.

2. Certain parts of the nervous system receive impressions, which are propagated along afferent fibres that terminate in ganglionic centres distinct from the sensorium ; and in these a reflex motor impulse is thus excited, which, being conveyed along the efferent trunks proceeding from them, excite muscular contraction, without any necessary intervention of sensation or volition.   Of this function (called by Dr. Hall, to whom the discovery of it is in great part due, the reflex function), we shall find that the portion of the spinal cord of Vertebrata which is not continuous with the fibrous structure of the brain, together with the portion of the nervous trunks which are connected with it alone, is the instrument.

3. Another division of the nervous system appears to have for its object to combine and harmonize the muscular movements immediately connected with the maintenance of organic life, and to bring these into relation with certain conditions of the mind.   There is also reason to believe (though this is less certain) that it also influences and brings into connection the processes of nutrition, secretion, &c. ; and though these, like the muscular movements just mentioned, are essentially independent of it.

Now, in reference to the first class of operations, it is well to explain that, when the physiologist speaks of the intellectual powers, moral feelings, &c. as *functions* of the nervous system, they are not so in the sense in which the term is employed in regard to other operations of the bodily frame. In general, by the *function* of an organ, we understand some change which may be made evident to the senses, as well in our own system as in the body of another. Sensation, thought, emotion, and volition, however, are changes imperceptible to our senses, by any means of observation we at present possess. We are cognizant of them in ourselves without the intervention of those processes by which

we observe material changes external to our minds ; but we judge of them in others only by inferences founded on the actions to which they give rise, when compared with our own. When we speak of sensation, thought, emotion, or volition, therefore, as functions of the nervous system, we mean only that this system furnishes the conditions under which they take place in the living body ; and we leave the question entirely open, whether the ψυχη has or has not an existence independent of that of the material organism by which it operates in man as at present constituted.

In regard to the second class of actions, it may be remarked that they are nearly all connected, more or less closely, with the organic functions, or with the protection of the body from danger. Thus the movements of the pharynx supply to the stomach the alimentary materials it prepares for the nutrition of the body ; those of the muscles of the thorax, &c. maintain the constant interchange of air in the lungs which is necessary for the aeration of the blood : whilst those by which a limb is involuntarily retracted from any cause of pain or irritation, are obviously adapted to the latter of these two ends.

Nature of the nervous structure.—Wherever a distinct nervous system can be observed, it is found to consist of two kinds of structure ; the presence of both of which, therefore, may be regarded as essential to our idea of it as a whole. One of these is that which is designated the *white* or *fibrous* matter. This constitutes (with the neurilema or nerve-sheath, and the cellular tissue which it encloses), the whole of the nervous trunks wherever they occur, and forms a large part of the central masses with which they are connected. The other is termed *cineritious* or *grey* matter. It seems to consist principally of a plexus of blood-vessels, in which the fibres of the former appear lost ; and amongst these lie a number of granules which do not seem to have any definite arrangement. This is usually disposed in the *centre* of the larger masses with which the nervous trunks are connected. It forms the *nuclei* of the ganglia which are the centres of the nervous system in the Invertebrata : it occupies part of the interior of the spinal cord of Vertebrated animals, which may be regarded as a chain of similar ganglia ; and in the distinct ganglia which occur among the latter, it holds the same relative position. In the brain of Vertebrata, however, it is disposed externally, and forms a sort of coating to the mass beneath, which almost entirely consists of fibrous structure ; hence it has been called the *cortical* substance, whilst the fibrous portion has been termed *medullary* matter. There can be little doubt that the functions of these two divisions of the nervous system are different. That of the

fibrous structure, as it exists in the nervous trunks, is unquestionably to conduct or convey the influence of changes which have taken place elsewhere. And, in accordance with what has previously been stated of the mode in which the mind is brought into relation with the external world through this nervous apparatus, we find that there are (in the higher tribes of animals, at least, if not all) two sets of fibres ; one of which has for its office to convey external impressions *towards* the nervous centres, whilst the other conveys the influence of these central organs to the structure at large, and especially to the muscular system. Hence it will be convenient to denominate the first *afferent* fibres, and the second *efferent*. These are to be regarded as general terms, expressing only the direction in which they propagate the changes to which they are subservient. The nature of these changes will be a subject of future inquiry.

Distinct course and function of nervous fibres.—Every fibre, there is reason to believe, runs a distinct course from the central organ, in which it loses itself at one extremity, to the muscle or organ of sense in which it terminates at the other. Each nervous trunk is made up of several fasciculi of these fibres ; and each fasciculus is composed of a large number of the ultimate fibres themselves. Although the fasciculi occasionally intermix and exchange fibres with one another, (as occurs in what is termed a *plexus*), the fibres themselves never inosculate. Each would seem, therefore, to have its appropriate office, which it cannot share with another. The objects of a plexus are two-fold. In some instances it serves to intermix fibres which have endowments fundamentally different : for example, the spinal accessory nerve is, at its origin, exclusively motor, and the roots of the par vagum are as exclusively sensory ; but by the early admixture of these, a large number of motor fibres are imparted to the par vagum, and distributed, in variable proportion, with its different branches, whilst a small proportion of its sensory filaments seems to enter the spinal accessory. In other instances the object of a plexus appears to be to give a more advantageous distribution to fibres which all possess corresponding endowments. Thus the brachial plexus mixes together the fibres arising from five segments of the spinal cord, and sends off five principal trunks to supply the arm. Now if each of these trunks had arisen by itself from a distinct segment of the spinal cord, so that the parts on which it is distributed had only a single connection with the nervous centres, they would have been much more liable to paralysis than at present. By means of the plexus every part is supplied with fibres arising from each segment of the spinal cord ;

and the functions of the whole must therefore be suspended before complete paralysis of any part can occur from any cause which operates above the plexus. It is not unlikely that, by this arrangement, a *consentaneousness* of action is, in some degree, favoured ; for comparative anatomy shows that something resembling it may be traced, wherever a similar purpose has to be attained. Thus, in the Hymenoptera, there is a similar interlacement between the nerves of the anterior and posterior pairs of wings, which act very powerfully together ; whilst in the Coleoptera, in which the anterior wings are converted into elytra, and are motionless during flight, the nerves supplying each pair run their course distinctly. In the Octopus, again, the trunks which radiate from the cephalic mass to the eight large arms surrounding the head, are connected by a circular band, forming a kind of plexus, which evidently contributes to the very powerful and harmonious movements of the arms of this Cephalopod.

In those nervous centres of which the bulk is not great in proportion to the size of the nerves connected with them, there is commonly but little difficulty in tracing the fibres of the latter into their substance, and observing their termination in the gray matter of their nucleus. But, in the brain of the higher vertebrata, and especially in that of man, the case is somewhat different. The great mass of this organ is composed of fibres communicating between the different portions of its own cortical substance ; and those which are connected with the nervous trunks cannot be so readily distinguished. Still there can be little doubt that there is here, also, a conformity with the general proposition, that each fibre, at its central termination, passes towards the grey matter, in which it loses itself, and maintains its distinctness from the rest, even through the most complex interlacement.

As the structure of the medullary matter of the brain and spinal cord does not present any essential difference from that of the nervous trunks, and as the fibres of the latter are continuous with a part of their fibres, there appears some ground for the belief that the function is the same in both instances ; and that the tubular fibres, wherever they present themselves, serve as *conductors* of the changes which take place (usually at least) at one of their extremities. We then come to inquire how these changes are *originated ;* and, finding at the central extremity a substance of peculiar character, and evidently (from the quantity of blood sent to it) the seat of important and energetic operations, we are naturally led to inquire if any such structure can be detected in the peripheral terminations of the nervous fibres. Microscopic examination of those

which are connected with sensory organs, shows that they come into relation with a substance very analogous to the grey matter of the centres, though its elements are somewhat differently arranged. It is evident, both in the retina, the expansion of the auditory and olfactory nerves, and in the papillæ of the skin and tongue, that the fibres terminate in close approximation with a vascular plexus ; and a granular structure is always present, which seems (as in the cortical substance of the brain) to be intermediate between them. We may regard this point, therefore, as the *origin* of the *afferent* fibres ; and it would seem to be here that those changes are effected by external impressions, which are propagated by the fibres to the central organs. Now it is an interesting discovery, recently made by Foville, that the fibres which radiate from the *sensory* tract of the medulla oblongata towards the cortical substance of the hemispheres, *do not terminate* in it ; but that they form a series of loops, passing through it and converging again towards the centre from which they had diverged. Some of these loops do not reach the exterior of the hemispheres, but pass through the isolated tracts of grey matter which the brain contains.

On the other hand, the influence which produces muscular contraction is transmitted *from* the central organs, and probably from their grey matter ; and this we may regard as the *origin* of the *efferent* fibres. These efferent fibres are distributed on the muscles nearly in the same manner that the afferent spread through the brain ; that is, they do not terminate in free extremities, but a series of returning loops is formed by them.

It may be argued against this view of the respective functions of the granular and fibrous structures, that sensation may be produced by pinching an afferent trunk in its course, and that motion may be excited by irritating an efferent nerve ; so that the changes which have been spoken of as occurring at their points of origin in the vascular plexus are not to be regarded as the means by which such influences are produced. But this argument will have little weight when it is recollected that, on the same ground, we might infer that neither the organs of sensation, on the one hand, nor any part of the brain, or spinal cord, on the other, are the sources of the changes in question. The effects are obviously due to the fact that the artificial stimulus imitates the natural one ; and thus it is that, if a sensory nerve be compressed, the sensation produced is referred to the part of the surface to which its branches are distributed.

The belief that all changes in the nervous system, whether they take place at the centre or at the periphery, originate at the points

in which the fibres come into relation with the vascular plexus, derives confirmation from the well-known dependence of these changes upon the activity of the circulation through the part at which they occur. Thus, if the circulation of blood through the brain be suspended for an instant, insensibility supervenes. If the cause of suspension be local only, the remainder of the nervous system may still be excited to action. This was the case in the experiments of Sir A. Cooper. After having tied both carotid arteries in a dog, he compressed the vertebral trunks, and immediate insensibility resulted, proving the inactive condition of the brain ; whilst convulsions also occurred, showing that the functions of the spinal cord were not suspended, but only deranged. But if, as in syncope, the circulation through the spinal cord also be weakened, its power of producing motions in respondence to impressions is diminished in like proportion. In the same manner, the production of impressions on the peripheral origins of the afferent nerves appears equally dependent upon the active influence of the vascular system. Every one knows that cold, which retards the circulation of blood through the skin, diminishes also its sensibility ; and obstruction to the circulation by any other cause, such as pressure on the arterial trunks, produces the same effect. We have no opportunities of observing such affections of the *special* sensory organs, except when the whole supply of blood to the head is checked ; and then, as the brain is also affected, there is no proof that the absence of sensation is partly due to the suspension of *their* impressibility, though it can scarcely be doubted that this is the case. Moreover, it is always found that an increase in local circulation is accompanied by an exaltation of the sensibility of the part. This may be especially noticed in the genital organs of animals during the period of heat ; and in those of man when in a state of venereal excitement. It may be remarked, also, in those affections so closely bordering upon inflammation, to which the term *active congestion*, or *determination of blood*, has been applied. The *pain* which usually accompanies inflammation may be partly referred to this source ; but it seems principally dependent upon other causes.

The foregoing is, perhaps, all the information we at present possess respecting the elementary structure of the nervous system, which can be directly brought to bear upon physiological inquiries. Recent microscopical observations, however, have informed us of several facts which should not be overlooked. The cavity of the nerve-tubes is filled with a sort of medulla or pith, which, when squeezed from them, has a granular consistence ; but, when lying *in situ*, this substance is stated by Remak to be itself a continuous fibre, divisible into minute filaments. At some of the extremities of the nerves these minute filaments can be seen to separate from each other, spreading out in a loop-like manner over the surface to which they are distributed, on which a complete network is thus formed, consisting of filaments much more minute than can be elsewhere distinguished. The diameter of the fibres varies among the Invertebrata from $\frac{1}{48}$ to $\frac{1}{1000}$ of a line ; but in the vertebral animals the extremes are not so distant, the tubes being commonly from $\frac{1}{120}$ to $\frac{1}{240}$ of a line in diameter. A similar fibrous structure is evident in the brain ; and here the tubes seem to contain a viscous fluid, not altogether unlike the medulla of the fibres of nerves, but of less consistence. A different structure has been described by Ehrenberg, under the name of *varicose* tubes, which he states to exist in the brain, spinal cord, and nerves of special sensation. These tubes were so named from their not being cylindrical; but presenting dilatations at intervals, so as to resemble a string of beads ; and the appearance of these dilatations has given rise to the opinion that the brain is composed of globules. It is now, however, satisfactorily shown that they are the result of the pressure and other manipulations to which the objects are subjected in preparation for the microscope ; and that, if the nervous fibres of the brain and other parts are examined in a recent state, they are cylindrical, like those of the nervous trunks in general. Still there is some difference in their structure, since they exhibit this tendency to become varicose, which is elsewhere wanting.

Besides these tubular fibres, which constitute the white portions of the nervous matter, there are other filaments of a grey colour, and of much smaller diameter, without distinct cavities, which exist especially in the sympathetic nerves, but which may also be detected in others. These fibres may be termed *organic ;* those existing in the sympathetic system of nerves may be traced to its ganglionic centres ; whilst those which are formed in the cerebro - spinal nerves are connected with the ganglia upon their posterior roots.

Our simplest idea, then, of a nervous system, includes a central organ—of which the grey matter, formed by the intermixture of nervous fibres and blood-vessels, is the essential part,—and a double set of fibres connected with it ; one conveying to it the impressions produced by external changes upon the periphery (where also the nervous structure comes into peculiar relation with the vascular system) ; and the other conducting from it the motor stimulus, originating in itself, to the contractile tissue. This is precisely what we find in the lowest animals, in which a nervous apparatus can be distinguished, as will be explained in the

next lecture. At present it will be desirable to consider some other questions which early present themselves in the study of neurology.

Mode of determining the functions of nerves.—Various methods of determining the functions of particular nerves present themselves to the physiological inquirer. One source of evidence is drawn from their anatomical distribution. For example, if a nervous trunk is found to lose itself entirely in the substance of muscles, it may be inferred to be chiefly, if not entirely, motor or efferent. In this manner, Willis long ago determined that the third, fourth, sixth, portio dura of the seventh, and ninth cranial nerves, were almost entirely subservient to muscular movement ; and the same had been observed of the fibres proceeding from the small root of the fifth pair, before Sir C. Bell experimentally determined the double function of the division of that nerve into which alone it enters. Again, where a nerve passes through the muscles, with little or no ramification among them, and proceeds to a cutaneous or mucous surface, on which its branches are minutely distributed, there is equal reason to believe that it is of a sensory, or rather of an afferent, character. In this manner Willis came to the conclusion that the fifth pair of cranial nerves differed from those previously mentioned, in being partly sensory. Further, where a nerve is *entirely* distributed upon a surface adapted to receive impressions of a *special* kind, as that of the Schneiderian membrane, the retina, or the membrane lining the internal ear, it may be inferred that it is not capable of transmitting any other kind of impressions; for experiment has shown that the *special sensory* nerves do not possess common sensibility. The case is different, however, in regard to the sense of taste, which originates in impressions not far removed from those of ordinary touch ; and it is probable that the same nerves minister to both. Anatomical evidence of this kind is valuable also, not only in reference to the functions of a principal trunk, but even as to those of its several branches, which, in some instances, differ considerably. Thus, some of the branches of the par vagum are especially motor, and others almost exclusively afferent; and anatomical examination, carefully prosecuted, not only assigns the reasons for these functions, when ascertained, but is almost in itself sufficient to determine them. Thus the superior laryngeal nerve is distributed almost entirely upon the mucous surface of the larynx, the only muscle it supplies being the crico-thyroid ; whilst the inferior laryngeal or recurrent is almost exclusively distributed to the muscles. From this we should infer that the former is an afferent, and the latter an efferent, nerve ; and experimental inquiries (hereafter to be detailed)

fully confirm this view. In like manner it may be shown that the glosso-pharyngeal is an afferent nerve, since it is distributed to the *surface* of the tongue and pharynx, and not to the muscles of those parts ; whilst the pharyngeal branches of the par vagum are chiefly, if not entirely, motor. Lower down, however, the branches of the glosso-pharyngeal cease, and the œsophageal branches of the par vagum are distributed both to the mucous surface and to the muscles ; from which it may be inferred that they are both afferent and motor—a deduction which experiment confirms.

We perceive, therefore, that much knowledge of the function of a nerve may be obtained from the attentive study of its ultimate distribution : but it is necessary that this should be very carefully ascertained before it is made to serve as the foundation for physiological inferences. As an example of former errors in this respect, may be mentioned the description of the portio dura of the seventh, at first given by Sir C. Bell: he stated it to be distributed to the skin as well as to the muscles of the face, and evidently regarded it as in part an afferent nerve, conveying respiratory impressions as well as motions. In the same manner, from inaccurate observation of the ultimate distribution of the superior laryngeal nerve, it was long regarded as that which stimulated to action the constrictors of the glottis. But the knowledge obtained by such anatomical examinations alone is of a very general kind ; and requires to be made particular,—to be corrected and modified,—by other sources of information. One of these relates to the connection of the trunks with the central organs. The evidence derived from this source, however, is seldom of a very definite character ; and, in fact, the functions of particular divisions of the nervous centres have been hitherto rather judged of by those of the nerves with which they are connected, than the latter have been determined by the former. Still, this kind of examination is not without its use, where there is reason to believe that a particular tract of fibrous structure has a certain function, and the office of a nerve · whose roots terminate in it is doubtful. Here again, however, very minute and accurate examination is necessary before any sound physiological inferences can be drawn from facts of this description ; and many instances might be adduced to show that the real connections of nerves and nervous centres are often very different from their apparent ones.

Experimental inquiries into the functions of particular nerves are also liable to give fallacious results, unless they are prosecuted with a full knowledge of all the precautions necessary to insure success. Some of these will be here explained. Suppose that, upon

irritating the trunk of a nerve, whilst still in connection with its centre, muscular movements are excited; it must not be hence concluded that the nerve is an efferent one, for it may have no *directly* motor powers. The next step would be to divide the trunk, and to irritate each of the cut extremities. If, upon irritating the end separated from the centre, muscular contractions are produced, it may be safely inferred that the nerve is, in part at least, of an efferent character. Should no such result follow, this would be doubtful. If, on the other hand, muscular movement should be produced by irritating the extremity nearest the centre, it will then be evident that it is occasioned by an impression conveyed *towards* the centre by *this* trunk, and propagated to the muscles by some other; in other words, to use the language of Dr. M. Hall, this nerve is an excitor of motion, not a direct motor nerve. The glosso-pharyngeal nerve has been satisfactorily determined to be a purely afferent nerve by experiments of this kind performed by Dr. J. Reid.

It is from the want of a proper mode of experimenting that the functions of the *posterior* roots of the spinal nerves have been regarded as in any degree motor. If they be irritated, without division of either root, motions are often excited; but if they be divided, and their separated trunks be then irritated, no motions ensue; nor are any movements produced by irritation of the roots in connection with the spinal cord, if the *anterior* roots have been divided. Hence it appears that the motor powers of these fibres are not direct, but that they convey an impression to the centre, which is reflected to the muscles through the anterior roots. Another source of fallacy is to be guarded against, arising from the communication of a nerve, in its course, of properties it did not possess at its root, by inosculation with another nerve. Of this many instances will hereafter present themselves.

The same difficulties do not attend the determination of the *sensory* properties of nerves. If, when the trunk of a nerve be pricked or pinched, the animal exhibits signs of pain, it may be concluded that the nerve is sensible to ordinary impressions at its peripheral extremity. But not unfrequently this sensibility is derived by inosculation with another nerve, as is the case with the portio dura, which is sensory after it has passed through the parotid gland, having received there a twig from the fifth pair. A similar inosculation explains the apparent sensibility of the *anterior* roots of the spinal nerves. If these be irritated, the animal usually gives signs of uneasiness; but if they be divided, and the cut ends nearest the centre be irritated, none are exhibited; whilst they are still shown, when the farther ends are irritated, but not if the posterior roots are divided. This is explained by the fact that, from the point of junction of the two roots, sensory fibres derived from the posterior root pass backwards (or towards the centre) in the anterior; and thus its apparent sensory endowments are entirely dependent upon its connection with the posterior column of the spinal cord, through the posterior roots.

The fallacies to which all experiments upon the nerves are subject, arising from the partial loss of their powers of receiving and conveying impressions, and of exciting the muscles to action, after death, are too obvious to require particular mention here; yet they are frequently overlooked. Of a similar description are those arising from severe disturbance of the system, in consequence of operations, which also have not been enough regarded by experimenters.

Nature of the changes in the nervous system.—Of the actual nature of the changes by which impressions are received upon the peripheral origins of the afferent nerves, or communicated to the central origins of the motor, and are conducted along each to their opposite extremities, physiologists have no certain knowledge. That they are electrical has been, and still continues to be, a favourite theory with some : and that there is a great *analogy* between the propagation of nervous and that of electrical influence cannot be denied. But the reasons in favour of their *identity* are not greater than those which might be adduced to prove that nervous influence is identical with other physical forces; since mechanical and chemical stimulation will, equally with electricity, imitate to a certain extent the natural changes in this system. On the other hand, there are many valid reasons against such a supposition; of which one is, that by putting a ligature round a trunk, its functions as a conductor of nervous influence are paralysed, whilst it is still capable of conveying electricity. The various fibrils, too, are not as completely insulated from each other in regard to the passage of electricity, as we know them to be in respect to nervous agency. To the influence (whatever its nature may be) which the nerves convey, the term *vis nervosa* has been provisionally applied; and it is convenient to employ a term of this nature, when the laws according to which it operates are being specified. It must be remembered, however, that nothing is really gained by the use of such a term, which resembles one of the unknown quantities in algebra. It is quite possible that the changes in the afferent nerves may differ from those that take place in the efferent; and that the changes which convey some kinds of impressions through the former may differ from those concerned in others. No real progress is made, therefore, by attributing any phenomena of the nervous

system to the vis nervosa ; any more than
by referring the various material changes in
the organism to the operation of the *vital
principle*.   The laws according to which
these changes take place are, however,
legitimate subjects for physiological inves-
tigation.   Those regulating the propagation
of nervous agency may be briefly stated as
follows.   They evidently result from the
facts already mentioned respecting the
isolated character of each fibril, and the
identity of its endowments through its whole
course.   They are here stated, with some
modification, in the language of Müller.

1. When the whole trunk of a sensory
nerve is irritated, a sensation is produced,
which is referred by the mind to the parts
to which its branches are ultimately dis-
tributed ; and if only part of the trunk be
irritated, the sensation will be referred to
those parts only supplied by the fibrils it
contains.   This is evidently caused by the
production of a change in the sensorium,
which corresponds with that which would
have been transmitted from the peripheral
origins of the nerves, had the impression been
made upon them.   This change only requires
the integrity of the afferent trunk between
the point irritated and the sensorium ; and
is not at all dependent upon the state of the
extremity to which the sensations are re-
ferred.   This may have been paralysed by
the division of the nerve ; or altogether
separated, as in amputation ; or the relative
position of its parts may have been changed.
It results from the foregoing, that, when
different parts of the thickness of the same
trunk are separately subjected to irritation,
the sensations are successively referred to
the several parts supplied by these divisions.
This may be easily shown by compressing
the ulnar nerve, in different directions,
where it passes at the inner side of the elbow-
joint.

2. The sensation produced by irritation
of a branch of a nerve is confined to the
parts to which that branch is distributed, and
does not affect the branches which come off
from the nerve higher up.   The rationale of
this law is at once understood ; but it should
be mentioned that there are certain conditions
in which the irritation of a single nerve will
give rise to sensations over a great extent of
the body.   This is due, however, to a par-
ticular state of the central organs ; and not
to any direct communication among the
sensory fibres.

3. The motor influence is propagated only
in a centrifugal direction, never in a retro-
grade course.   It may originate in a spon-
taneous change in the central organs : or it
may be excited by an impression conveyed
to them by afferent nerves ; but in both
cases its law is the same.

4. When the whole trunk of a motor
nerve is irritated, the muscles which it sup-

plies are caused to contract ; and when only
a part of the trunk or a branch is irritated,
the contraction is produced only in the
muscles which receive their nervous fibres
from it.   This contraction evidently results
from the similarity between the effect of an
artificial stimulus applied to the trunk in its
course, and that of the change in the central
organs by which the vis nervosa is ordinarily
propagated.   In this instance, as in the
other, there is no lateral communication
between the fibrils.

ARSENIC IN SULPHURIC ACID.

To the Editor of the Medical Gazette.

Sir,

A MEDICAL friend of mine yesterday
pointed out to me a letter, dated the
3d instant, in the MEDICAL GAZETTE of
Friday last (Feb. 5), by Mr. G. O. Rees ;
wherein that gentleman announces the
fact of the sulphuric acid of commerce
being contaminated with arsenic.   He
states that the proportion of oxide of
arsenic which he has found in twenty
fluid ounces of the acid, procured from
an operative chemist in London, is
22·58 grains, and that he has found
even a greater proportion in some ob-
tained from the Apothecaries' Hall.   I
beg to remark, that this fact of the
contamination of the sulphuric acid
obtained by the combustion of the sul-
phur of pyrites instead of Sicilian sul-
phur, though, as would be inferred
from Mr. Rees's letter, not generally
known about London, yet has been
known for many months by the more
intelligent of the manufacturing che-
mists of this neighbourhood ; and that
in the early part of last year, Mr. H.
Blair, an extensive manufacturer of the
acid, obtained, in conjunction with
myself, a patent for improvements in
the manufacture of sulphuric acid, part
of which improvements consist in the
separating, in the course of manufac-
ture, the arsenic contained in pyrites
sulphuric acid.   Mr. Blair, at his Works,
adopts the process alluded to for sepa-
rating the arsenic, though less exten-
sively than he intends to do as soon as
he has made more extensive arrange-
ments : it is effectual in making the
acid sufficiently pure for the several
purposes to which it is applied in the
arts and manufactures, in many of
which the unpurified acid cannot be
advantageously used.

The smallest proportion of oxide of

arsenic which I have found in twenty fluid ounces of the unpurified pyrites acid is 35½ grains. The proportion is often considerably more.

An instance occurred a few months ago, not far from here, of an operative having nearly lost his life in consequence of the inhalation of arseniuretted hydrogen produced in the manufacture of hydrochloric acid, by the diluted unpurified pyrites sulphuric acid acting upon the iron retort employed.

In conclusion I may add, that I have had a paper, dated Jan. 25, 1841, read at a meeting of the Philosophical Society of Manchester, "On detecting the Presence of Arsenic, particularly in reference to the employment of Marsh's test;" in the course of which I mentioned the great necessity of minutely examining the sulphuric acid used, on account of that of commerce being strongly impregnated with arsenic. I also mentioned the necessity of examining any hydrochloric and nitric acid which might be used, these being also liable to be impregnated with arsenic.—I am, sir,

Your obedient servant,
HENRY HOUGH WATSON,
Consulting Chemist.

Bolton-le-Moors, Feb. 10, 1841.

P.S.—Since writing the above I have found 1000 grains by weight, of a sample of commercial sulphuric acid, specific gravity 1·845, to contain 5½ grains of oxide of arsenic. And as the weight of 20 fluid ounces of acid of this specific gravity is 17712 grains, it follows that the weight of oxide of arsenic in the same is 97·416 grains.

Feb. 15, 1841.

KING'S COLLEGE HOSPITAL
REPORT FOR 1840.

By Wm. Augustus Guy, M.B. Cantab.

Professor of Forensic Medicine, King's College, London, and Assistant-Physician to the King's College Hospital.

[*For the Medical Gazette.*]

In order that the facts contained in this report may be received at their true value, it will be necessary to make a few remarks by way of preface. The hospital was opened for the admission of patients April 15, 1840; and the report embraces the period which elapsed from that date to December 31—a period of

upwards of eight months. The facts are taken from the tabular forms prepared for the registry both of the in and out-patients. These forms consist of the following headings :—Name ; Residence ; Parish ; By whom recommended ; Medical Attendant ; Number of Ward ; Age ; Married or Single ; Occupation; Disease; Assigned Cause; Date of Discharge ; Event of Disease ; with a column of remarks. The same form has been made to serve for all the patients.

The record of the in-patients, when they amount to a sufficient number, will furnish many interesting and useful particulars illustrative of the prevalence of different diseases, their nature, and their fatality ; that of the out-patients must necessarily be incomplete, as the event of the disease can rarely be known. The age, sex, occupation, and disease of the out-patients, are the only points which can be correctly and uniformly ascertained ; but these alone, after a term of years, may be expected to yield much interesting information. The form for the out-patients is filled up at the first visit of each patient by the clerk for the out-patient physician or surgeon : the in-patient register is kept by the clinical clerk, who fills up the tabular form from the case books. Urgent cases are registered by the resident medical officers.

Those who have had any experience of hospital records will be prepared to expect the occasional omission of cases from registers kept by more than one individual; indeed it would be unreasonable to expect an equal degree of care and accuracy from all who are employed in keeping such records, and much is accomplished if the greater part of the cases are accurately registered. By far the majority of the cases have been entered on our books, and are available for statistical purposes. Wherever any doubt has existed as to the real name of a disease, the case has been omitted from the report. I must also add that care has been taken not to enter the same patient twice, in consequence of his having been transferred from the in-patients to the out-patients, or from the out-patients to the wards of the hospital. The report, therefore, merely states the diseases or accidents occurring among the patients entered on the register, and not the total number of cases under treatment.

In preparing the report, I have had before me Dr. Willan's reports of the Carey Street Dispensary, published quarterly in the Edinburgh Medical and Surgical Journal, the report of the Registrar-General, and Major Tullock's army returns. It will be seen that I have not followed any of these authorities implicitly, though I have derived some aid from each of them. I have not thought it necessary to state my reasons for the arrangement I have adopted, nor to defend the mixed nomenclature which I have used. Both the one and the other admit of much improvement, and will be more or less modified in future returns. The diseases are thrown into groups, which are named in the general abstract. This is done rather for the sake of convenience than because the diseases thus thrown together have any very close connection. A sufficiently minute subdivision has been adopted, in order that the report may, without much difficulty, be compared with other similar returns.

There now only remains to make one or two short observations on some of the diseases, or groups of diseases, contained in the table.

Febris continua.—The febrile affections included under this head were, for the most part, of a mild character: a few only were admitted into the house, and the rest were treated as out-patients. A small proportion might be correctly designated by the term typhus.

Febris infantum remittens —This head includes all the febrile affections of children dependent on functional disorders of the stomach and bowels, and contains some cases entered under the title marasmus. The remittent character of the fever is marked in different cases with different degrees of distinctness, and sometimes assumes a continued form. Febris infantum might be preferable in some cases; but I have followed the example of Bateman in using the term febris infantum remittens.

Muscular rheumatism.—This head includes many cases of muscular pains confined to one part of the body. Females are peculiarly subject to such local affections; and hence the larger number of cases of muscular rheumatism occurring in that sex.

Articular rheumatism. This head, too, includes other cases besides the so-called acute rheumatism, or rheumatic fever, and there is no doubt that some of them might have been, almost with equal propriety, classed with gout.

Melancholia includes a case of suicidal monomania, first treated as an out-patient, and subsequently admitted into the hospital for an attempt to poison himself by laudanum.

Phthisis. — This head presents so marked an excess of males over females, that there is room to doubt whether or not the disease has been correctly entered. As by far the majority of these cases were out-patients, the correctness of the diagnosis could not be tested by the result; and the greater facility of examining the chest of males leads to many cases of phthisis being detected in the male which may possibly have been entered as bronchitis in the female. As, however, the excess of cases of bronchitis in the female is considerably less than the excess of cases of phthisis in the male, and as I have very little doubt of the correctness of my diagnosis in the majority of the cases, I cannot help regarding the number stated as a near approximation to the true proportion.

Dyspepsia and gastritis mucosa. — The term dyspepsia embraces many different forms of chronic affection of the stomach : that of gastritis mucosa is restricted to inflammation of the mucous membrane of the stomach, as determined by pain of the epigastrium, increased by pressure ; pain immediately after eating, accompanied with nausea or vomiting ; and a red tongue, or tongue furred in the centre, and red at the tip and edges. These cases are readily cured by a strict farinaceous diet, and gentle aperient medicines, if the bowels require them. More active treatment is rarely necessary.

Gastro-enteritis mucosa — The so-called English cholera ; a disease which commonly yields to the same simple treatment as the last named disorder.

Diarrhœa.—This includes some cases which might more aptly be termed enteritis mucosa. When recent it rarely requires any treatment beyond a regulation of the diet, though it is usual to administer purgatives, or astringents, or both. In the report of the Registrar-General, diarrhœa is classed with the epidemic, endemic, and contagious diseases.

The general headings, diseases of the heart, diseases of the skin, &c. apply to

cases in which the precise seat or name of the disease was not registered.

Imperfect as this and all similar reports must be, in the present state of our knowledge, it may possibly supply some data which may be advantageously compared with other returns of a similar kind. There is at present a great want of information as to the prevalence of those diseases which do not terminate fatally; and this information can only be supplied from registries of the out-patients as well as the in-patients of our hospitals and dispensaries. If this report, then, have no other value than as an example, it will not be thrown away. The proper title of the report will be the following:—

Analysis of 4250 Registered Cases of Disease, treated at the King's College Hospital, from April 15th to December 31st, 1840.

R E M A R K S

ON THE

PHYSIOLOGY OF THE ORBITAL OBLIQUE MUSCLES, AND ON STRABISMUS.

By Edward Hocken, M.D.

(For the London Medical Gazette.)

The diversity and direct contradiction which exists in the received opinions concerning the normal functions of the oblique muscles, incontestibly prove that but little sound discretion has been employed in this investigation, the results of all of which have been most unsatisfactory. Many physiologists formerly supposed that the superior oblique turned the eyeball upwards: hence the absurd appellation of musculus patheticus which was given it. The principal opinions which are at present extant are, that the superior turns the globe downwards and outwards, whilst the inferior directs it upwards and inwards; second. Mr. Duffin tells us that the superior rotates it downwards and inwards, the inferior in the contrary direction, viz. upwards and outwards: in his book on the subject he says, " towards the nasal canthus, and upwards:" third. Mr. Walker asserts that the superior oblique turns the axis of the eye, that is to say, the pupil, directly inwards; the inferior in the precisely opposite direction, and likewise turns it inwards ; fourth, some learned individuals imagine that the superior turns the eye upwards and inwards ; and so divide, or attempt to divide, it in convergent strabismus, when the eyeball is directed upwards and inwards !

I shall endeavour to overturn the whole of these fanciful theories and statements, giving, at the same time, what I believe to be their true physiology, based on the laws of muscular action and direct experiment.

1st, That muscles can only act in the direction of their fibres, or of that of their tendons, as modified by a pulley.

2d, That when acting over a sphere, or the segment of a sphere to which they are attached, the spherical body itself will receive a rotatory motion in compliance with the foregoing law: the fixed attachments being approximated, and the sphere rotated, to the extent and in the direction allowed by such connections.

3d. That a corresponding and antagonizing power, acting in the opposite direction exactly, would rotate such a body back again through the same arch, and carry it (supposing its sphere of action similar) to a corresponding distance in the opposite course.

4th. That both forces acting simultaneously would exactly antagonize each other, giving rise to a new force, the medium of the two, and thus causing traction in the intermediate direction of the two previously existing powers.

On these foundations I will base the following deductions and experiments. The tendon of the superior oblique runs obliquely backwards and outwards in the orbit, from its cartilagineous pulley in the frontal bone, to the junction of the posterior and middle thirds of the sclerotica, and curved in correspondence to the convexity of the eyeball. The inferior arises from the superior maxillary directly opposite to the pulley of the superior, and also passes obliquely dorsal and lateral to the junction of the posterior and middle thirds of the sclerotica, adapted in its curve to the under and lateral surfaces of the globe, and separated by rather more than half an inch from the tendon of the superior : it is in this interval that the ciliary nerves perforate the tunica sclerotica. Hence we shall see that the posterior, superior, and outer surface of the sclerotica, will be approximated to the orbital edge of the frontal bone, close to the inner canthus of the eye, by contraction of the superior oblique; and that the posterior, inferior, and outer part, will be drawn towards the orbital edge of the superior maxilla, opposite to the pulley of the superior oblique, by contraction of the inferior oblique muscle; the curved conditions of the tendons imparting a corresponding rotatory motion to the sphere over which they act.

The motions thus imparted to the

eyeball and pupil are the following, when no counteracting force is in existence :—The superior oblique rotates the globe obliquely downwards, inwards, and then outwards, bringing the posterior and outer part inwards and superficially, and carrying the lower and outer part upwards and more deeply in the orbit. In this course the pupil is carried, from its natural position in the centre of the orbit, slightly nearer the nasal side, in a curved direction downwards, inwards, and finally outwards. The inferior oblique rotates the globe from the position in which it was left by the superior, upwards, inwards, and then outwards; or, if it commence whilst the pupil retains its normal axis, in a curved direction upwards, inwards, and outwards, and *vice versâ ;* the pupil, during this motion, being directed in a similar curved manner; the final action of each being to turn the globe and pupil outwards, the superior downwards, the inferior upwards.

The following experiments may serve to prove that such is in truth the real action of these muscles separately *, bearing in mind the laws of muscular action with which I commenced this paper.

Exp. 1.—In a recent subject, expose the tendon of the superior oblique just after it has passed through its cartilaginous pulley in the frontal bone, without disturbing the situation of the globe ; or, to ensure accuracy, let the muscle be dissected just before its tendon enters the pulley, and traction be employed in the natural direction. During the continuance of this force we find that the eyeball is rotated on an oblique axis, and that the globe and pupil become directed as previously described, being finally turned downwards and outwards. The same experiment may also be performed on the inferior oblique. The best mode of accomplishing these experiments is the following : feel for the trochlea of the superior oblique, immediately internal to the super-orbital notch or foramen, and make an oblique incision over its course of about an inch in

extent, and then carefully divide the cellular tissue, muscular fibres, and fibrous expansion of the tarsal cartilages running to the orbital edge ; and thus we bring into view the tendon of the superior oblique running outwards and backwards, which may be readily taken up by a convenient hook, and thus traction exerted on the globe. If it be taken up internal to the pulley, depress the eye-ball, and follow the muscle slightly backwards within the orbit lying superior to the rectus superior ; a hook, with its point directed from below upward, and from without inwards, will easily include its tendon.

Exp. 2.—Take an apple or an orange, and cut off a thin slice from its anterior surface, holding the portion corresponding to the eye of the fruit forwards; then place a tack, with a circular flat head, in the centre, but rather nearer its inner than outer side, and affix to the junction of the posterior and middle thirds of its circumference two narrow slips of paper or ribbon, placed exactly in the oblique course held by the two oblique muscles, alternately making traction with each, and observe the direction given to the fruit, and to the circular head of the tack which corresponds to the pupil : it will be that oblique rotation which I have already described.

Exp. 3.—We can even put the obliqui in action, and observe the effects, in our own persons : close one eye, and steadily regard some object placed immediately in front, with the other ; we find that we possess the power of rotating the eye downwards, inwards, and then outwards ; regularly so at first, but after the organ has reached the centre the rectus internus interferes, and then it is carried suddenly downwards and outwards : by a counteraction it is carried backwards, performing an oblique rotation upwards, inwards, and then upwards and outwards. No such rotation can take place on the outer side of the eye, in any direction : the eye-ball stops abruptly when directed upwards and outwards, at the outer canthus, or downwards and outwards.

We will now consider the combined operation of these muscles. If both act simultaneously no rotation can occur, but the globe will be drawn in the medium direction of the two opposing forces : hence it will be drawn forwards.

* The experiments performed recently on living dogs, &c. to determine the normal actions of these muscles, are, I believe, quite useless, from the differences which exist in their anatomy, &c. We even find Mr. Dalrin remarking that, " So far as may be inferred from the foregoing experiments, very little of a conclusive nature can be deduced," in answer to his own question of the uses of the superior.

and compressed inwards, against the os planum of the ethmoid, producing elongation of the axis of the globe in proportion to the violence or force exerted by the obliqui. Do we not produce this very action when we endeavour to distinguish distant objects? I am sure that any one will be conscious that it is so, if he make the effort in his own person. We are conscious, during this effort, that the eyeball is thrust forwards, and at the same time compressed. Their combined action is thus obviously to antagonize the recti muscles, since the obliqui elongate the axis of the eye-ball, draw it inwards, and thrust it forwards, altering the figure of the globe to adapt it in viewing distant objects; whilst, on the contrary, the combined action of the recti is to retract the eye-ball within the orbit, and to shorten its antero-posterior axis, adapting it as an optical instrument to view near bodies. In this case, as in all other similar instances, if we weaken or destroy one force, the antagonizing power will gain the mastery, and hence the eye would project unnaturally from division of the recti, or morbidly increased action in the obliqui;[*] or on the contrary be retracted abnormally from section or paralysis of these latter muscles, or increased action of the recti.

It is well known that certain occupations and employments will eventually modify the usual distance of correct vision; and this is effected by an alteration in the balance of these antagonizing muscles, alteration in the shape of the globe from their habitual action, and probably some adaptation of the retinal function to meet existing circumstances: thus the sailor acquires presbyopic or long vision, by the constant habit of eagerly searching the distance for objects which he either desires or dreads; the mechanic becomes myopic, or near-sighted, from the minute and careful vision which accuracy of adaptation, and perfection in finish, require in operating on small and delicate bodies or substances.

Pathology of the obliqui in strabismus†. —If a squinting eye be unusually pro-

minent, it follows as a matter of induction that the obliqui are overpowering the recti muscles, provided that no mechanical cause is producing exophthalmos, or the globe is not enlarged from hydrophthalmia[*]. But this loss of balance in their actions may be occasioned either by deficient power in the recti, or excessive in the obliqui, or, if the globe be obliquely prominent, by the excessive action of only one of the latter muscles: hence follows the question, is it ever necessary to divide one or both oblique muscles under these circumstances? It may be so, but in all the cases that I have myself seen, or heard of from friends, no such necessity existed: it might, however, be employed should the organ remain prominent after division of the appropriate rectus; at all events it would not be quite rational to divide the superior oblique when the eye is turned upwards and inwards.

Few, I should imagine, would wish to contend with Mr. Elliot for the merit of having first introduced the double operation in all cases of strabismus, whether single or double; yet, strange to say, both Messrs. Guthrie and Duffin have asserted their claims to what either of these gentlemen would avoid in practice. The double operation is applicable only to four forms: first, in those cases where the opposite eye becomes considerably inverted on covering it; secondly, in habitually double strabismus; thirdly, where the strabismus is transferred to the originally sound organ, although removed at the time of the operation†; fourthly, where

---

contains many valuable facts, has made perfectly free with the author's ideas on the etiology, pathology, and form; and this without one word of acknowledgment. In many cases he quoted nearly word for word: for instance, "An ulcer of the cornea may be the first originating cause of strabismus, &c. &c., the diagnosis of double squint, &c.; and yet calmly palms them off as "the result of his own original experience." My papers were published in September and November. By the by, Dr. Watson, in his Lectures on Medicine, mentions amaurosis as originating from hysteria, and gives a case in illustration: the only mention of his source of information is contained in the following passage:— "Amaurosis has been spoken of as arising from hysteria." The author was the first to mention and describe such a symptom: he detailed a case in the Lancet for Nov. 1839, and treated of the symptoms, diagnosis, prognosis, &c. of its chronic variety, in the same journal, for August 1840.

* These may always be diagnosticated by their own peculiar symptoms.

† Vide author's paper, in MED. GAZ. Nov. 13, 1840, vol. i. 1840-1, p. 285.

---

* I am speaking of division, &c. of both muscles; one would cause the globe to project obliquely: hence the explanation of the projection of the eye-ball from the division of one muscle in Mr. Duffin's experiments on dogs.

† Mr. Hall, in his paper on Strabismus, in the MEDICAL GAZETTE for Jan. 23d, which

some inversion of the squinting eye remains after complete division of every mechanical inverting cause ; becoming straight by excluding the other from light.

But there is one practical deduction at which I have arrived which I should wish to enforce, namely, that where sufficient evidence of the necessity for a double is not afforded at the time of its single performance, and yet the strabismus returns in the opposite eye, little time should be lost in operating on this also: for if a considerable interval be allowed to intervene, the habitual consent of mutual action is the condition of squinting ; and on coming to operate on the secondarily affected eye, the previously deranged organ will be found to be in the same relation to it which the originally healthy organ held to the originally squinting eye ; viz. it will be inverted, or prevent the complete rectification of its fellow, and thus again call for a double operation. For the laws regulating the mutation of strabismus, *vide* the author's paper in the MEDICAL GAZETTE, already referred to.

No doubt can now exist that fibres of condensed cellular tissue occasionally prevent the complete success of the division of the rectus tendon, yet I have no doubt that in many of the cases thus circumstanced the connecting medium would be found to be an undivided portion of the tunica albuginea, which, in fact, is but condensed cellular tissue, uniting the opposed edges of the four recti tendons, and not the submuscular cellular tissue itself. This connecting medium passes in the form of arches from one tendon to the other, their concavity being directed backwards, and thus a small portion of the superior or inferior cornu of the arch being left undivided, would be drawn backwards by the action of the muscle, and simulate the subtendinous or muscular tissue.

Strabismus may be simulated by opacities of the outer or inner circumference of the cornea*. The eyeball is in truth holding its proper axis, and the pupil its normal situation, but a portion of the outer or inner circumference of the cornea is occluded by a dense opacity, giving rise to the appearance of either an external or an internal squint, since the apparent (transparent) portion of the cornea seems to be turned either too much inwards, or too much outwards, from the opaque part not being readily distinguishable from the white of the eye; and hence the whole globe appears to be affected with divergent or convergent strabismus.

Some months since I had a modification of Mr. Guthrie's knife made for my own use—a similarly-shaped blade, but with a small, flat, and blunt point, which would do away with the necessity of a director. It is to be introduced beneath the tendon after division of the superjacent conjunctiva, whilst its fine sharp edge, continued to the very point, effectually divides every fibre under which it is passed : with it, therefore, there would be no danger of wounding the sclerotica.   The conjunctiva must be taken up and divided by a sharp knife or scissors.

Exeter, Feb. 1841.

USE OF SECALE CORNUTUM.

To the Editor of the Medical Gazette.
SIR,

SHOULD you deem the following case of sufficient interest and importance to the medical public to merit a place in your journal, its insertion will oblige
<div align="right">Your obedient servant,
JOSEPH HODGSON.</div>

Spitalfields, Feb. 4, 1841.

Mrs. M., residing at Salvador House, Bishopsgate Street, of fair complexion, and other general characteristics of the strumous diathesis, has been married eight years, and is now 34 years of age. Within twelve months of her marriage, at the full period of gestation, after a tedious labour of forty-eight hours, she was delivered of a living female child. Two years subsequently she miscarried at the fourth month; and then, after eighteen months, gave birth to a stillborn child at the seventh month.

On the 17th of May, 1839, she came under my observation, being again threatened with premature labour at the seventh month, which was averted by placing her under favourable circumstances ; and her pregnancy continued to the eighth month, when labour came on, and after seven hours

---

* Mr. Wormald, I believe, first noticed this simulated strabismus.

the breech descended, with the abdomen towards the sacrum. But notwithstanding the chin was depressed upon the chest, I could not succeed in extracting the head without lessening it by the operation of craniotomy.

Taking all the circumstances into consideration, and being of opinion that the pelvis had contracted in size, I desired my patient, the next time she became pregnant, to inform me at the seventh month, in order that I might have an opportunity of bringing on labour at that time, as the only likely means of insuring the birth of a living child. Accordingly, in the middle of November, she informed me that she was then pregnant, and could trace her pregnancy from the middle of June. She continued in very good health during the remainder of the time, up to the 16th of January last, when I found her in good spirits.

Noon, January 16th.—I prescribed pulv. secale cornut. grs. x. 4tis. horis, to six doses. Visited her at nine o'clock in the evening, one hour after taking the third dose. She stated that every dose produced pains in the back, which continued about half an hour, or from that to three quarters.

17th, 10 A. M.—She had taken the sixth and last dose of the medicine, which at that time was causing her pain; and on making an examination I found the os uteri softened, and readily admitting one finger, and then a second, between which I passed the stilet of the female catheter, and ruptured the membranes. Presentation natural, and the child's movements distinctly felt. I then returned home, requesting to be called when pains came on.

5 P.M.—Seven hours from the time the membranes were ruptured, and os uteri fully dilated, the pains became regular; but having waited until half-past seven, and being quite satisfied that they were insufficient to complete the delivery, and also fearing the child would be destroyed by the pressure of the uterus, I mixed pulv. secale cornut. ʒj. in aqua ʒiv.; one third to be given every ten minutes until the uterus acted rigorously: it was not before the third dose had been exhibited that any increase of uterine action took place, and then, at the end of an hour, a female child was expelled, which, with the mother, is now doing well.

REMARKS.—The exhibition of the secale cornutum previously to rupturing the membranes by mechanical means, appears to soften the os uteri, and generally to stimulate the action of that organ: and the practice accords with that recommended by Dr. F. H. Ramsbotham, in his valuable work now in the course of publication. The novel feature in this case is the renewed administration of the secale after the evacuation of the liquor amnii, when the uterus was powerfully contracting, but its expulsive action feeble. To such administration I attribute the preservation of the life of the infant—an opinion in which Dr. Ramsbotham fully concurs.

RARE MALFORMATION OF THE HEART.

To the Editor of the Medical Gazette.

Sir,

Should the following be deemed of sufficient interest to merit publication, you will oblige me by giving it insertion in your journal.—I am, sir,

Your obedient servant,
ALBERT NAPPER.

Guildford, Feb. 1, 1841.

A. W., ætat. five years ten months, a lively, intelligent boy, but rather short of his age. Till he was six months old his mother observed nothing unusual in him, except that his head was rather larger than natural. About that time he received a fall, after which he was affected with cyanosis, and was from that time always subject to dyspnœa, and palpitations of the heart, greatly increased by exertion and mental emotions, as was also the purple hue. He had had measles, hooping-cough, and small-pox: the latter very severely.

A short time since I was requested to see him; when he complained of pain in the head, accompanied with drowsiness, pyrexia, and other symptoms of acute hydrocephalus, which quickly carried him off. On examination of the brain, extensive ramollissement of the right hemisphere, and serous effusion, was found to exist.

Before describing the formation of the heart, which is one of those singular instances of monstrosity but seldom displayed by nature, I must mention a peculiarity, doubtless in connection

with it, exhibited by the lungs, which were extremely small and flaccid, and of a bright crimson throughout, but evidently not the effect of inflammatory action, for no other indication of inflammation was present, nor was there any thing during life which at all led to a suspicion of its existence; on the contrary, in expressing a wish to be carried down stairs, he spoke so loud and distinctly, that his mother, who was below, heard every word. His wish was complied with, and within three minutes he was a corpse.

On opening the pericardium, the heart was seen of normal dimensions, with both ventricles contracted, and *both* auricles extremely congested with dark-coloured blood. The parietes were of usual thickness, and the valves natural. In the situation of the foramen ovale was an opening, about half an inch in length and a line in breadth, with a band of fibres, extending across the centre, attached to either lip. Judging from the valvular form of the opening, it is probable that no blood passed through it, except perhaps during the impetus of the circulation from excitement. But another and more remarkable deviation was exhibited in the aorta. The orifice, instead of its usual commencement from the left ventricle, was placed directly over the septum ventriculorum, communicating *equally* with *both* ventricles. The ventricular orifice of the pulmonary artery was extremely contracted, scarcely admitting the large end of a common silver blow-pipe. At a short distance from the origin, the artery became much larger, but had more the appearance of a vein. The sigmoid valves were exceedingly small, but otherwise perfect. From the situation and contracted orifice of this vessel, and from the ready passage of the blood into the aorta, it is evident that but a very small portion of blood could have passed to the lungs; which may account for their being so much below the usual size. Considering the very small quantity of arterialized blood that could have entered into the circulation, it is surprising that this child should have attained the age of nearly six years, have passed through some of the worst diseases of childhood, and that the functions of the system (excepting those above mentioned) should have been naturally performed.

P.S. — There is a case somewhat similar to the preceding related in the Medico-Chirurgical Review for July, 1831, p. 211.

SOME REMARKS

ON

PNEUMONIA IN CONNECTION WITH, OR AS A CONSEQUENCE OF, SURGICAL OPERATIONS AND INJURIES.*

By J. E. ERICHSEN,

Formerly House-Surgeon to University College Hospital.

[For the Medical Gazette.]

THAT form of pneumonia which occurs in connection with, or as a consequence of, surgical operations and injuries, is, as Sir Charles Bell justly observes, one of those neutral subjects which stands between the provinces of the surgeon and physician, and consequently has received less attention than its frequent occurrence and fatal character entitle it to.

The systematic treatises on surgery with which I am acquainted, are, with few exceptions, silent upon this subject. Some of the older writers, indeed, have noticed that in injuries of the head the lungs occasionally become affected: Morgagni states that Valsalva was induced, by his own observations, to come to this conclusion. In the memoirs of the Académie Royale de Chirurgie cases are mentioned by Quesnay, Bertrandi, and Androuille, of the deposition of pus into the lungs after injuries; but no attention seems to have been paid to inflammation of these organs in similar cases, unless when attended by the formation of abscess. Pott (Chirurgical Works, vol. i. p. 127) relates a case in which a fatal pneumonia followed the operation of the trepan: but he appears to have regarded this as an accidental occurrence, and not as a consequence of the injury of the head.

By the surgical writers of the present day we find that more attention has been paid to this important subject. Dupuytren, in his Leçons Orales, in the article on burns, has pointed out the occurrence of inflammatory affections of the lungs as a consequence of these injuries. Sir Charles Bell, with

* Read before the Medical Society of University College, February 5th, 1841.

that justness of observation which characterizes all his inquiries, enters at some length upon this subject in the third number of his "Surgical Observations," where he devotes one report to the consideration of "Pulmonary diseases in connection with local irritation, and consequent upon wounds and surgical operations." After pointing out the importance of this, and of several other subjects, which it is to be wished were better cultivated, he says, "when I look back on former cases, I cannot resist the belief that I have seen patients cut off after operations by a more sudden and acute attack of inflammation of the lungs;" and again, a little farther on, "but inflammation of the lungs is by far the most frequent cause of death in severe wounds, and especially in compound fractures." He then gives several examples of pneumonia following compound fractures, and amputations after gunshot injury. In the first and second numbers of the same work he relates a case of stricture of the urethra, with abscess in the perineum, and also a case of fracture of a dorsal vertebra, in both of which pneumonia was found after death. Guthrie, in his Treatise on Gun-shot Wounds, (3d edit. p. 257) speaks of pneumonia as a cause of death after operations, more especially secondary amputations: he points out the latent character and obscurity of the symptoms of this form of the disease, which he believes to depend upon a determination to, or irritation in, a particular part; and that in each person the organ that is most predisposed to disease is most likely to be affected; "therefore," he says, "among Englishmen, and in Great Britain, the lungs are most liable to be affected."

Writers on medicine make, as we should expect, but little mention of pneumonia as a consequence of surgical operations and injuries. Dr. Forbes, however, speaks of it in a note appended to his translation of Laennec's work, and Dr. Williams, in his very valuable treatise on diseases of the chest, in the Library of Practical Medicine, enumerates this as one of the varieties of pneumonia.

Under the names of typhoid, bilious, putrid, malignant, scorbutic, erysipelatous, latent, and congestive pneumonia, we find described by various authors, among whom I may enumerate, Hux-

ham (on Fevers, pp. 186-210), Good (Study of Medicine, vol. ii.), Frank (De Cur. Hom. Morb., lib. ii. p. 135), Laennec (3d edit. of Transl., p. 241), Andral (Clinique Médicale), Louis (Recherches, p. 39), Mackintosh (Practice of Medicine), Williams (Cycl. of Practical Medicine, and Library of Medicine, vol. iii. p. 143), Stokes, and Dr. Hudson (Dublin Journal, vol. vii.), a form of this disease which is, I think, analogous to that met with in surgical cases; the difference being rather in the cause that has given rise to the inflammation than in the essential nature of the disease itself.

The observations of Dr. Williams, and of Dr. Hudson, tend to prove that the form of pneumonia usually called typhoid is essentially "a complication of pneumonia, with a superadded passive congestion." "By some unknown cause," says Dr. Williams, "the blood stagnates in particular viscera generally, to some degree, under the influence of gravitation; there is, at the same time, more or less irritation, which may give to the congestion the semblance of inflammation; but neither by the free effusion of plastic lymph, nor by the formation of pus, is a true inflammatory orgasm manifested." That this view of the question is correct, is proved, not merely by the signs and general symptoms, but by the appearance after death. Dr. Williams attributes this stagnation of the blood in particular viscera, either to the altered condition of the blood itself, or of the affected capillaries, or of both. That the proximate cause of that form of the disease which occurs in surgical cases is the same as that of the so-called typhoid pneumonia, cannot, I think, be doubted—the lung, in both cases, being in a state of passive, rather than of active hyperemy. The condition of the system, also, in which typhoid pneumonia is found, is closely allied to that produced by the irritative fever which occurs in patients suffering from severe operations and injuries.

The anatomical characters of these two forms of the disease are also very similar. When the pneumonia is still in the first stage, the part of the lung that is affected will be found of a deep purple, almost black colour; from being gorged with blood it does not collapse as a healthy lung does; it is heavy, and when squeezed comparatively little blood can be forced out,

but a frothy, reddish, turbid serum escapes in considerable quantity ; it still contains air, being crepitous, and floats in water; the tissue of the lung is, in some cases, softened, breaking down readily under the finger into a pulp, having somewhat the appearance of redwine lees; in other instances, however, it is increased in density to a greater degree than mere accumulation of blood would occasion, but is still crepitous. When the disease has advanced to the second stage, to that of hepatization, the tissue of the lung is dense, sinks in water, and does not crepitate. When cut into, the sides of the incisions have a smooth uniform aspect, not granular, as in the active form of pneumonia, but presenting the characters of that variety of the disease described by Dr. Williams as " Intervesicular," which he regards as the result of inflammation confined to the vessels and intervesicular tissues, and which MM. Hourmann and Déchambre have shewn to be very common in the pneumonia of the aged (Archives Générales. 1835).

The causes of pneumonia consequent upon operations and injuries are no doubt those which usually give rise to idiopathic inflammations of the lungs, such as cold, transitions of temperature, damp beds, &c.; but, besides these, there are some circumstances which more especially seem to predispose to this form of the disease ; such as the long confinement of patients in the vitiated and close air of an hospital, especially when the nature of their complaint obliges them to maintain the recumbent position, the depressing effect of profuse discharges, and of the irritation that attends severe injuries and the greater operations. These circumstances tend to exhaust the energy of the nervous system, and thus favour congestions in internal organs; and of these, the lungs, from their vascular and cellular structure, are more liable to be affected. The recumbent position long continued, by a patient in a state of great debility, must mechanically produce congestion of the posterior part of the lungs. We find this congestion occurring in the more depending part of the surface of the body, and we should, therefore, expect to meet with it in so spongy an organ as the lungs.

For the free circulation of the blood through the lungs, it is necessary that the contractility of the right side of the heart be unimpaired, that the respiratory movements continue, and that certain chemical changes take place in that fluid in its passage through the lungs. Now in persons who have been subjected to any of the depressing influences just enumerated, and in whom the energy of the nervous system is consequently much lowered, the contractility of the heart and of the respiratory muscles must necessarily, as well as that of the muscular system generally, be diminished. The congestion of the lungs, already perhaps existing from the position of the patient, will thus be increased by the right side of the heart being less able to propel its blood through these organs, and to overcome the mechanical congestion and distension of the capillaries in their more depending parts. The chemical changes, which are also necessary for the proper circulation of the blood through the lungs, will be arrested proportionably to the degree of congestion of these organs, and to the weakness of the respiratory movements. Thus the respiratory process being interfered with, and the circulation through the lungs being impeded, these viscera will become more and more congested, and, as the vital powers are diminished, the blood, altered probably in its qualities, is brought more under the influence of the laws of gravity, and tends to accumulate in the more depending parts. We can easily understand how an imperfect degree of inflammatory action may be set up in an organ already disposed to it, by the existence of an abnormal quantity of blood in its vessels, more especially in subjects who have been rendered highly irritable, and predisposed to irritative fever, by long suffering and profuse discharge.

Diminished nervous energy, whether arising from the irritation of an operation, from the depressing effect of confinement in a hospital, (and I may mention that Dr. Stokes states typhoid pneumonia to be more common in hospitals than in private practice; and this, no doubt, also holds good with regard to the form of pneumonia following operations and injuries), or profuse suppuration, is, no doubt, one of the chief predisposing causes of this congestive pneumonia. Any circumstance which lowers the energy of the nervous system necessarily causes the respiratory movements to be lessened in acti-

vity in proportion to the loss of that nervous influence which is requisite to maintain them; and thus the due performance of the respiratory changes being interfered with, a tendency to accumulation of blood in the lungs is the consequence. We see this to be the case in the operations of the sedative poisons, and in apoplexy; and can easily understand, as I have already said, how the lung, being already congested, the supervention of any irritation will dispose it to run rapidly into an inflammatory state, generally of a low type, as the powers of the system are below their normal standard. The experiments of Dr. J. Reid* on Section of the Pneumogastrics bear directly on this point. Dr. Reid has shown that that section of both vagi, by interrupting the nervous circle, which is necessary for the proper performance of respiration, diminishes the frequency of the respiratory movements, which become more prolonged and heaving: the blood consequently becomes less perfectly arterialized, and the animal dies of asphyxia. The congestion of the lungs which takes place in these cases is very apt, if the animal live a sufficient length of time, to run on to pneumonia, and even to gangrene of the lung. The morbid appearances found by Dr. Reid, after division of both vagi, were a congested state of the blood-vessels of the lungs, and an effusion of frothy fluid into the bronchi and air cells. In eight out of seventeen cases, in which he experimented, these appearances were strongly marked; and in some parts of the lung the quantity of blood was so great as to render the tissue dense: the more solid parts of the blood appearing to be effused: the degree of congestion varied in different parts of the same lung, but was always greatest where it was most dependent.

In five cases there were distinct evidences of pneumonia. (hepatization?) and in two it had run on to gangrene. Dr. Reid observes that the congested state of the lung is the first departure from a healthy condition, and that the effusion of serum is the consequence of this. He also observes that in fevers he has met with a condition of the lung similar to that which occurs after division of the vagi; this

is doubtless the typhoid form of pneumonia, which so frequently occurs in fevers of a low type where the energy of the nervous system is lowered; and the anatomical characters of which, as well as of that variety of the disease which occurs after operations and injuries, closely resemble, if they be not identical with, those described by Dr. Reid, as being found in animals in which he had divided the par vagum.

That this congestion occurs during life, and is not a post-mortem effect, there can be no question, for not only is there found a congested state of the blood-vessels, which might, however, in some cases occur after death, but invariably, even when hepatization has not taken place, is the tissue of the lung altered, being in some instances denser than natural, as if there were an approach to solidification, but that the vital powers were not of sufficient strength to allow of this taking place fully; and in other cases it is softened and friable, breaking down most readily under the pressure of the fingers. In further confirmation that this condition of the lungs occurs during life, I may state that in eighteen of the cases in which it was found, and in which a note of the length of time after death that the autopsy was made has been kept, the average duration of this time was twenty-seven hours and a half; and of thirteen of the cases in which no congestive pneumonia was found, this average time was twenty-seven hours; the difference being so trifling as not to be worthy of notice: the bodies in all the cases being placed under the same circumstances, and in the same position; again it has been found as early as thirteen hours after death, and not met with in bodies seventy hours after that event.

It is very probable that this condition of the lung does not occasionally occur until a very short period, even a few hours before death; in these instances it is the immediate cause of that fatal event, by asphyxiating the patient; and I am persuaded that the greatest number of deaths which occur in surgical practice are directly or indirectly produced by the lungs falling into this state of congestive pneumonia.

By referring to the annexed tables it will be seen that out of forty-one deaths occurring from various injuries and diseases in the surgical wards of

University College Hospital (in which an account of the state of the lungs has been kept), these viscera were found in twenty-three cases to be in the first or second stages of pneumonia. Of the remaining eighteen cases, the lungs, with the exception of a few cases in which scattered tubercles were found, were healthy in ten; and of the eight cases in which there was disease of the lung, but no pneumonia, bronchitis was found in four; œdema of the inferior posterior part of both lungs in one; vomicæ from tubercles in another; and of the remaining two, the lungs were emphysematous in one case, and gorged with fluid blood, the patient only living six hours, in the other.

Of the twenty-three instances in which pneumonia was found, that disease had advanced to hepatization in eleven cases; the remaining twelve being in a state of congestive pneumonia in the first stage of the disease.

That the depressing circumstances which attend confinement in a hospital, together with the recumbent position, have some effect in predisposing to this disease, is shewn by the fact, that of the 18 cases in which no pneumonia was found, 11 died before the 3d day after admission, viz. 4 on the 1st day, 2 on the 2d day, and 5 on the 3d day. Of the remaining 7, 1 died on the 5th day, another on the 14th, and 4 at periods varying from one month to two months and a half. Of these last 4, one died of phthisis after amputation of the leg, and two of the others were not confined to a recumbent position until a very short time before death; one, in fact, with sloughing ulcer of the neck, and sloughing ulcer over the trochanter, died in her chair.

On the other hand, of the 23 cases in which pneumonia was found, only 1 died before the 3d day, and that was an old bed-ridden woman, moribund on admission; 4 died on the 4th day, 2 on the 5th day, 6 between the 8th and 14th days, and 9 between the 16th day and 6th week. In all the cases in which the congestive pneumonia was found, the patient was, from the nature of his injury or disease, required to be kept in the recumbent position; and this, no doubt, together with other causes that I have already mentioned, must have disposed him to the occurrence of the disease, by giving rise to congestion of the lungs.

Inflammation of the lungs, occurring in a person already suffering from a severe injury or a capital operation, is of course a complication greatly to be dreaded, and one which, it has been shewn, is much more frequent than is usually believed. It is a complication against which it is necessary to guard as strictly as possible, both on account of it being of a very dangerous nature, and of it assuming very frequently a latent character; that is to say, the rational symptoms are in a great measure, or altogether wanting, and the presence of the disease can only be ascertained with certainty by a carefully conducted physical examination of the chest, which, as it is the posterior part of the lung that is almost constantly affected, it is extremely difficult to institute in the great majority of surgical cases; as it must be obvious to every one that it would be extremely injurious to place a patient suffering from a severe injury, or one who has lately undergone a capital operation, in such a position as would enable us to examine the posterior part of his chest with care. When this can be done, however, we find the same physical signs that occur in typhoid pneumonia, namely, dulness on percussion, with sibilous or bronchial respiration. The crepitation is not so well marked in this as it is in the more active forms of the disease. Sometimes it is entirely absent, and when present it only exists for a short time, and is, as Dr. Hudson observes to be the case in typhoid pneumonia, quickly lost by the accumulation of blood in the surrounding vessels compressing the air cells. As the latency of this disease is usually increased by the low condition of the patient, or by the existence of some severe injury which may chiefly attract the surgeon's attention, it behoves him to watch with the utmost care any appearance, however slight, of the supervention of a chest affection. He must not wait for the marked symptoms of active acute pneumonia to show themselves; but if the respiration be at all hurried and short, if there be any dyspnœa, lividity of the lips, or occasional slight cough, although there be no expectoration, no pain, and little or no pyrexia, he should immediately be on his guard, and, if possible, examine the chest with his ear, to ascertain if there be any of the well-marked and

easily recognized signs of pneumonia present; and, if so, have recourse to as active a mode of treatment as the circumstances of the case will warrant.

The knowledge of this tendency in severe injuries and operations to give rise to pneumonia, should always make us cautious in using the knife whilst there is any disposition in the patient to disease of the lungs, and should teach us the necessity, after operating, of guarding most carefully against those circumstances which are, in health even, exciting causes of inflammation of these organs, and which will act with increased vigour on a constitution already lowered by irritation. On this account it would be prudent to defer operations during very severe weather, or during the prevalence of an epidemic pneumonia.

In conclusion, I have but few remarks to make on the treatment of this disease. It is agreed by most writers, that in typhoid pneumonia general blood-letting is quite inadmissible, being not only hazardous, but, as Dr. Williams remarks, useless, as we might empty the great blood-vessels, and stop the action of the heart, before the congestion of the lungs could be relieved, or their vessels enabled to contract. The same observation applies to that form of the disease which occurs in surgical cases, if any thing, with more force, as the patient, before the supervention of the pneumonia, is already very probably weakened by profuse discharge, or, at all events, lowered by the irritation of his injury. Local bleeding must be regulated by the circumstances of each individual case: if the patient be of rather a full habit, and the disease be not of a very low type, cupping, or the application of a few leeches, may be had recourse to over the part affected, followed by the application of a blister. Dry cupping is also useful in some cases where local blood-letting cannot be ventured on. In the constitutional treatment the chief reliance is, I think, to be placed on calomel and opium, followed by the stimulating expectorants, such as decoction of senega, combined with carbonate of ammonia, which no doubt act on the over-distended capillaries of the lungs as local stimuli do in other passive or atonic inflammations. I have seen this plan of treatment of essential service in several cases under Mr.

Quain's care, at University College Hospital. The patient's body should, at the same time, be kept warm by means of flannel underclothing; and as this form of pneumonia usually occurs in persons who are weakened by previous disease, and in whom the energy of the nervous system is lowered, the strength must be supported by wine, brandy, or ammonia, and such nourishment as the patient may be able to take.

MUSCÆ VOLITANTES.

To the Editor of the Medical Gazette.

Sir,

As medical journals are intended for the improvement of medical science, I consider that it is the duty of all who are capable, to refute any incorrect statements which appear in such journals. The paper to which I allude appeared in the MEDICAL GAZETTE, p. 719. The author attributed muscæ volitantes to " an opacity of the lachrymal fluid," which fact he says he has " ascertained beyond a possibility of doubt." Now the circumstances forwarded as proof tend to prove that the author is ignorant of what is understood by the term muscæ volitantes ; for he says, in proof of the opacity of the lachrymal fluid producing muscæ volitantes, " To be convinced of this, it is only necessary to fix the eyes steadily on some stationary object, and abstain from letting fall the eyelids. Chains of luminous rings, black spots, little brilliant annular specks, and other fantastic forms, fall down in a sort of shower." Independently of such a congregation of strange things not constituting muscæ volitantes, I deny the statement that any such effect is produced when the experiment mentioned is tried, no matter whether the experimenter be a subject of muscæ volitantes or not; although the author would wish to make us believe that the effect will be produced in any one, if the trial is made; for he says, "The conviction produced by this simple experiment is at once so complete, and so instantaneous, that I never yet met with a man who required a single word to be added to confirm his belief." That opacities of the cornea, morbid growths, or changes of structure of the conjunctiva, or foreign bodies imme-

diately opposite the pupil, produce ef-
fects different from muscæ volitantes,
is known to every surgeon who has seen
any ophthalmic practice: yet the author
says, " Now naturally different degrees
of opacity and adhesiveness (?) may give
the form of black spots, annular specks
of light, (single or in chains), the
phenomena are easily explained." The
author betrays his ignorance again,
when he states that " in the immense
majority of cases the disease is not
connected with constitutional or general
disturbance." The cure mentioned is
too rich to be forgotten, since the dis-
ease " may be removed by a collyrium
of sea water, or the application of a
blister, not larger than a sixpence, near
the lachrymal gland, and a collyrium
composed of one grain of sulphate of
quinine to three ounces of distilled
water, with just sufficient excess of
sulphuric acid to keep the fluid tran-
sparent."—I am, sir,

                    Your obedient servant,
                            M. R. C. S.

Feb. 8, 1841.

MEDICAL GAZETTE.
Friday, February 19, 1841.

SIR ASTLEY COOPER.

WE have lost one of the master spirits
of the age !—Ere this meets the eyes of
our readers, there will probably be
none among them unaware of the event
to which we allude : yet it is a mark
of respect due to the deceased that we
should add one more to the list of
those who have recorded, as calculated
to excite general interest and regret—
the death of SIR ASTLEY PASTON COOPER.

Sir Astley Cooper was born August
23d, 1768, at Brooke, in Norfolk, and
died at his house in London, Feb. 12,
1841, being in his seventy-third year.
He was the son of a clergyman in the
church of England—Dr. Samuel Cooper,
of Yarmouth, who married Miss Bransby,
of Shottisham, a lady of talent, herself

an authoress, and connected with the
family of Paston,—a circumstance which
led to this name also being given to Sir
Astley.

It has often been remarked that some
circumstance, apparently accidental, has
tended to influence the future career of
those concerned; and an anecdote is told
of Sir Astley which, if true, seems to bear
out this idea. It is said that when a
boy he saw a lad fall from a cart, and
tear his thigh in such a manner as to
wound the femoral artery; our young
hero immediately took his handkerchief,
applied it round the thigh, and twisted
it so tightly as to control the bleeding
till further assistance could be procured.
    At the age of fourteen he was re-
moved to Yarmouth, where he was
soon after apprenticed to Mr. Turner,
a general practitioner in that town.
In this situation, however, he remained
but a very short time ere he proceeded
to London, to be under the care of his
uncle, Mr. W. Cooper, one of the
surgeons of Guy's Hospital, by whom,
however, he was in a few months trans-
ferred, at his own request, to Mr. Cline,
then in the height of his reputation at
St. Thomas's. On the completion of the
ordinary course of study, and while yet
in his apprenticeship, he became de-
monstrator of anatomy to his distin-
guished master; and in 1791 he began
to lecture on surgery, giving the first
regular course on that subject ever
delivered in London; as, anterior to
this time, what surgery was given con-
stituted but a collateral branch of the
anatomical course.

In 1787 he spent the winter in at-
tendance on the medical classes in
Edinburgh ; and in 1792 he went to
Paris, having previously married Miss
Cock, a connection of Mr. Cline, by
whom he had one daughter—his only
child, who died in her second year.

During his residence in the French
capital he attended chiefly to the lec-

tures and practice of Desault, at that time the most distinguished surgeon in France, and of whose instructions he entertained a very high opinion. Here Sir Astley was present during some of the horrors of the revolution, and among other things was a witness of the celebrated attack upon the Tuilleries, and the massacre of the Swiss Guards, on 10th of August, 1792.

On his return from Paris, Sir Astley permanently settled in practice. In 1800 he became surgeon to Guy's Hospital—an appointment which he retained till 1826, when he was created consulting surgeon.

Sir Astley's first house was in Jeffrey's Square, St. Mary Axe—not a very fashionable part of the town certainly, but where he was content to sojourn not less than six years. He then removed to New Broad Street, where he remained for seventeen years in very extensive practice, and in daily increasing reputation. His income was certainly at one time greater than that of any other medical man of the present day, having, we believe, on more occasions than one, exceeded £20,000 within a year. He also received some very large fees, among which not the least remarkable was that of a thousand guineas thrown at him in his night-cap by a patient whom he had cut for the stone — an anecdote which we heard the deceased tell with no small animation, on retiring from a patient upon whom he had just performed the same operation, and who had likewise in his agony flung his cap at the surgeon, but without its containing on this occasion the cheque which gave so much force to the original incident.

In 1815, when at the height of his reputation, he removed to Spring Gardens ; and he was one of the few with whom the migration from the city to the west end has proved fully successful. A few years afterwards he was employed professionally by George IV. to remove a small tumor from the scalp — an operation which he performed with all his wonted coolness and dexterity.*

Soon after this (in 1821) he was created a baronet, the patent extending to his nephew and name-sake, Astley Paston Cooper. fourth son of his brother—the present holder of the title. From this time till 1827 he continued to enjoy an extensive practice, and to make a very large income. He then, in the full zenith of his fame, voluntarily retired into the country to enjoy the riches he had accumulated, and spend the remainder of his days in the dignified repose of a country gentleman. But Sir Astley was not made for the *otium cum dignitate*, and a very short time saw him back again in the metropolis, where, on more than one occasion, he publicly referred to the period of his seclusion, and declared that if he had remained idle he should certainly have hanged himself. His nephew, Mr. Bransby Cooper, having been installed in his old residence in New Street, Spring Gardens, Sir Astley took a house in Conduit Street, where he gave a series of *conversazioni*, which were attended by nearly all the medical world in London, and which were intended apparently to convince his brethren of the reality of his return. He brought with him his great name and unblemished reputation, but never had, and probably never desired to have, the same immense business as before his temporary retirement; others, of scarcely inferior note, had gained possession of, and retained a considerable portion, of what had before been almost exclusively his own.

* There is no truth whatever in the story which appeared in the newspapers some days ago, in which it is stated that Sir Astley lost his presence of mind on this occasion, and was recalled to himself by an admonition from Lord Liverpool : his Lordship was not even present.—ED. GAZ.

His first wife having died in 1827, he married Miss Jones, of Cardiganshire, the following year, and from this time used to reside some portion of each season on his estate in the country. He also visited Paris more than once, and received marked attention from M. Dupuytren.

We have already mentioned that Sir Astley began to lecture on surgery at an early age (in 1791), and he continued to do so till 1826. We attended his course somewhat more than twenty years ago, and our recollections vividly remind us of one who carried conviction to those who heard him, that he was a master of his art. He was not particularly studious of elegance, but his language was always fluent and clear ; his ideas were precise, and his meaning never doubtful; the more important points of his subject always had their due prominence, and were deeply impressed on his hearers.

As an operator we need scarcely say that he was bold, rapid, and skilful, almost without parallel, — qualities which tended greatly to enhance his own reputation, and to heighten the character of English surgery. We well remember having been present at a conversazione at M. Maunoir's in 1817, attended by most of the scientific men in Geneva, when the fact was communicated of Sir Astley having cut down upon and tied the aorta in the living subject ; nor shall we readily forget the expressions of admiration, not quite unmingled with consternation, with which the announcement was received.

Probably no surgeon of ancient or modern times has enjoyed a greater share of reputation during his life than has fallen to the lot of Sir Astley. The old and new world has alike rung with his fame ; and, perhaps, we cannot give a better example of this than one to which we remember having alluded on a former occasion—we mean, the fact

of his signature being received as a passport among the mountains of Biscay, by the wild followers of Don Carlos. A young English surgeon, seeking for employment, was carried as a prisoner before Zumalacarregui, who demanded what testimonials he had of his calling or his qualifications ? Our countryman presented his diploma of the College of Surgeons ; and the name of Astley Paston Cooper, which was attached to it, no sooner struck the eye of the Carlist leader, than he at once received his prisoner with friendship, and appointed him a surgeon in his army.

Sir Astley had, for years, been subject to occasional attacks of giddiness, which he was naturally anxious to conceal, but which sometimes proceeded so far as to compel him to desist from whatever he was employed about ; and, on one occasion, he even fell in the street. During the latter part of his life he also suffered a good deal from occasional fits of the gout, which, however, did not present any thing remarkable. For some time his countenance exhibited a purplish tinge, as from some embarrassment in the circulation ; and, latterly, he had been heard to protest, that he must decline visiting patients who were up two pairs of stairs—a threat which, though meant as a joke, had evidently originated in the exertion distressing him. Indeed, we understand that he had repeatedly expressed his belief that there was "something wrong," and that he had not long to live.

The last and fatal attack, however, was of recent date, and in it he had the assistance of Dr. Chambers and Dr. Bright. The body was examined after death, when the diagnosis previously given was confirmed, by the heart being found to be enlarged, with some atheromatous deposits in the aorta, and effusion into the pericardium and cavities of the pleura.

The Chapel of Guy's Hospital has been appropriately chosen as the place

of his interment, which is to take place to-morrow (Saturday) at three o'clock.

Sir Astley Cooper was a handsome man, and of striking appearance, well deserving the " c'est un bel homme !" which was often bestowed upon him as he walked round the Hôtel-Dieu with M. Dupuytren. His manner was open, free, and encouraging to his patients ; altogether void of affectation, as well as of all excessive or artificial polish.

Throughout his whole career nothing could exceed the uniform fairness of his conduct towards all his brethren, or his kindness towards the younger members of the profession, especially those whom he saw to be possessed of merit. There are few among us who do not feel personally grateful to him for his conduct on some occasion.

Sir Astley, as we have seen, long enjoyed a large share of public patronage ; but we believe the actual amount of his fortune, when stated at half a million, is considerably over-rated. His personal expenses were not great ; but he was very liberal to his relations, on whom, we have heard, on what we believe to be good authority, that he bestowed between two and three thousand pounds annually. He is also said to have spent £20,000 in bringing his brother into Parliament*. Nor was his liberality confined to his own family :— when Dr. Baillie and some others made up a purse for Dr. Pemberton, in the difficulties brought upon him by his ill health, Sir Astley contributed the munificent sum of £500.

Besides his Baronetage, Sir Astley had numerous honours conferred upon him : he was Serjeant-Surgeon to three successive monarchs—George IV., William IV., and her present Majesty. He

received the Grand Cross of the Guelphic Order from his own Sovereign, and the cross of the Legion of Honour from Louis-Philippe. He was an honorary member of the French Institut, Doctor of Civil Law in the University of Oxford, and twice President of the College of Surgeons.

The leisure of his advanced age was not spent in idleness, but was devoted to scientific pursuits ; — dissecting, making preparations, and other most industrious investigations of disease. We subjoin a list of his principal contributions to science — more honourable than all the dignities which have been bestowed upon him, and which will constitute the most enduring monument of his fame*.

LIST OF SIR A. COOPER'S WORKS AND PAPERS.

WE believe that Sir Astley Cooper's first contributions to science are to be found in the *Medical Researches,* published in 1798. We therein find two papers,—

1. " The dissection of a case of hernia through the diaphragm, which proved fatal ;" and
2. " Account of three cases of obstruction of the thoracic duct."

We next find him appearing in the *Philosophical Transactions* for 1800, to which he contributed

3. " Observations on the effects which take place from the destruction of the membrana tympani of the ear :" and in the same work for 1801, connected with the former paper, we have

4. " Account of an operation for the removal of a particular kind of deafness." For these he obtained the Copley medal.

5. In 1804 appeared " The anatomy and surgical treatment of inguinal and congenital hernia :" and in 1807

6. " The anatomy and surgical treatment of crural and umbilical hernia," which, thus completed, may be regarded

---

* It is amusing to see Sir Astley's success attributed, in a memoir recently published, to his brother being in Parliament—just the converse being the fact, viz. that his previous success enabled him to make his brother an M.P.

* In our last leader, for " crediti posteri," read " credite ;" and for " a practice *what* has crept in," read, " a practice *that* has crept in."

as his great work, and that which first stamped his reputation with the strong impress which it ever after retained. As a treatise on the subject, it is still, and, perhaps, may always remain, unrivalled.

His next contributions appeared in the *Transactions of the Medico-Chirurgical Society*, the 1st volume of which contains

7. " Two cases of ligature of the carotid artery," being the first recorded cases of that operation; and the 2d volume has

8. " The dissection of a limb on which the operation for popliteal aneurism had been performed;" and also

9. " Some observations on spina bifida."

The 6th volume gives us

10. " The History of a case of premature puberty," and

11. " An Account of the anastomosis of the arteries of the groin." and the 8th

12. " Three cases of calculi removed from the bladder without the use of cutting instruments." In the 11th volume we have

13. " An Account of a case in which numerous calculi were extracted from the urinary bladder of the male without employing cutting instruments;" in the 12th volume is

14. " The History of an operation in which a fatty tumor, weighing above 37 lbs., was removed from the parietes of the abdomen;" and in the second part of the same volume is a

15. " Further account of the extraction of calculi from the bladder."

16. The next work we have to notice is the one containing surgical essays, by Sir Astley and Mr. Travers, in which the papers by the former are on Dislocations, on Exostosis, on Unnatural Apertures in the Urethra, on Encysted Tumors ; and though last, not least, the case in which Sir Astley tied the Abdominal Aorta.

17. In 1822, the " Essays on Fracture and Dislocation" appeared as a distinct work, with numerous engravings ; and, in 1823, an appendix was added, in reference to fractures of the neck of the femur. This is excellent as a contribution to science, while, as a text-book for students, it is invaluable.

18. The " Illustrations of the Diseases of the Breast" appeared in a quarto volume in 1829; and, in 1830, those

19. " On the Structure and Diseases

of the Testis," in the same form, and also illustrated by expensive engravings.

20. Again, in 1832, we were presented with " The Anatomy of the Thymus Gland;" and, in 1839, we have Sir Astley again,

21. " On the Anatomy of the Breast," constituting the last of his great works.

In the interval between the two volumes last mentioned, several papers were published in the *Guy's Hospital Reports*, besides some observations appended to the papers of others. Among his papers, given to the public through this channel, are two very interesting dissections, viz. " A Case of Femoral Aneurism, for which the external Iliac Artery was tied : with an Account of the Preparation of the Limb, dissected at the expiration of thirteen years ;" and an " Account of the First Successful Operation performed on the common Carotid Artery in 1808 ; with the postmortem examination in 1821." Again, we have " Some Experiments and Observations on tying the Carotid and Vertebral Arteries, and the Pneumogastric, Phrenic, and Sympathetic Nerves ;" again, we find a paper " On Spermatocele, or Varicocele of the Spermatic Cord :" once more we have a paper " On Dislocation of the Os Humeri upon the Dorsum Scapulae, and upon Fractures near the Shoulder-Joint :" and lastly we have the " Dissection of a supposed Hermaphrodite." This is contained in the " Reports" for October, 1840 ; and is, we believe, the last of Sir Astley Cooper's numerous contributions to surgery.

We fear that Sir Astley's death has interrupted the completion of other works in which he was engaged. The second part of the " Illustrations of the Diseases of the Breast," which was to treat of malignant affections, was promised some time ago, but has not yet appeared. We hope that the materials which he collected for it will still be given to the public.

COLLEGE OF SURGEONS.

HUNTERIAN ORATION.

THE Hunterian Oration was delivered by Mr. Callaway, on Tuesday, before a crowded audience. The most remarkable point in it was the just and well-timed eulogy which he bestowed on Sir Astley Cooper.

ROYAL MEDICAL AND CHIRUR-GICAL SOCIETY.

Tuesday, Feb. 9, 1841,

Sir B. C. Brodie, Bart. in the Chair.

History of a Remarkable Case of Phlebitis; with Observations. By Thomas Hookham Silvester, M.D. Member of the College of Physicians, and Physician to the South London Dispensary.

Much difference of opinion exists in regard to the treatment of phlebitis, and much remains to be known respecting its cause, nature, and consequences. All are agreed as to its danger. It is the object of the author of the paper to describe the disease, its phenomena during life, and the pathological appearances after death, as they occurred in an isolated case. The patient, about sixty years of age, the subject of piles and large varicose veins in both extremities, received a slight wound, probably from his razor, in the upper lip, which was followed by enormous swelling of the part, but not much constitutional disturbance. At the end of fourteen days the disease seemed to have finished its course, and the patient to be recovering. It quickly, however, reappeared in the veins on each side of the nose, and progressively extended through the numerous ramifications of the frontal and temporal vessels, which, on opening with a lancet, poured forth in abundance "laudable" pus. Incrustations something like the scabs of rupia appeared along the track of each vessel, and when these were removed the interior of the vein became exposed, and the healing process went on by granulation. The symptoms of the disease were, from the commencement to the termination, of a very mild character. The patient appeared to sink under exhaustion at the end of the ninth week, at a moment when pus existed only in a few of the vessels about the vertex ; the process of reparation having been completed in the lip, sides of the nose, and forehead. The autopsy discovered pus in the trunks, and a fibrinous crumbling substance in the ramifications of part of the venous system of the scalp. The minuter branches contained a little fluid blood, of which, however, there was a very small quantity in the whole body. No pus globules could be traced by the microscope. Deposits of pus were sought for in the several large organs and in the muscles, but fruitlessly.

Dr. James Johnson said it would be highly interesting to hear the opinions of the many able surgeons then present, respecting the mode of treatment best to be adopted in the early stages of phlebitis ; whether, he par-ticularly meant, the antiphlogistic or the tonic plan of treatment should be followed.

The President said the question was one to which it was impossible to give a definite answer. Phlebitis occurred under such a variety of different circumstances, and put on so many different characters, that it was impossible to lay down any general rule of treatment. The cases of phlebitis, for example, which were attended with great enlargement of the leg, and passed by the name of phlegmasia dolens, were almost always quite chronic in their course, and required no active treatment at all. Other cases, on the contrary, were most rapid and acute : he had known them terminate fatally in three or four days from the commencement of the symptoms ; and one case he had seen had proved fatal in only forty-eight hours. He could give no general statement for the ordinary cases of phlebitis, but, as far as his experience went, he should say that general bleeding was rarely useful : the condition of the patient was more commonly such as to require support.

Mr. Skey said, that his experience led him to regard the antiphlogistic treatment of phlebitis as very rarely beneficial, and often injurious. In the practice at St. Bartholomew's Hospital he had had opportunities of observing how very frequently the disease supervened in those who were of a weak debilitated state of system, and more especially in those who had suffered from great loss of blood. He remembered in particular one case, of a man, who was bled there to 120 ounces in the course of an hour, for the reduction of a dislocation of the hip : about 25 grs. of tartar emetic were given to the man in the same time ; and at the time he (Mr. S.) expressed his conviction to a friend standing by, that the patient would die of phlebitis. He anticipated this partly from the quantity of blood lost, and partly from the more than ordinary violence which it was necessary to employ, in order to obtain so considerable a quantity of blood from the arm. The hip was happily reduced, and the man was put to bed apparently well ; but phlebitis came on, as he had anticipated, and the man died. He remembered another case very similar to this, in which, however, the quantity of blood abstracted was less, and no unusual injury was inflicted on the vein ; but in this also phlebitis ensued, and ended fatally. From these cases, and from the general results of his experience, he believed that bleeding should not be employed in cases of phlebitis.

Mr. Dalrymple related a case in some measure confirmatory of the same view, which was still partially under his care. It was that of a medical student, who had reduced himself to a state of great weakness by the abstinence and energy with which he

pursued his studies : eating meat only three times a week, that it might not prevent his application, and sitting up reading till two or three o'clock in the morning. In the condition which these habits, united with an originally very irritable constitution, brought on, he received a slight injury : he had scratched and irritated a slight eczematous eruption in his leg, and it was followed by swelling in the groin, and phlebitis of the veins of the leg and thigh. He was, under the care of a physician, treated by severe antiphlogistic measures : his diet was reduced to the lowest quantity, and leeches repeatedly applied, and reducing measures were administered. By these means he was soon brought to the lowest possible stage of debility ; and at length, from the typhoid state which came on, it was found absolutely necessary to administer cordials, and to support him. A deep abscess now formed on the inner side of the thigh, which was opened, the incision being extended through the fascia, and a quantity of matter discharged : he now seemed going on well, but some days afterwards hæmorrhage to a considerable extent took place from the opening into the abscess. The signs of phlebitis now again returned, and fresh abscesses formed in the course of the veins of the leg. The hæmorrhage was removed at several times, but was checked by pressure ; on one day, however, he suddenly lost nearly a quart of blood in a very short time. Mr. Liston and Mr. Travers being then called in, it was determined to tie the femoral artery ; and this being done, the hæmorrhage did not again return, and the patient again began to rally and to make progress. He went on well till one day he exerted himself too much, and moved his leg about, when again phlebitis came on, and only a few days ago a large abscess in the thigh had burst. Now, however, he seemed in so much more favourable a state, that recovery might fairly be anticipated. The whole course of the disease, however, in this case seemed to indicate clearly that reducing measures were injurious ; and he could not but think that had the treatment been from the commencement more calculated to support the strength of the patient, the result would have been much more satisfactory.

Mr. Arnott said he could not agree in the condemnation of antiphlogistic measures, and especially of the abstraction of blood, for he held that, in a certain form, that measure was the most advantageous that could be employed ; and indeed, in his opinion, the only one of real benefit. Much had been said of the tendency of phlebitis to occur in the debilitated and reduced, and especially in those who had suffered from large losses of blood. Such cases, no doubt, did occur ; but they did not constitute the majority of

cases. He conceived that it must be familiar to the members that, after amputation, phlebitis is much more common in the cases in which the operation is performed directly after an accident in robust and previously healthy persons, than in those who had been previously exhausted by long-continued scrofulous or other disease. He had seen numerous proofs of this, but he would mention only one : a lad, 15 years old, was brought to the hospital, having had his leg crushed by a railway-engine : within three hours of the accident he amputated the thigh, and found the femoral vein already blocked up by coagulum. He expressed at once his assurance that the boy would have phlebitis ; and he had, and died. The vein had, no doubt, received a severe injury by the accident, and inflammation had at once commenced in it. Now it was contrary to all that had ever been taught, and to what daily experience constantly confirmed, to imagine that cases of this kind should be benefited by any thing but antiphlogistic treatment : but he would make a distinction as to the kind of bleeding to be employed. He did not believe that bleeding from the arm was generally useful : the plan to be followed was to apply leeches again and again over the inflamed veins : to keep the blood constantly flowing from around them. And with this mode of treatment the administration of nourishment was not, in cases where it was deemed necessary, at all incompatible : the two measures might be employed together without any impropriety.

With respect to the case now before the Society, he regretted the author was not present, that he might have asked for explanation of several points connected with it. He confessed that he had doubts whether it were a case of phlebitis at all ; it had rather the characters of inflammation of the lymphatics ; and he should like to know whether any of the collections of pus had been fairly traced to have connection with the veins of the scalp.

Dr. Williams said he was present at a part of the examination of the body, and he could state certainly that the deposits of lymph and pus were traced into the veins. The question raised to-night with reference to the connection between a reduced state of the system and inflammation of the veins, was one of great interest. He was not aware that in medicine there was any class of cases comparable with these which fell under the care of the surgeon ; unless, indeed, it were those of dropsy from diseased kidneys with albuminous urine. In these, in which it was well known that the blood becomes greatly impoverished, he had of late noticed a remarkable tendency to the occurrence of disease of the arteries and their valves. In the last six cases observed at St. Thomas's, this

had been the case; it seemed certain that before the dropsy occurred, and keeping pace with the impoverishing of the blood, extensive disease had been going on in the large arteries and the aortic valves. The author had alluded to his having regarded this case, in the first instance, as one of ordinary erysipelas: he (Dr. W.) thought the connection of the two diseases a subject well worthy of inquiry. He believed that it was held by M. Velpeau that phlebitis is very frequently coincident with erysipelas.

The President said there was no doubt of the fact; he had often examined cases of erysipelas, in which, with sloughing of the subcutaneous cellular tissue, the veins were highly inflamed. With reference to the occurrence of phlebitis in persons in previously good health, there could be no doubt that it was a common occurrence. When he was a student at St. George's Hospital, it was the custom to tie the vena saphena for varicose veins of the legs, and cases of phlebitis were then very common. The operation was discontinued partly because it did no good; for the patients used to come back three or four months afterwards with their legs as bad as ever; and he believed that all the good it did for the short time was only owing to their having been kept in bed. But the chief reason for giving it up was, that many of the patients had severe phlebitis after the operation, and died. Now these were all people in previously perfectly good general health. In many of these he remembered blood-letting was employed to a considerable extent, and it seemed to produce benefit in some instances. He had himself, when assistant-surgeon, at the suggestion of Mr. Abernethy, divided the saphena vein in a healthy man for a varicose state of the veins of the leg. In this case phlebitis of great severity came on, and the man was largely bled, and recovered.

Mr. Arnott said he had also had several occasions of examining cases of erysipelas, in which he had found both the veins and the lymphatics of the part highly inflamed and filled with pus. The case related by Dr. Sylvester, he must still remark, differed widely from ordinary cases of phlebitis. In the first place, its origin was different; it was not usual for phlebitis to be produced by the irritation of a pimple, or to commence with a slight local inflammation: but this was very commonly the case with inflammation of the lymphatics. In the second place, the course of the disease was different; phlebitis almost always proceeded along the large trunks of the veins; this had gone through a number of branches: and, lastly, the character of the matter discharged was different; it was described as pure laudable pus; but that of phlebitis was ordinarily, not

perhaps always, but still generally, of a reddish colour, and sanious.

Dr. Ashwell said he thought that in relation to the question of bleeding, a distinction ought to be made between cases that occur from any accidental injury, or from any other traumatic cause, and those that come on as if spontaneously. In the former class he had no doubt blood-letting was highly beneficial; but, in other cases, in those, for example, which occurred after a severe labour, he had never seen it of any value.

Mr. Macilwain said it appeared to him that there was a certain character of constitution common to all cases of phlebitis, with which it was necessary to be acquainted before it could be determined what treatment was adapted to it. It was difficult, perhaps impossible, to define exactly what this character was; but, as far as he had observed, it was always marked by a want of power. He should, therefore, not be inclined to adopt active antiphlogistic measures; and he almost regretted that Mr. Arnott should have given the weight of his authority to the almost unlimited employment of local bleeding. He did not regard leeches as very formidable things; but he doubted whether such a profuse employment of them could be beneficial. In children especially he had seen them productive of great injury when so extensively applied.

Mr. Rutherford Alcock said his experience, which had been rather considerable in cases of phlebitis after injuries and amputations, had led him to the conclusion that there could be no general rule laid down for the employment or non-employment of bleeding. There were some cases in which the disease assumed all the characters of an acute and active inflammation, with a full and hard pulse, and high inflammatory fever. In all these he had freely employed bleeding with the most satisfactory results. But there were other cases in which the affection from its very commencement assumed a typhoid character; and in these, of course, no bleeding could be employed. He should think its use nothing less than manslaughter. The patient must in these cases be supported by all possible means. He did not think with Mr. Macilwain that there was any common character in those affected with phlebitis; and if there were, and it could not be defined, he did not know how it could be made subservient to the treatment of the disease. Besides the extreme cases he had mentioned, there were others in which the affection assumed a mixed character; the fever was neither typhoid nor acutely inflammatory, but something between the two. In these he was inclined to think the plan recommended by Mr. Arnott, of copious local

bleeding, to be the most beneficial that could be adopted.

Dr. Elliotson said it was plain that in phlebitis, as in most other diseases, there were some cases that must be treated in one way, and others that required just the opposite management. His own experience included only those cases in which the disease had occurred in the course of some medical disorder for which he was in attendance on the patient ; as a kind of accident, therefore, to some other disease. In all these he had certainly found the best treatment to be that of supporting the patient ; and by this he meant, not that which was commonly confounded with it, the administration of stimulants, brandy, wine, and so on, but the giving of good nutritious food, such as strong beef-tea, eggs, and other things of that class.

Mr. Macilwain would make but one observation in reply to Mr. Alcock. It was said it would be of no use in treatment to know what was the peculiar general condition on which these diseases depended. The subject was too long to be entered on now, and he had given to the world his opinions as to what these general conditions were ; but he would give now one example of their application. It was probably generally known and agreed upon what iritis is ; that it is an acute inflammation : now when, in cases of iritis, could it be said,—this case depends on suppressed secretion, or other disorder, of the skin, or the kidneys, or some other organ, and when that secretion is restored the iritis will disappear, without either bleeding or any other part of the ordinary treatment ; and if these prophecies were repeatedly fulfilled, he thought it was something to learn the real condition of the system on which these diseases depended. Numerous cases of the kind were constantly occurring to him, and he had long invited the attention of the profession to them, in which, by determining what organ was out of order, and by remedying its condition, these local inflammations disappeared as certainly and as speedily as they ever did under the ordinary treatment by bleeding, mercury, and other remedies of that class.

An Account of Two Cases of Imperforate Hymen. By Sir B. C. Brodie, Bart. F.R.S. &c. &c.

The author was induced to give to the Society the narrative of the cases in question, not so much in consequence of any thing unusual in the cases themselves, as from a wish to awaken attention to the difference between these instances of true imperforation of the hymen and such as are usually described as belonging to the same category, but which are in reality nothing more than

cases of congenital closure of the vagina, or accidental adhesion of the walls of that canal.

The President hoped some information on the subject would be afforded by the numerous gentlemen of more experience in these matters than himself, whom he saw around him.

Dr. Merriman said he had seen two cases of imperforate hymen. The first was in a girl fifteen years old, who was under his care with the late Mr. Chevallier. The case was at first supposed to be one of closure of the vagina, but on a careful examination there was no doubt that the closure was produced by the hymen. At his request Mr. Chevallier operated on the patient, making a crucial incision through the hymen, and the patient ultimately did well. She, however, exhibited a result of the operation which had occurred in a case mentioned by Dr. Denman, who particularly alludes to the danger of its occurrence after these operations ; she had acute peritonitis, and required all the active treatment for that disease. The other case he (Dr. M.) had seen, was with Sir Charles Bell ; it was that of a married woman, who had never menstruated ; but who, after marriage, finding an enlargement of the abdomen, thought herself pregnant. On examination, both he and Sir Charles had no doubt that the hymen was imperforate ; the latter operated, and a very large quantity of menstrual fluid was discharged. The woman did well, and had since been pregnant, and bore a living child in a perfectly satisfactory manner. It was remarkable that in this case, though she had been married nearly two years, neither the woman nor her husband had any idea of any unnatural formation existing. Another case, somewhat similar to the second mentioned in the paper, had occurred to him, in which the aperture in the hymen was so small as to admit only a small probe ; this he had treated with perfect success by introducing a bougie daily, and gradually increasing the size till he had made the aperture of its ordinary size.

Dr. Moore said he knew of some cases of imperforate hymen similar to those related, and he related a remarkable case that had been communicated to him by Dr. Munk. A girl, who had never menstruated, was treated for amenorrhœa ; at length a swelling formed in her abdomen, and gradually became so large that she could only walk in a very constrained stooping posture. One day she felt something give way in her abdomen ; and in two or three days after died with acute peritonitis. On the examination the abdomen was found to contain a large quantity of chocolate-coloured fluid, like menstrual discharge, which had proceeded

from a rent in the right fallopian tube. The uterus was very much distended and soft; and contained a quantity of similar fluid. About two inches from the orifice of the vagina it was completely closed. .

Dr. Ashwell said he was not prepared to have heard of the imperforate state of the hymen being so rare an occurrence. He could call to mind four cases in which he had observed it. He could confirm what Dr. Merriman had stated respecting the occurrence of peritonitis after these operations, and could add that it was more likely to occur after operation for closed vagina than after that for imperforate hymen. He mentioned also the difficulty that commonly exists in keeping open the apertures made through the vagina in the operation to cure its closure from disease; and detailed one case in which, after a second operation for the purpose, fatal peritonitis ensued.

The President said he supposed such cases were more common than he had been led to imagine, from the statement of Dr. Blundell and Sir Charles Clark that they had neither of them met with a case of the kind. He had seen, if he remembered rightly, four cases of closure of the vagina, which are commonly described as imperforate hymen. One of these was an out-patient of St. George's Hospital; she was operated on, but she would not come into the hospital, and at her own home she very narrowly escaped death from peritonitis. Another was also in the hospital; and soon after the vagina had been punctured symptoms of acute peritonitis came on, and she died. On examination, the abdomen was found to contain a large quantity of menstrual fluid; but there was no rupture of the uterus or fallopian tubes, and it was impossible to explain the presence of the fluid in the abdomen except by supposing that it had passed from the uterus backwards through the fallopian tube.

Dr. Elliotson related a case of imperforate hymen, that was in St. Thomas's Hospital; and another in which a woman, who had no trace whatever of vagina, had been married for some time without either her husband or herself having any idea that she was ill-formed. She had been under his care for amenorrhœa before marriage; and after marrying she came to him again, saying that she had still not been ever unwell. On examination, no appearance of vagina could be found. Mr. Henry Cline, who saw the patient with him, made, at his request, an incision in the direction of the vagina, but without finding any cavity. The operation was performed a second time, the incision being carried as deep as it could be with safety, but still no vagina could be found; and it seemed therefore probable that none whatever existed.

APPRENTICESHIP SYSTEM.

SIR,

THE very able article on the apprenticeship system, in your number for January 29, and a letter on the means of improving the finances of the College of Physicians, &c., would probably convince any reasonable reader of the necessity of a medical reform. The profession, however, whilst they are almost unanimous as to its necessity, feel strong doubts of deriving any benefit from such bills as those proposed by Messrs. Warburton and Hawes. Mr. Wakley's has not yet appeared, and some wags say never will; they suspect that the Lancet would feel a sad falling off in its circulation, should it do away with the feverish excitement of hundreds of discontented members and students of the profession, who week after week purchase the said publication, solely in hopes of seeing its editor's promised bill, and the laws which are to regulate a new college.

With the great number of licensing bodies we at present possess, and the different titles and privileges they confer, it might be supposed that all the good desired could be obtained by conferring additional powers, or, if necessary, compelling one of the existing institutions to enlarge its sphere of usefulness, and oblige all persons in future to obtain its license previous to practising medicine in any way, or under any title — say, for instance, the College of Physicians. Let it require of candidates a certificate from a medical practitioner of having studied and practised pharmacy under his direction for the period of two years; then of having attended lectures, dissections, and hospital practice, for three years, on all the branches at present required by the Apothecaries' Company, and College of Surgeons; after this let him be examined, and if he prove competent, grant him his license to practise medicine, surgery, and midwifery; and further, to dispense his own prescriptions, and supply medicines, and all medical appliances (ordered by himself) to his patients. Call this person a licentiate of medicine and surgery, and let his license give him power of presenting himself ten years after he obtained it, or at any period after that, for another examination, conferring on him the title of doctor, and retaining the same privileges as formerly. Thus there would be two grades in the profession, which I do not view with horror, especially as, according to the above, it would only be the junior licentiate and senior doctor : neither should keep an open shop, or sell drugs he did not himself prescribe, whilst the chemist or druggist

should be a tradesman only, not even pre-
scribing in his own shop : the latter might
be made effectual by empowering any magis-
trate to inflict a penalty of £5 on the offender,
half of which should go to the informer.

Some medical men are of opinion, with
Shakspeare, that there is nothing in a name.
I think differently, and would hope some
day to possess a more intelligible title, the
inconvenience of which I felt last summer as
follows :—Being on a diligence from Paris
to Calais, I got into conversation with a
Frenchman, who asked me my profession.
I told him I was a " Praticien General ;"
immediately after which I saw him adjust-
ing his coat pockets safely under his nates ;
he dropped all conversation, and, as I sup-
pose, took me for a practising member of
the swell mob, which idea my ambiguous
title might well suggest : in fact, nothing can
puzzle a foreigner more than our medical in-
stitutions.

If you think the above, or any part of it,
worth publishing, by giving it insertion you
would greatly oblige,

Your obedient servant.

ARGUS.

Feb. 13th, 1841.

CLAUSES PROPOSED TO BE INSERTED

IN THE

POOR LAW CONTINUANCE BILL.

To the Editor of the Medical Gazette.

SIR,

I BEG you will do the question of Poor
Law Medical Relief the justice to correct
the announcement at the close of your last
number, headed " Reform Deputations."

The conference with Lord John Russell
had nothing at all to do with " Medical Re-
form." The gentlemen whose names you
mentioned, and Mr. Ceeley on the part of
the Provincial Association, waited on his
Lordship to request him to introduce cer-
tain provisions for regulating Medical Re-
lief, into the Bill now passing through Par-
liament for the continuance of the Poor
Law Commission.

Lord John replied, that until he saw
the precise measure on which the pro-
fession had decided, and had consulted the
Poor Law Commissioners, he could give no
positive answer, but that if a clear and
intelligible set of propositions were sub-
mitted to him, he would inform the deputa-
tion of his intentions regarding them.

Accordingly, on Monday and Tuesday
last, Mr. Ceely and myself, as delegates
from the Provincial Medical Association,
conferred with Dr. Webster and Mr. Farr,
as representing the British Medical Asso-
ciation, and agreed on recommending the
series of clauses which I now inclose ; and

which I solicit you to publish in the next
GAZETTE.

Mr. Sergeant Talfourd and Mr. Wakley
have concurred in forwarding these clauses
to Lord John Russell, who it is believed
will refuse a " Medical Director ;" and
since the consent of the crown is necessary
before making such a proposition, it cannot
be moved for in committee if his lordship
withhold assent.   In that case, however,
it will become doubly important to endea-
vour to procure the enactment of the other
clauses, substituting the present com-
missioners for the proposed director, and
omitting also the tenth clause, which, with-
out a medical director, would be needless.

Probably in a fortnight or three weeks
these clauses will be submitted to the House
of Commons. If the little time that re-
mains for action be well employed by the
profession, *some* parliamentary support may
be obtained.

The question is so perfectly distinct from
the agitation on Medical Reform, that I
trust the corporations and their friends will
be prompt in petitioning for the adoption
of these clauses, and in securing parliamentary
votes in their favour.—I am, sir,

Your obedient servant,

H. W. RUMSEY.

Gloucester, Feb. 15, 1841.

1. And be it enacted, that it shall be
lawful for Her Majesty, her heirs, and suc-
cessor, by warrant under the Royal Sign
Manual, to appoint one fit person, being a
physician or a surgeon lawfully qualified to
practise in physic or surgery, for a period of
not less than ten years to superintend all
matters concerning the medical relief of the
poor in England and Wales, under the au-
thority and subject to the approval of the
Poor Law Commissioners, and to be styled,
" The Poor Law Medical Director for Eng-
land and Wales ;" and also from time to
time, at pleasure, to remove such medical
director ; and upon any vacancy in the office
of medical director to appoint some other
such person to the same office : and all rules,
orders, and regulations, relating to medical
relief shall be sealed or stamped with the
common seal of the Poor Law Commissioners,
and shall have the same force and effect, and
be received in evidence in like manner with
other orders, rules, and regulations, sealed
or stamped with the said seal.

2. And be it enacted, that the Poor Law
Medical Director, under the authority of the
Poor Law Commissioners, shall, after the
passing of this Act, proceed with all con-
venient dispatch to take into consideration
the size and population of every district for
the administration of medical relief through-
out England and Wales to be committed to
the charge of a medical officer, in order to

settle the extent and boundaries thereof upon the scheme following; that is to say, that no district shall include a larger population than ten thousand persons:—

That districts of greater area than eight thousand acres shall not include a population of more than four thousand persons.

That districts of greater area than one thousand acres shall not include a population of more than six thousand persons.

That districts of area less than one thousand acres may contain a population not exceeding ten thousand persons.

And that the medical directors shall within three years after the passing of this act complete the regulation of all districts throughout England and Wales, and submit the schemes thereof, specifying the extent and boundaries and population of all such districts, to one of the principal Secretaries of State; and such scheme shall be laid before both Houses of Parliament within six weeks after the receipt of the same by such principal Secretary of State, if Parliament be then sitting, or if Parliament be not then sitting, then within six weeks after the next meeting thereof.

3. And be it enacted, that on or before the   day of   next, after the passing of this Act, the Guardians of the Poor of every Union shall, for each parish belonging to such Union, cause to be prepared a list to be called the Medical Paupers' List, which shall contain the names of all poor persons residing in such parish, who at the time above specified are in the actual receipt of out-door parochial relief of any description; and to these names shall be added on the same list the names of any other individuals of the same parish not in the actual receipt of parochial relief; but for whom the said Guardians might be willing to provide medical relief in the event of sickness or bodily ailment, or injury from accident, or otherwise.

And on the said   day of   in each succeeding year the said guardians shall revise and amend the several Medical Pauper-Lists of their Union by erasing the name or names of any person or persons who may be deceased or have quitted the parish, or have been removed into a workhouse, or for whom the said guardians intend no longer to provide medical relief, and by adding at their discretion the names of such other poor persons only, residing in the parish, as shall not be then sick or suffering from bodily injury, and for whom the said guardians intend to provide medical relief when necessary.

And the said guardians shall, as soon as possible after the preparation and revision of the said List, transmit a copy thereof to the medical officer appointed to attend the parish to which it refers, and such medical officer on application being made to him by or on behalf of any person sick or suffering from bodily injury, whose name shall at the time of such application be upon the said List, shall forthwith afford to such sick or injured person the necessary medical relief.

4. And be it enacted, that on or before the said   day of   in every year the guardians of every Poor Law Union shall fix and determine for the ensuing year, within the limits specified in the schedule marked A hereunto annexed, and subject to the approval of the Poor Law medical director, and subject also to the several augmentations hereinafter designated, the sum or amount of remuneration to be paid to each medical officer appointed to attend such Union, or any district or separate parish thereof, for every individual on the Medical Pauper List; and the sum or amount of remuneration so fixed and determined by the said guardians and approved by the said director shall be augmented in the following ratio; that is to say, whenever the area of the parish which such medical officer may be appointed to attend shall exceed one thousand acres, and be less than eight thousand, the amount of such augmentation shall be equal to one-fourth part of the said sum or amount of remuneration, and to two-fourth parts thereof when the area of such parish shall contain eight thousand acres and upwards.

And in addition to this augmentation, according to the extent of the parish, a further augmentation shall be made according to the distance in the case of every parish which shall not contain the place of residence of the medical officer appointed to attend it; that is to say, for every mile of distance from the residence of such medical officer to the nearest boundary of the parish he is appointed to attend, he shall receive a further augmentation equal to one-fourth part of the amount of remuneration fixed and determined as aforesaid; such distance to be computed in all cases by the course of the accustomed highway.

5. And be it enacted, That if in any parish belonging to a Poor Law Union, any poor person whose name is not on the medical pauper list of such parish, shall be seized with sickness or sustain bodily injury, so as to render medical assistance necessary, it shall be lawful for the relieving officer or overseer of such parish, or for any justice of the peace, to grant to such poor person an order in writing, addressed to the medical officer appointed to attend such parish, which order shall be in force during three calendar months from the date thereof, and upon the receipt of such order the said medical officer shall promptly afford to the said sick or injured person the necessary medical relief, and shall continue to do so until the patient shall be recovered in the said term of three calendar months expired; provided that if

the patient shall not be recovered at the expiration of the said period of three calendar months, a new order shall be obtained.

And as a remuneration to the said medical officer for such casual attendances, he shall in addition to his other remuneration of whatever kind, receive for every such order a sum double the amount of the aforesaid sum, and of any augmentation thereof, to be paid for every individual on the medical pauper list of the parish, in which any such casual attendance may occur : Provided always, that in cities and towns containing a population of more than ten thousand persons, the sum to be paid for every such order shall be fixed and determined as aforesaid, within the limits of the schedule B, hereunto annexed.

6. And be it enacted, That on or before the said   day of   , in every year, the guardians of every Poor Law Union shall fix and determine for the ensuing year within the limits specified in the schedule marked C, hereunto annexed, and subject to the approval of the Poor Law Medical Director, the sum or amount of remuneration to be paid to the medical officer appointed to attend any workhouse belonging to the said Union : Provided always, that the amount of such remuneration shall depend upon the average weekly numbers of inmates of such Union Workhouses.

7. And be it enacted, That if by virtue of any order to be hereafter made by the Poor Law Medical Director, the guardians of any Union shall think proper to provide medicines and other necessaries appertaining to medical relief, for the uses of the pauper patients of their Union, paying competent persons to prepare and dispense the same, and appointing medical officers for the sole purpose of attending and prescribing for the poor of the Union who may be sick or suffering from bodily injury ; the said guardians shall in such case deduct one-half from the remuneration to be paid to the medical officer, exclusive of and without affecting the augmentation made as aforesaid, on account of the extent of any parish, or the distance of such parish from his residence.

8. And be it enacted, That on or before the aforesaid   day of   in every year, the Guardians of every Poor Law Union shall fix and determine, subject to the approval of the Poor Law Medical Director, the amount of remuneration to be paid to any Medical Officer, appointed to attend such Union or any District thereof, for attending any poor woman in childbirth, whether she be an inmate of a workhouse or not.

Provided, however, that if such Medical Officer be called upon to attend any such poor woman in labour, at the instance or during the attendance of any female midwife employed or paid for such attendance by the

said Guardians, he shall receive for every such attendance the sum specified in the schedule marked D, hereunto annexed.

9. And be it enacted, That the Medical Officers of every District, shall, on or before the   day of   in every year after the passing of this Act, transmit to the Medical Director a District Report, stating the numbers of persons who shall have received Medical Relief during the preceding year without his District, the expenses of such relief, and the proportions and manner in which such expenses have been, or will be, defrayed; the distance of his own place of abode from the most remote inhabited part of his District, and, if he shall not reside therein, in addition to such particulars as aforesaid, the distance of his place of abode from the nearest inhabited part of such District, and all such other matters as the Poor Law Medical Director, under the authority of Poor Law Commissioners, and by their orders, shall from time to time require to be included in such District Report, for which he shall be paid by the Guardians the sum of one Guinea. And that the Poor Law Medical Director shall once in every year prepare a General Report, comprising the substance of such District Reports, and all proceedings relating to medical relief in such year, and cause such General Report to be annexed to the Annual Report of the Poor Law Commissioners, in order that the same may be submitted therewith to one of the Principal Secretaries of State, and laid therewith before both Houses of Parliament.

10. And be it enacted, that if any medical officer appointed to attend any union, or district, or parish, or workhouse thereof, shall neglect or refuse to administer medical relief to any poor person, within the said union, district, parish, or workhouse, entitled to such relief, under this act, he shall forfeit his appointment, on sufficient evidence of such refusal or neglect being furnished to the medical director who shall adjudicate thereon.

11. And be it enacted, that the schedules marked A, B, C, and D, hereinbefore mentioned, and annexed hereunto, shall severally continue in force for the space of three years after the passing of this act. And it shall be unlawful for the guardians of any Poor Law Union to attempt, by advertisement or other public notification, or in any manner whatsoever, to obtain tenders or offers relating to the remuneration specified in this act, to be given for the performance of the duties of medical officers, or to be received under any contract made, or to be made, according to the provisions of an Act of Parliament passed in the Session of the third and fourth years of the Reign of Her Majesty Queen Victoria, intituled, " An Act to Extend the Practice of Vaccination."

12. And be it enacted, that no person shall hereafter be eligible to receive the appointment of medical officer of any dis- trict not being duly qualified to practise as a surgeon and physician, or as a surgeon and apothecary, unless he shall be in actual practice as a surgeon or apothecary at the time of passing this act, and that no person shall be so eligible until he shall have been in surgical or medical practice for three years.

Schedules to which these clauses refer.

(*A*) Not less than 3s. nor more than 4s. for each individual on the Medical Pauper List.

(*B*) Not less than 4s. nor more than 5s. for each case.

(*C*) Not less than 4s. 6d. nor more than 6s. for each individual of the average weekly number of inmates.

(*D*) One guinea, and in addition to the same 1s. 6d. for every mile of distance between the place where the patient is and the residence of the medical officer.

FOREIGN MEDICAL DEGREES.

To the Editor of the Medical Gazette.

Sir,

In your journal of last Saturday is a letter on the subject of foreign degrees, which, being a foreign graduate myself, I feel called upon hastily to analyze. In the first place, I must be allowed to observe that your cor- respondent has not acted over prudently in confessing himself to have graduated at Giessen, a degree from which university is, as a general rule, regarded with some little suspicion by the professors at least of the Saxon and Prussian universities. During my residence at one of the last-mentioned schools, I well recollect the amusement created amongst a coterie of mature medical students by the sudden elevation of an elderly Greek student to the rank of M. D. At the university of which I am speaking, and at which, for the sake of convenience, he re- sided, our worthy Hellenist had not the slightest chance of graduating, for, in one word, of medicine he had learnt *nothing*. Another university, however, proved less scrupulous, and, in return for the usual fees and three paltry exercises on medical sub- jects, TRANSCRIBED—*not composed*, by the candidate, he received a formal diploma of M. D. This not inflexible school was no other than *Giessen*. I can assure you, sir, that the above story, so far from being ex- aggerated, falls short of the real flagrance of the case, although I by no means wish it be inferred from it that all graduates from Giessen have been treated with equal indul- gence.

The next point to which I would briefly refer is the declaration on the part of your correspondent that, whereas some years ago he was as conversant with minute anatomy and with chemistry as with his own name, he is wholly unprepared to answer questions on those subjects *now*. I maintain that if *he really have been so great a proficient in those sciences*, even though he may in the course of years have forgotten them in part, a few weeks' application would refit him for all the purposes of examination. That he should so entirely have forgotten his Latin as he confesses or professes to have done, goes far in my opinion to prove that his knowledge of it can never have been very perfect. " Ignora utiam non excusat lex," is a maxim as applicable, I should think, to the law of medical examinations, as to the laws by which society is governed in general.

Your correspondent, after proposing that foreign graduates already in practice in Eng- land should be exempted from an examina- tion, is by no means so indulgently disposed towards those whom Germany and Scot- land may still hold in store for us. Mag- nanimously,—perhaps rather naively,—cer- tainly not quite *un-Irishly*, doth he ex- claim : " let the iniquities of the past be buried in oblivion, but most carefully guarded against in future enactments." So that those who have persisted in practising medicine in defiance of the laws of the Col- lege, are at length to be rewarded for their patient perseverance in error ! And our Giessen M.D. has even the assurance to talk of the " rights enjoyed" by him and by others similarly qualified (?) for practice ; as if continuance in error constituted pre- scriptive right.

Finally, your correspondent has attacked the contemplated measure of the College upon the ground of its inexpediency, as being productive of retaliative measures abroad. On this ground you appear not wholly disinclined to agree with him. I know the continent well, and it is my firm belief that not a single English physician would be allowed to practise in any con- tinental city whatsoever, if such indulgence were not deemed by the local authorities to be an additional inducement to English families to reside there, and thus to deposit there a portion of their wealth. In what continental town is a graduate ever con- sulted by the British stationary inhabitants, unless it be by the very poor, whom he will probably have to bestow something more than a mere prescription upon ? In fact, the permission to practise in foreign coun- tries, if the English practitioner is fortunate enough to obtain one, refers always and ex- clusively to his own countrymen. Let, then, the College be similarly indulgent towards

the *foreign physician*, but let it pause ere it extends its liberality too widely.

I have the honour to be, sir,

Your most obedient servant,

A LICENTIATE.

London, February 15, 1810.

MR. CHILDS IN ANSWER TO MR. CHALK.

[We have received Mr. Childs' second note, but, as before, must decline inserting his letter, except in the *extra limites*. We give, however, two extracts, which contain all that appears to us essential.]

In the season of 1838 I was appointed, by the Medical Board in London, House-Surgeon to this Institution, during which time it appears Mr. Chalk has thought proper to accuse me of stealing from him the *little* knowledge he possessed on the peculiarities and treatment of certain affections which have come under his notice ; but I deny, *in toto*, that any observation of his ever served to enlighten my views respecting the treatment of scrofulous affections ; on the contrary, they always appeared to me theoretical and visionary.

*   *   *   *   *   *

I beg leave to state, that Mr. Chalk is indebted to me for many of the views which he possesses on this subject. I would not arrogantly assert them as original, but derived from the practice and long experience of a zealous and honoured member of the profession, one who has long since been numbered with the dead*.

I do not recollect ever having ten minutes' conversation with Mr. Chalk on the subject of sea-bathing : my information has been derived from a silent but close attention to its effects on different constitutions and diseases.

Mr. Chalk states, that he had shown me Mr. Coulson's letter ; that I promised secresy in everything that related professionally to this Hunter of his age, and admitted that I had been requested by Mr. Coulson to furnish him with a report of particular cases under his care. Now every one of these assertions I positively deny.

APOTHECARIES' HALL.

* Any one who has consulted Dr. Armstrong's " Practice of Physic," must have had his attention directed to this subject.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXIII.

Acute and general inflammation of the encephalon. Period of excitement. Modes in which the disease may commence. Period of collapse. Treatment. Delirium tremens.

ACUTE inflammation does sometimes appear to invade at once the whole of the parts that are lodged within the skull; or, beginning in one part, it extends rapidly to all the rest. As the contents of the cranium are called, collectively, the encephalon, so the disorder which I am about to consider has been named *encephalitis*. It is an uncouth appellation, but it will serve its purpose. Cullen, and many others, apply the term *phrenitis* to the same disease. You may choose between these names, taking care to remember what they signify. The malady is sometimes described as inflammation of the *membranes* of the brain. I believe this to have arisen from the circumstance that the effects of the inflammation, which become visible after death, are often more striking and obvious on the surface of the brain, or in its ventricles, than in the cerebral substance itself. An *abscess* in the nervous mass can scarcely be overlooked : a *softening* of the cerebral pulp may escape the notice of a hasty or inexpert observer : and those changes of colour, which sometimes denote increased vascularity of the same part, may very easily be passed over without attracting much attention.

Phrenitis, or encephalitis, or acute and general inflammation of the brain and its membranes, as it occurs in adults, presents two periods, which are marked by different symptoms, and in most instances are very distinctly observable. In the first period what are called symptoms of excitement predominate ; the functions of the organ are exaggerated as well as disordered : in the second period those symptoms appear which are comprised under the term collapse. Sometimes these two periods, instead of following each other, are more or less mixed and confounded together. But the distinction is real, and requires to be attended to.

Period of excitement.—The symptoms that characterize the period of excitement, are pain of the head, often intense and deeply seated, or extending over a large part of it ; a sense of constriction across the forehead ; throbbing of the temporal arteries ; flushing of the face ; injection of the eyes, which have a wild and brilliant look ; contraction of the pupils ; preternatural sensibility to external impressions, amounting frequently to impatience of light, and of sound ; violent delirium ; want of sleep ; paroxysms of general convulsion ; a parched and dry skin ; a frequent and hard pulse ; a white tongue; thirst ; nausea and vomiting ; constipation of the bowels.

You are not to look for all these symptoms in every case ; nor to conclude that your patient has not inflammation of the brain because the symptoms I have been enumerating do not all present themselves, or do not take place in any regular order of succession.

Modes in which the disease commences.— In fact, we find, in actual practice, that encephalitis is apt to come on, to commence I mean, as far as symptoms are concerned, in three or four different ways.

Sometimes there is a sudden alteration of manner, and the patient, complaining probably of his head, becomes all at once and furiously delirious ; and fever is lighted up. These are symptoms which cannot pass with-

out notice, and which immediately direct one's attention to the head.   They may, however, be fallacious, as we shall see by and by.

In other cases the first thing noticed is nausea and vomiting : and these symptoms may soon cease ; or they may continue several days, and even sometimes throughout the whole course of the disease. Great quantities of yellow bitter fluid are brought up, evidently containing a good deal of bile ; and whatever is introduced into the stomach, even a small quantity of the most simple drink, is immediately rejected.   With this state of matters there is generally much constipation, and the bowels refuse to act except under the influence of strong purgatives.

It is important to attend to these symptoms ; for occurring, as they usually do, with headache, they may easily deceive a person who is not previously aware of what they may portend.   If the patient has not been accustomed to sick headaches, and if the epigastrium and abdomen be natural, not tender, nor distended, as they are apt to be when the stomach itself is in fault, we have the more reason to look narrowly into the case, and to suspect that some serious mischief, of which the nausea is a token, is going on in the brain.   I may observe by the way, that where there is much vomiting of bile, persons are apt, both patients and their doctors, to blame the liver, to set down the disorder as bilious; but you ought to be aware that whenever vomiting is often repeated, or long continued, bile is to be expected in the matters brought up : the action of the duodenum, as well as that of the stomach, is inverted ; and the bile passes in the wrong direction.   If you have ever suffered from sea-sickness, you must know that after the puking has gone on for a little while, bile is constantly voided.

Again, some cases of acute inflammation of the brain set out neither with sudden and great disturbance of the intellectual functions, nor with sickness and vomiting, but with a paroxysm of general convulsion, such as often ushers in an attack of meningitis. This symptom, according to Andral, is a much more certain sign of cerebral inflammation, than the occurrence of active delirium : and I quite agree with him in so thinking.

It is probable (but I speak conjecturally only) that this diversity of symptoms, marking the onset of encephalitis, may depend upon the part in which the inflammation begins ; and that it is soon propagated from that part to the whole of the organ. I should suppose that when nausea and vomiting are the earliest symptoms, the inflammation has taken its point of departure in the cerebral pulp : in the substance of the brain : and that when the attack comes on with a sudden

fit of convulsion, the inflammation has commenced in the pia mater or arachnoid. This is consonant with what we know of inflammation of those parts, when they are separately affected.   Again, it seems to me presumable that the cases which are characterized by early and fierce delirium are cases in which the inflammatory action has invaded the whole of the encephalon, substance and membranes, simultaneously.   I say I offer these as conjectures of my own : what it is of importance for you to remember is, that inflammation of the brain does commence in the three several ways that I have been describing.

There are some cases, however, that cannot be brought within even this general rule. They begin in some irregular or obscure manner, or with some unusual phænomenon. Andral states that he has seen a few striking instances of inflammation of the brain, of which the first sign was a sudden loss of the power of speech : and Dr. Abercrombie relates a very remarkable case in which the same thing happened.   I call it very remarkable, as well on account of the singular manner in which the disease first shewed itself, as that it furnishes an example of encephalitis produced by direct exposure to intense heat of the sun —insolation ; an event very uncommon in our climate.   It occurred in the practice of a surgeon at Selkirk, in Scotland :—

" A young man, aged 16, bathed twice, on the 5th of June, 1818, in the river Tweed. After coming out the second time he lay down on the bank, and fell asleep without his hat, and with his head exposed to the direct beams of a hot sun.   On awaking, he was speechless ; but walked home, and seemed to be otherwise in good health.   He was bled and purged, and the next day recovered his speech, but lost it again at intervals several times during the three or four following days. He was forgetful, and his look was dull and heavy : he made little complaint, but when closely questioned said he had a dull uneasiness at the back of his head.   After a few days more he had squinting and double vision, and a very obstinate state of bowels, and his pulse was 60.   After farther bleeding the pulse rose to 86 ; but he sank gradually into coma, and died on the 30th."

The substance of the brain in general was found highly vascular, and a very considerable extent of it was in a state of softening mixed with suppuration.   The ventricles were distended with fluid, and the membranes in many places were much thickened.   One very curious circumstance (affording perhaps some explanation of the readiness with which the inflammation was produced) was, that the cranium was of very unequal thickness at its upper part ; one spot, as big as a sixpence, was as thin as writing paper, and transparent.

Period of collapse.—However, the phæ-nomena which I mentioned at first constitute the common and ordinary symptoms of acute inflammation of the brain and its membranes. They continue for a variable period; from twelve hours, to two days, or more; and then they are succeeded by others, which characterize the second stage of the complaint, or the period of collapse, as it is called. They result, I apprehend, from the events and products of the inflammatory action; the violence of which is over or abated. The patient ceases to complain of headache; instead of being excited or wildly delirious, he mutters indistinctly, and falls into a state of stupor, from which it is difficult, and at length impossible, to rouse him. His vision and hearing are no longer painfully acute, but dull, or perverted; strabismus and double vision are not uncommon; and the pupil, from being contracted to the size of a pin's head, becomes first oscillating, then widely dilated, and ultimately motionless. The patient is not shaken, at this period, with violent convulsions; but twitchings of his muscles, and startings of their tendons come on, and some of his limbs are agitated with tremors, or become powerless and palsied; the countenance is ghastly and cadaverous; cold sweats break out; the sphincters relax : at length the coma becomes profound, and life ceases.

The disease, when it proves fatal, as it too often does, mostly runs a rapid course. It may kill in as short a time as 24 or even 12 hours; or the patient may struggle on for two or three weeks. The morbid appearances met with in the dead body are very various. Serous or puriform effusion into the ventricles, and into the meshes of the pia mater; layers of coagulable lymph between that membrane and the arachnoid; softening of the cerebral substance, with pus infiltrated into the softened parts; or great vascularity, shewn by a pink or purplish mottling of its cut surface, giving it a stained appearance.

Treatment.—Let us next consider the treatment required for this frightful disorder.

It is quite plain that in an organ so essential to life, and of such delicate organization as the brain, and in which changes so irreparable in their nature as many of those I have just enumerated. so readily take place under acute inflammation, we cannot hope to be of much service unless we see and treat the case at an early period. On this account it becomes exceedingly important to recognize the nature of the disease at its very commencement; and, therefore, I have taken pains to point out to you the various forms which it may assume, while it is yet within the reach of remedial measures.

The principal of those measures are *blood-letting, purging, and the application of cold*

to the head. All the particulars of the antiphlogistic *regimen* are to be rigidly observed; the patient should be kept as much as possible in silence, and darkness, with his head high, and on a firm pillow. And the antiphlogistic *remedies* are to be employed with decision and energy.

Blood-letting.—With respect to bleeding I can only repeat what I have said before : the blood should be taken in a full stream, and suffered to flow till some decided impression is made upon the pulse; or until syncope occurs, or is evidently at hand. After the patient has rallied a little, blood should be taken by cupping or leeches from the back of the neck, or the temples, or the mastoid processes; and these depletory measures must be repeated according to the violence or continuance of the symptoms which first demanded them.

Cold.—The application of cold to the head is a remedy of great importance in this disease. The head must be first shaved; and the mere removal of the hair is sometimes followed by a manifest abatement of some of the most urgent symptoms; of the pain, for example, and of the delirium. In cases such as I am now supposing, it will not be enough to apply wetted cloths to the head : the application must be colder than the ordinary temperature of cold water; and it may be made colder by ice; and the best way to ensure a permanent depression of the superficial heat is to put some pounded ice with a little water into a thin and flexible bladder, and to lay it on the patient's head : there should not be too much ice, or its weight may be injurious. This is generally very grateful and pleasant to the feelings of the patient; and we often have the satisfaction of perceiving that, with the reduction of the external heat of the head, there is also an evident mitigation of the violent symptoms; the agitation and delirium are calmed, and the patient sleeps, or recovers his senses.

Another excellent and most powerful method of applying cold, is by pouring cold water in a slender stream upon the vertex of the head, until it produces some marked effect. Of course this, as well as all other strong measures, must be adopted with great caution, and its influence closely watched : I mean it is not to be left to the discretion, or indiscretion, of domestics and nurses. Dr. Abercrombie tells us that he has seen a strong man, submitted to the operation of this cold douche, " thrown in a very few minutes into a state approaching to asphyxia, who immediately before had been in the highest state of maniacal excitement, with morbid increase of strength, defeating every attempt of four or five men to restrain him." He gives an instance of the use of this measure in a somewhat different morbid condition, which I will quote, because it shews in

the first place the striking power of the remedy ; and, secondly, the simple mode of applying it. A strong plethoric child, five years old, after being for one day feverish, oppressed, and restless, fell rather suddenly into a state of perfect coma. She had been in that state about an hour when Dr. Abercrombie saw her. She lay stretched on her back motionless, and completely insensible ; *her face flushed and turgid.* She was raised into a sitting posture, and, a basin being held under the chin, a stream of cold water was directed against the crown of the head. In a few minutes, or rather seconds, she was completely recovered ; and the next day was in her usual health.

This measure also is to be repeated, according to the circumstances of the case.

Some persons recommend that a constant dripping of cold water upon the patient's shaven head should be kept up. This may easily enough be managed by means of a sponge and funnel placed a little above the head. Andral mentions his attending with another physician, (M. Recamier) a young man who laboured under all the symptoms of acute inflammation of the brain. Cold water was made to drop slowly upon his head, and a complete recovery took place, although no other active treatment of any kind was adopted.

In strongly recommending this efficient remedy to your notice, you will not understand me to advise that it should supersede the use of copious blood-letting : it is to be employed as an auxiliary to the lancet ; not as a substitute for it.

Purgatives.—The third remedy which I named, that it to say, purging, is also of great importance and efficacy. But it must be *hard* purging. There is a great tendency to obstinate constipation in most cases ; and this must be overcome, and free and frequent evacuations from the bowels obtained : five grains of calomel and fifteen of jalap should be followed in three or four hours by a strong black dose ; and after that I should give, in such cases, three or four grains of calomel every four hours, and repeat the black dose at least every morning, until the symptoms gave way. If the mercury thus exhibited affects the gums, so much the better ; but we must not, in this disease, combine it with opium, to prevent its passing off by the bowels. Dr. Abercrombie uses this strong language in reference to the value of purgative medicines in acute inflammation of the brain. " In all the forms of the disease active purging appears to be the remedy from which we find the most satisfactory results ; and although blood-letting is never to be neglected in the earlier stages of the disease, my own experience is that more recoveries from head affections of the most alarming aspect take place under the use of

very strong purging than under any other mode of treatment. In most of these cases, indeed, full and repeated bleeding had been previously employed, but without any apparent effect in arresting the symptoms.'' He has found the croton oil the most convenient medicine for this purpose.

Dr. Abercrombie is disposed to regard mercury as being useful in affections of the brain, chiefly in virtue of its purgative operation : and the opinions of a physician of his large experience, and observing mind, must and ought to have great weight. But I must not conceal from you my own persuasion that, in the early periods of acute inflammation of the encephalon (and it is of the early periods that I have hitherto been speaking), if the mercury comes in a short time to produce its specific influence upon the gums, a great change for the better will often be perceived : such is the result of my own observation. Recollect, however, that you are not to give calomel with the direct object of affecting the gums, but as part of the purgative plan, and you take the chance of its specific effect. You must not combine opium with it, for two reasons ; first, you would thereby shut up the bowels, and deprive yourself of the use of one of your best weapons ; and, secondly, you would incur the risk of augmenting and perplexing your patient's head symptoms, and of puzzling yourself ; since you would not be able to determine how much of the coma that ensued was owing to the progress of the disease, how much to your remedy.

When the second order of symptoms have arrived, those which are included under the general phrase of collapse, and which commonly result, I fancy, rather from the products of the inflammation than from the inflammation itself ; from softening, that is, and from pressure exerted by effused serum, or lymph : when this order of symptoms make their appearance, I believe the time for doing much good by active bleeding has gone by. If, however, blood-letting has not yet been employed, and especially if the pulse continue hard, whether blood has been already abstracted or not, it will be right to give the patient the chance of that remedy. Of the propriety of doing so, take the following illustration :—" A girl, aged eleven, had violent headache and vomiting, with great obstinacy of the bowels ; and these symptoms were followed by dilated pupils, and a degree of stupor bordering upon perfect coma ; pulse 130. She had been ill five or six days : purgatives, blistering, and mercury to salivation, had been employed without benefit. One bleeding from the arm gave an immediate turn to this case ; the headache was relieved, the pulse came down, the vomiting ceased, the bowels were freely acted upon by the medicines which they had

formerly resisted, and in a few days she was quite well." (*Abercrombie*). I must recite one other case—from among many which go to the same effect—to shew the occasional influence of *hard purging*. "A young man who had had cough and dyspnœa, and been bled for those symptoms, appeared convalescent. One evening he became affected with headache, and some vomiting. About midnight, having got out of bed to go to stool, he fell down in a state of violent and general convulsion. The convulsion returned during the night six or seven times with such violence that one of the paroxysms continued without intermission for an hour. The pulse, during the night, varied from 60 to 120. (I should have mentioned before these great and rapid fluctuations of the pulse in respect to its frequency, as being a very common circumstance and sign, in inflammatory affections of the brain.) At first it was found impossible to bleed him, on account of the violence of the convulsions; but about seven in the morning a full bleeding was obtained, after which the convulsions ceased, except some slighter attacks during the day, which appeared to be arrested by pouring cold water over his head. The next day he was oppressed; with occasional tremors of the limbs, and some vomiting, and he had one or two threatenings of convulsion. He took repeated doses of active purgatives with little effect; and on the following morning he appeared to be sinking into a state of perfect coma, with a pulse at 50. Croton oil was now given, which operated powerfully seven or eight times. He passed a good night; and the day afterwards was free from complaint.

Having this evidence of the separate efficacy of the three remedies—blood-letting, strong purgatives, and the local application of cold to the head—we have much encouragement to put them into combined operation in these very serious cases, especially when we have the opportunity of using them at an early period. Should the disorder happily yield to these measures, great care will long be required on your part, and great prudence on the part of the patient and his friends, lest the recent mischief should rekindle. A relapse is even more perilous than the first assault of the disease. Such prudence and care will consist chiefly in the avoidance and denial of all that might excite and disturb the brain; whether it be a premature return to animal food; or indiscreet and fatiguing interviews and conversations; or the too early resumption of the cares and concerns of business.

Are we to employ blisters in this disease? Not in the outset, during the period of excitement. They only add to the irritation, and make matters worse. And especially you should avoid putting them, as many are apt to do, upon the head itself, at that stage of the disease. We should not suppose, *a priori*, that they could then, and in that place, have any beneficial effect. They cannot divert the blood from the inflamed part; but they may attract it into the external vessels of the head, and therefore towards the encephalon; and so add to the stress of the general circulation upon the arteries of the brain. If they could be supposed to do any good at all, it would be when they are placed upon the feet or legs. But this kind of revulsion is better accomplished by means of mustard poultices, or fomentations with hot water, which are often of much apparent service, in addition to the measures already spoken of. Experience confirms what reason teaches us to expect in this matter.

When, however, the patient has sunk into a state of coma, he has sometimes, in my experience, emerged from that condition after a cap of blistering plaster has been put upon the head. It is only when the violent symptoms of excitement have abated that I can venture to advise you to employ blisters: they may then be applied to the nape of the neck, or behind the ears, or to the head itself.

The symptoms which I enumerated as marking the period of collapse or sinking, are fearful symptoms; but the conditions on which they depend are not, necessarily, hopeless conditions. These symptoms do not always proceed from fatal disorganization of the brain, but sometimes (there is reason to believe) from simple exhaustion of the nervous power. And this is a point of critical importance. Patients apparently moribund are occasionally saved by the judicious administration of stimulants and restoratives; of ammonia, Hoffman's anodyne, beef-tea, wine, and, it may be, of well-timed opiates. This plan of treatment you must therefore cautiously try, when an extreme degree of collapse occurs. If the structure of the brain be already seriously injured, and the case is irretrievably mortal, no harm can be done; while in doubtful cases, and when the symptoms result from mere depression of the vital powers, the patient may be rescued: and this chance in his favour must not be thrown away.

Do you ask whether there be any mode of discriminating these opposite conditions, one of which is within, and the other beyond the range of possible recovery? I believe there is. If the tendency to *death by coma* be strong, the prospect is very discouraging: if, on the other hand, the symptoms that mark the mode of dying by *asthenia* predominate, you may hope to push the patient through. But to succeed, you must watch him hour by hour. Pallor, a feeble and flying pulse, extreme debility and tremors,

coldness of the extremities, a want of power to respond to external impressions ; these are alarming, but not absolutely desperate symptoms, especially if the mental faculties remain. Whereas profound stupor, partial palsy, profuse sweats, are of the worst omen; yet even these do not preclude the trial, together with blistering the head, of internal stimuli ; and no other plan affords even a gleam of hope.

There is just one caution that I wish to mention before I leave the subject of acute encephalitis ; and it applies to all cases of coma and insensibility, and especially when there is any paralysis mixed with the coma : it is, that you should daily ascertain that the bladder is emptied. Always make the attendants show you the urine that has been passed ; and lay your hand upon the hypogastric region, and try whether there is any undue hardness and prominence there, produced by the distended bladder. I shall revert to this matter more particularly at some future time ; and I content myself with merely suggesting its importance to you now, in all cases of head affection. If the patient *does not* or *cannot* empty his bladder, of course it must be emptied for him, by means of a catheter.

Delirium Tremens.—It would seem perhaps the most natural arrangement if I next proceeded to speak of inflammation of the brain when it is chronic, or partial. These forms of disease are more common, in adults, than acute and general encephalitis. I shall be obliged also to treat, separately, of inflammation of the brain as it is modified by its occurrence in young children,—of what is called acute hydrocephalus. But before I touch upon any of these, I am desirous to bring under your notice at once a very singular and extremely interesting complaint, which is not, I am persuaded, in its essential nature, inflammatory, but which may easily be mistaken, and has over and over again been mistaken, for acute inflammation of the brain and its membranes, with the consideration of which we have just been occupied. And the mistake is the more serious, because the remedies that I have been recommending for encephalitis, and especially blood-letting, not only are not required, but are in most cases positively injurious, in the disorder of which I am now about to speak ; and which is best known under the appellation of *delirium tremens.* Nay this affection of the nervous system may actually be brought on, in a predisposed subject, by the abstraction of blood. I go apparently out of my way in taking notice of this disease now, but I do so that I may have the opportunity of contrasting it with encephalitis, while the phenomena of that disease are fresh in your memory. It

certainly resembles it also in many respects : and it has been considered as being an inflammatory disorder by some excellent pathologists.

The symptoms which mark a decided attack of *delirium tremens,* and which have sometimes been found so equivocal, are very striking. You will be summoned to a man who is supposed to be mad, or to have brain fever. You find him with a red face, perhaps, and injected eyes, talking incessantly, fidgetting with his hands, affected often with tremors of the limbs, having a rapid pulse, and bathed in sweat. Now it is very natural that a person not on his guard should look upon these symptoms as indicating inflammation within the head. But if you look closely into the matter you will find in the state of the patient, or in his history, some things very peculiar. The delirium you will generally find to be not a fierce or mischievous delirium, but a *busy* delirium : he does whatever you desire him to do, but he does it in a hurried manner, with a sort of anxiety to perform it properly. During the approach of the malady, while he yet is able to go about, he manifests great impatience of any interference, or advice, or assistance, in his ordinary duties, which he sets about in a bustling and blundering manner. His loquacity is extreme, and he refers to matters that are not present before him : he is not altogether inattentive to the objects and proceedings that are going on around him, but his mind wanders away to other subjects. There is an odd mixture of the real and the ideal in his thoughts and language. Sometimes he is very suspicious that those who are about him intend him some injury ; or that he is surrounded by enemies. You will find also that he does not sleep ; that he has not slept perhaps for several nights, but been restless and rambling : and you will generally learn that he has been habitually intemperate, or subject to some great source of care, or anxiety, or excitement : and in many cases he has recently been somehow or other debarred from his customary stimulus. Very frequently, in addition to these points in his history, you will be told that having been unwell, first he has been kept upon low diet, and then, as the delirium came on, he has been freely bled ; and that he has been none the better, but commonly the worse, for the bleeding. When you gather such particulars as these from his friends (for upon his own statements you cannot place any reliance) and when you find the delirium to have the characters I have been attempting to describe, and especially when there has been obstinate watchfulness, and the tongue is moist, and the skin is sweating, you may be pretty certain that your patient is affected, not

with inflammation of the brain, but with delirium tremens; and that if you bleed him further you will make him worse.

But what are you to do under such a fearful state of things? Why the great indication is to procure sleep; and the remedy which, in nine instances out of ten, you will find successful, is opium. The beneficial effects of this drug, in tolerably favourable cases of delirium tremens, are really surprising. I will give you an example or two, which will be more instructive than any abstract description.

In the year 1831, I was requested by a most respectable practitioner in this town, to visit a patient of his whom he reported to have had phrenitis, for which he had been freely bled, cupped from the back of the neck, and purged; and who, he believed, was now rapidly sinking, and not likely to survive many hours. I found the patient, a middle-aged man, with a red face, ferretty eyes, a frequent pulse, bathed in perspiration, busy with his hands, which trembled a little, and talking much and incoherently. He was particularly anxious that his legs should not be scarified, told me he was willing to do any thing I pleased, if I would not scarify his legs, nor let any one else scarify them. There was nothing the matter with his legs, nor had it entered any body's head, but his own, that they wanted scarifying. He had not slept for several nights. He had been intemperate, especially of late, drinking a good deal; and somewhat anxious about his affairs; he was a builder.

His former history was not very promising. He had brought up a good deal of blood a few months before, and some years previously he had had jaundice; latterly he had been troubled with indigestion.

I saw him in the afternoon, and prescribed one-third of a grain of morphia: in the evening he was just in the same state. I then directed half a drachm of laudanum to be given immediately, and twenty drops every two hours afterwards, *till he slept.* I said to the gentleman who had called me to the case, that I thought it very likely our patient might be well the next day; he smiled, and shook his head. I was obliged to leave London early the next morning, for two or three days; on my return, I learned from the medical man that the patient took five doses of the laudanum, and then fell asleep, and slept soundly and for a long time, and then awoke (to his attendant's extreme surprise and satisfaction) sane, and well.

I was asked by the apothecary of the Middlesex Hospital to see a publican in that neighbourhood. I found a large strong man, between 30 and 40 years of age. He had been without sleep for several nights, somewhat incoherent, and (what is not usual in such cases) violent, threatening and striking those about him because they refused him access to strong drink. He was joint proprietor with another in a gin shop, and for some time previously he had been a sot, and daily muddled with drink. He told me he was quite well; there was not much tremor. I found that the object of his partner and relations in sending for me was that I might sanction his removal to St. Luke's, for his strength made him altogether unmanageable, and his insane and extraordinary conduct was hurting the business of the house. I declined to take any part in consigning him to a mad-house, and recommended morphia. After one full dose he soon slept; and the next day he was quite rational, and comparatively well.

These are the broad outlines of delirium tremens; there are many other features wanted to complete the portrait of the disease, which I shall endeavour to paint at our next meeting.

CLINICAL LECTURES,

By Dr. Corrigan,

Delivered in the Theatre of the Richmond Hospital, Dublin,

At the Commencement of Session, 1840-41.

Introductory Lecture.

Gentlemen,— It is the usual practice to commence our course of clinical instruction with some introductory observations, and the accident of my lecture-day falling in an early part of the week causes this duty to devolve upon me. Introductory observations are generally directed either to explain the nature of the subject, or to impress you with an idea of its importance, in order to win your attention to it. Clinical medicine requires little or no explanation as to its nature. It is the study of disease by practical observation at the bed-side. Its importance can scarcely be overrated: whatever doubts may exist or have been entertained as to the necessity of some of the many courses of lectures which students are obliged to attend, there has never been the shadow of a doubt entertained as to the paramount importance of clinical teaching. And yet I am sorry to observe that this department is often more carelessly attended to, than any other branch of the student's pursuits. This is, I believe, not so much the fault of the student as our own; we do not explain sufficiently often, or sufficiently clearly, to him the reasons that should induce him to attend more closely and with greater diligence to the study of clinical medicine. To those reasons I purpose directing these prefatory observations.

It seems not to be sufficiently known or felt by students, that clinical medicine is to theory and systematic medicine, what practical dissection is to systematic anatomy. Bichat, that ornament of our profession, the John Hunter of France, made this memorable observation a short time before his death : " you ask me," said he, "how I have learnt so much ? It is because I have read so little. Books are but copies—why have recourse to copies, when the originals are before me ? My books are the living and the dead : I study these." Is it not singular, that the truth embodied in this observation should be recognised and acted on in every subsidiary branch of medical study, and yet cease to be remembered, or, if remembered, not acted on, in the most important part of the student's life—the part devoted to the study of disease. A student spends years at anatomy ; he knows that anatomy can only be learned by practical acquaintance with the subject before him ; he would laugh at the folly of his fellow student, who should be foolish enough to say, that it was not necessary to dissect in order to learn anatomy ; and that it was a much better way to read on the subject. How he would smile at the folly of his fellow student who should say, it was only necessary, in order to learn anatomy, to stroll through a dissecting room, throwing a glance now and then at each dissecting table as he passed ; and yet the student, who is quite alive to the absurdity of book anatomy, falls into the very mistake when he commences to study disease. Anatomy is not to be learned by strolling through a dissecting room, neither is clinical medicine to be acquired by walking through a ward. If absolute and practical acquaintance with every fibre, nerve, and muscle, in a dead body, is necessary in order to acquire a knowledge of anatomy, how much more is the same practical acquaintance requisite in order to acquire a power of recognizing disease in the living. The characters that belong to each muscle, each nerve, and each vessel, in the dead, can be accurately described, and once described are applicable to every instance ; and yet practical acquaintance is still requisite to make the anatomist. And if this be true— and all will admit it—how infinitely more true is it of disease in the living, where the most valuable information as to disease is given by the expression of an eye, the tinge of a skin, the touch of a pulse ;—characters that once seen are easily recognized, but which never can be described. It is a great error to suppose that a written description, however accurate, or however diffuse, can give a sufficiently clear idea to the mind of the object described. Read a description of a heart, a lung, or a brain : you can form no clear conception of the object described ;

you would not be able very often even to recognize it from description, when you meet it for the first time ; and if true of anatomy, how much more true of disease in all its delicate hues, its protean shapes. An anecdote which is often told of a late distinguished member of our University will illustrate this clearly : he prized book learning on all subjects, beyond demonstration ; he possessed a most accurate knowledge of natural history, but from books alone (just such as I fear many students alone acquire of disease), but he knew nothing of the objects of natural history from actual observation. In a hard winter a poor little sparrow sought shelter in his college rooms ; he seized it, and was determined not to lose the opportunity of shewing to his colleagues how ready he could reduce his book-knowledge to practical application. He ran over in his mind classes, genera, orders, and species, and then triumphantly pointed out how rapidly he had arrived at a determination of the species before him. And " pray what is it, said a fellow professor ? " What is it ?" replies the indignant vice provost : " as if I did not know ! it is a little crow to be sure." This anecdote creates a smile at the mistake and at the folly of the learned professor, who could have so readily avoided falling into such a ridiculous mistake, merely by having cultivated a practical knowledge of his subject : and yet do not you fall every day into the same mistake, and on a much more serious matter, involving both your own reputation, and perhaps your patient's life, when you wilfully pass over the opportunity of cultivating a practical acquaintance with the forms of disease, and trust for your knowledge to a verbal description, which can no more give you a correct notion of the subject, or be sufficient to enable you to recognise it when you meet it, than verbal description was sufficient for the innocent vice provost. You may acquire a knowledge sufficient for all the purposes of examination by mere reading, and you may imagine that having thus acquired it, you have done all that is necessary. So you could, to go back to our illustration, acquire a sufficient knowledge of anatomy for the same purpose ; but you will at once admit that such knowledge of anatomy would totally fail for all the practical purposes of surgery. Just in the same way will a book knowledge of medicine fail for all the useful purposes of the practices of medicine, directed either to the diagnosis or the treatment of disease. It is, therefore, necessary for you to bear constantly in mind, that the manner in which you acquire a knowledge of your profession is of as much importance as the matter.

A circumstance that came under my observation within a recent period will still farther illustrate this point. In an examination of my class on practice of medicine, two gentlemen

were so equal in their answering, that for some time it was doubtful as to which was the better. One of those gentlemen who answered remarkably well, and with so much credit, that he would extract praise from any court of examiners, I afterwards met in the ward of my hospital, and he positively was not able to recognise or distinguish the commonest disease. He answered altogether from book learning, and from power of memory. The other had acquired his knowledge from practical observation of, and actual acquaintance with, disease. Yet these two gentlemen, on mere verbal examination, were very nearly equal. But how different must be their fortunes in after life! the one, bewildered, and unable to recognise the nature of a case entrusted to him, flounders from one mistake to another, soon betrays his indecision and his ignorance to the scrutinizing observation of anxious and watchful patient and friends, and loses character just when it is of the greatest consequence that he should not make a false step. The other sees before him an object with whose features he is familiar; his manner is steady, his opinion is correct, his treatment is decisive, and the occurrence which has been the destruction of the hopes of the one has become the pedestal for the character and fortune of the other. Impressed with this truth, that the manner in which a knowledge of disease is acquired is of as much consequence to your after success as the knowledge itself, we have determined to give clinical prizes here, but on a new plan. The insufficiency of verbal examination to test practical knowledge is obvious. It is already admitted by some of our examining bodies, before whom it is now necessary for the student to prove his knowledge of anatomy, by making, in presence of his examiners, practical dissections. It is singular that this mode of distinguishing between parrot-like repetition of words and practical knowledge should not as yet have been applied to the most important part of medical examination—the student's acquaintance with disease. We shall, however, set the example. We will trust to no verbal examination; but for the last four months of the session, commencing at any time after the 1st January, we shall, without any previous notice, select such cases as shall seem proper for our purpose on admission into hospital, and require the candidates for our prizes to take those cases, writing down the symptoms, diagnosis, prognosis, and principles of treatment, and giving to each candidate from a quarter to half an hour for his examination of the case; requiring his notes, however, to be written on the spot. The notes thus written will be compared: they will afford at once an accurate test of the practical acquaintance of each candidate with clinical medicine, and the award shall be made from a public comparison of those notes. Our hospital establishment here affords an unequalled field for acquiring a practical acquaintance with disease.

The Whitworth Chronic Hospital contains 82 beds, the Hardwicke Hospital has 144 beds, devoted to fever and to contagious diseases—an extent of field for observation in clinical medicine unrivalled; so that there is not one of all who attend who shall not have the opportunity of being clinical note-takers, who have the good sense to seek for it. On similar advantages in surgery, presented by the Richmond Street Hospital, it is not necessary for me to dwell. The extensive field for surgery presented by that hospital, and the zeal with which it has been cultivated, are too well known to require any commendatory comment. Let me earnestly impress upon you the absolute necessity of accustoming yourselves to the practical investigation and note-taking of cases. Let the opportunity escape you now, and you can never again regain it; and you will bitterly repent it hereafter, when your own character and your patient's life are at stake.

One reason alone which remains to be noticed should be sufficient to induce you to acquire a knowledge of disease from observation in preference to reading; namely, that it is the easier mode. Read for hours, lose your rest in poring over page after page, and endeavouring to infix on your memory a description of any disease with its symptoms; then spend only fifteen minutes in a ward of an hospital, contemplating a case of the same disease. Is not one glance worth pages of description? Numerous associations fix in your mind, and for ever, the appearance and symptoms of a living case of disease which you have examined, and on which you have brought your senses of sight, touch, and hearing, to bear, while the mere verbal description of a disease gives to your mind no definite object; and it is not to be wondered at, that knowledge thus attempted to be acquired is learned with difficulty, is remembered indifferently, and is speedily forgotten. On the ground, then, of mere ease of acquirement, were there no better reason, you should learn disease from actual observation rather than from second-hand description; and yet how common is it to see the industrious student, through a most mistaken notion, lose his rest, and spend his nights in poring over pages of description, while he thinks a quarter of an hour too much to bestow on observation of the object itself, and which would give him the information he wants more easily and far more accurately. That you may have fallen into the error, to the correction of which I am directing these observations, is, however, perhaps more our fault heretofore than yours,

as we may not have taken sufficient pains to point it to you. I have, however, endeavoured to repair on our part this omission, and I am sure it will be met with a corresponding exertion on your part. On our outset now, and in our respective relations during the session, let us keep constantly before us these principles—

1. That clinical medicine is to theory and systematic medicine, what dissection is to sytematic anatomy. That as anatomy can only be truly learned at the table of the dissecting room, so can medicine only be well learned by practical observation at the bedside. And,

2. That, as Bichat has observed: *"we are not to look to books for information, when the sources from which books are compiled are before us; that our books are the living and the dead, and those are to be our study."*

ON HIP DISEASE AND LUMBAR ABSCESS.

By Wm. Oliver Chalk, Esq.

Resident Surgeon to the Royal Sea-Bathing Infirmary, Margate.

[Continued from p. 759.]

(For the Medical Gazette.)

If the limb had not been amputated, the patient might in all probability have lived for years, but the latent mischief being called into sudden activity, under the infliction of the local injury (the operation), the issue was fatal.

I was not present at the autopsy, but I learned afterwards that the substance of both lungs was thickly studded with tubercles, some of which had passed into the suppurative stage, forming cavities. The liver and spleen were also the seat of tubercular deposit. M. Dupuytren, when speaking of this case, and the result of the operation, recalled to the minds of his class his previous forebodings, and declared that he never would be induced to operate again under similar circumstances. It would be well if such cases were of rare occurrence; unfortunately, however, they are too numerous. Patients are frequently admitted into the infirmary (having lost a limb by amputation) with a scrofulous disease of the stump, and if it should so happen that cicatrization be fairly completed, they undergo the misery of a similar disease in the opposite limb. The baneful effects of the exanthematous

fevers, when they occur in scrofulous or phthisical habits, are most ably described by Andral, under the appellation of "maladies intercurrentes," and have not passed unnoticed by writers in our own country.

It is equally certain, however, that scarlatina, measles, hooping cough, &c. more especially the first of these, frequently give rise to the strumous diathesis. Oftentimes these maladies follow one another with surprising rapidity: for instance, I have known measles, scarlatina, and hooping cough, all occurring in the same individuals, in less than four months; and it rarely or ever happens that a patient so circumstanced does not become scrofulous at an after though distant period, unless great care has been bestowed on the general health during and for some time after these diseases. Of all the exanthemata, scarlatina, in my experience, is most productive of the phthisical diathesis. Dr. Graves has clearly shown that, during the fever, the liver is often in a state of active congestion[*]; this circumstance, too much disregarded or overlooked by the practitioner, is frequently the cause of subsequent mischief to the patient; if allowed to go unheeded, it soon passes into a chronic form, and thus arises that state of the organ so well described by Dr. Graves in a lecture delivered at the Louth and Meath Hospital, Dublin, when speaking of hypertrophy of the liver, induced by the abuse of mercury: his observations on the character of the evacuations are highly important. He says, "the cylinder of faecal matter was composed of parts differing in colour and appearance; two or three inches consisted of pale clay-coloured substance; and immediately after this another portion of about the same length was observed, presenting the ordinary bilious or brown-coloured natural excrement; and then again another mass of clay-coloured matter, without any obvious trace of bile," &c. "This peculiarity is noticed in many diseases of the liver, and it is important to remark, in attempting to explain the rationale of these hepatic affections, that in no disease of the liver is this symptom more frequently observed than in the scrofulous." Again, he

* I have of late years been in the habit of applying leeches to the epigastrium during the early stages of scarlatina, with excellent effect.

says, "you will frequently meet with this consecutive affection of the liver in cases of morbus coxæ, where the patient has been labouring for years under ulceration of the joint." In a passage preceding the last quotation, when speaking of scrofulous disease of the liver in children, after describing the state of the viscus itself, accompanied by a most accurate account of the general symptoms, he concludes by saying, "the little patient becomes what is termed pot-bellied, and labours under much debility and febrile excitement. This has been frequently called remittent fever, and disease of the mesenteric glands, but in my opinion unjustly." My own experience fully confirms the truth of these remarks, for it has frequently happened to me, when a patient has died under those symptoms which are said to characterize tabes mesenterica, to find, on examination, that the glands of the mesentery were comparatively free from disease, whilst the liver was invariably the seat of organic changes.

From all that I have been able to deduce from my own observations, and from a careful examination of the opinions of others, it would appear that the tubercular diathesis arises under the following circumstances, which may be thus arrranged :—

1st, As a consequence of the exanthematous fevers, and other infantile diseases, especially scarlatina.

2d, From want of proper and wholesome nutriment.

3d, From overfeeding.

4th, From hereditary predisposition ; the latter class being small compared with the rest.

It is the opinion of many that unwholesome nutriment, confined and low situations, &c. are the chief sources of scrofulous disease ; but this cannot be admitted if the scrofulous and phthisical diathesis are one and the same (of which there can be little doubt), phthisis being common to all classes of society. On a casual consideration of the subject, it would appear strange that two such opposite causes as the want of proper nutriment, and that of an overbundant supply of it, should give rise to a similar condition of the general system; yet, on a more attentive observation of them, it will be found that the circumstances of both are much the same. When a child is

overfed, the digestive organs resist for a certain time its baneful influence, and it is, to all appearance, robust and healthy; but on a sudden, or by degrees, it becomes languid, loses flesh, the appetite fails or is capricious, febrile accessions take place at intervals, and, to the surprise and dismay of the parent, the once thriving and healthy offspring is now always more or less ailing. If, then, the patient be subjected to a careful examination, the abdomen will be found to be more or less tumid ; the bowels inactive, or, perhaps, the reverse ; motions clay-coloured, and varying from time to time in their nature and consistence. Here, then, is established the similitude of the two cases : the overfed child is starved by repletion, whilst the other is starved for want of nutriment, &c. In the former the digestive organs have been overtasked, and henceforth the process of nutrition becomes defective ; the assimilative organs no longer possessing the power of converting the ingesta into nutriment sufficient for the supply of the system at large, the strumous diathesis ensues. Such cases pass daily under my observation, and must be familiar to most practitioners. It is a common circumstance for a mother to observe of her child that up to such and such a period it was strong and healthy, and to express herself totally unable to account for the change, little suspecting that, by overfeeding, she herself may have been instrumental in producing it. If any intercurrent malady supervenes at this time, the case is further complicated; and thus the deposition of tubercular matter in one or more structures of the frame may take place with great rapidity, giving rise to the various local phenomena observable among scrofulous individuals, such as phthisis, enlarged glands, spinal curvature, disease of the joints, &c.,&c., external and accidental causes often determining the site of the disease. To follow out this part of my subject more fully, I may here observe that, in my early inquiries into the causes of the local maladies to be discussed hereafter, I was often told by the patients themselves, or their friends, that for some months or years. prior to the invasion of the symptoms, they had experienced a fall, a blow, a sprain, &c. and that they could only attribute their origin to such a cause. At first, I paid little or no atten-

tion to these accounts, considering that an injury so remote, and which only produced slight and temporary inconvenience at the time, could exercise no influence in producing them: but at length the frequency with which the patients referred to such a source of the local malady arrested my attention, more especially as accident in some cases was the obvious and immediate cause of the scrofulous affection of the parts, if the strumous diathesis existed at the time, or prior to the injury. On instituting further inquiry, I found that external violence, transient only in its effects, had a most marked influence in determining the disease of a part.*

The frequency of affections of the liver in phthisical cases has of late been the subject of much remark. Fatty degenerations of this viscus existed in one-third of the cases (40 out of 130) related by Louis.† He observes, " the fatty transformation of the liver was the most frequent, and, at the same time, most remarkable alteration of this organ." From this it would appear, that there were other alterations, which, however, he does not describe. The constant occurrence of disease of the liver in scrofulous subjects has long occupied my attention, and I have found that local depletion and counter-irritants in the vicinity of that organ are absolutely necessary in a vast majority of cases, before any hope could be entertained of subduing the local affection. The sudden amelioration that often follows the application of a few leeches to the epigastrium is surprising, and not easy of explanation. Of late years I have ceased to treat hæmoptysis by abstraction of blood from the arm, preferring the application of leeches to the epigastrium (increasing or diminishing the number according to the pain produced on pressure in the region of the liver), as a safer and far more effectual plan than that of general bleeding. Andral notices their effect in quelling hæmoptysis,‡ but assigns the relief obtained to a different cause; namely the gastric symptoms. He observes, " it is in cases

of this description that one has seen the application of leeches to the epigastrium put an end to profuse hæmoptyses more surely and promptly than could have been effected by the opening of a vein." It seems somewhat strange that both he and Louis attribute the tenderness at the epigastrium to muco-gastritis; but it is quite certain that no part of the stomach presents in epigastrio, and whenever the liver is enlarged it extends over to the left hypochondrium, so that it is not very likely that the pain given on pressure should result from gastritis. And again, it is far more easily understood how relief may be obtained to the pulmonic symptoms by depletion from the liver, rather than from the stomach, when we consider the mutual dependence existing between the first mentioned organ and the lungs. I am quite aware that the affection of the liver in scrofulous individuals has not been regarded by some as inflammatory; but as merely functional. In the third volume of the Medical Cyclopædia I find the following observations. " The subsidiary organs of digestion and assimilation suffer also from scrofula; but the spleen and the pancreas are more frequently the seat of tubercles than the liver; yet the last mentioned of these organs is more or less functionally deranged in almost all strumous cases, which the chalky and various coloured motions of such patients sufficiently demonstrate." That the condition of the liver is essentially inflammatory in the earlier stages of strumous diseases I do not myself entertain the smallest doubt, the clay-coloured and variable state of the excrement being alone sufficient to demonstrate its existence; and under these circumstances, unless actual local depletion, repeated at intervals, be employed, we have no chance of restoring the hepatic secretions to their normal state. The pain given on pressure, in chronic congestion of the liver, is frequently by no means acute; but if we estimated the degree of mischief by that circumstance only, we should fall into a great error: it has often happened to me, whilst so examining patients, to find that they would scarcely admit of any pain resulting from the examination; yet, on a second visit, they would acknowledge that they had felt considerable uneasiness for some time afterwards. The

---

* It is well known that a sprain, or other injury, will determine gout to a part in a gouty subject; a blow on the head may, after years, give rise to cerebral disease. Cerebral affections, originating in this way, are ably described by my late and lamented friend, A. C. Hutchison, Esq. in his Surgical Observations.

† Vide Translation of his Work, p. 79.

case of Gardiner Stanley, æt. 23, admitted into the infirmary May 14th, 1835, may be cited among the many cases illustrative of this fact: he was suffering from scrofulous enlargement and ulceration of the left foot; the inguinal glands of the same side were enlarged and suppurating; the skin and surrounding parts were highly tense and painful, and contributed to form a tumor of very considerable size. On inquiring into the state of his health, he said it was, generally speaking, good, but he thought it had lately suffered from being too much confined to his desk (he was a lawyer's clerk). I made a careful examination of the abdominal and thoracic viscera; whilst examining the liver I observed him to shrink from my touch, but he did not admit that he felt any inconvenience at the time. On my visiting him the next morning he stated that he had felt a good deal of pain in epigastrio ever since. Eight leeches were applied the following evening in the hepatic region, and a pill of calomel and opium was ordered to be taken nightly. Upon seeing him the next day he said he was greatly relieved, the foot was much smaller, the ulcers bore a healthier aspect, and the tumor in the groin had entirely disappeared, the only trace left being two or three glands about the size of a small walnut, with two sinuses leading towards them. From this time the case continued to progress favourably, until he experienced an attack of rheumatic fever, from sleeping near an open window: the articulations of the knees, wrists, and ankles, were severely affected, and the right knee became the seat of a copious suppuration; his general health suffered greatly, and he returned home October 22d in a very debilitated condition. He came again to the infirmary in May 1837, apparently dying; for it seemed scarcely possible that he could survive the effects of his journey, such was the state of weakness to which he was reduced by it: he rallied, however, and continued to improve up to the time of his return home the October following. During the severe winter of 1837-38 he suffered from a renewed and severe attack of rheumatic fever: he lingered on from this time until June 20th, of the latter year, on which day he died. On a post-mortem inspection the liver was found to be enormously enlarged, weighing twelve pounds and

three-quarters, as was likewise the spleen, which was slightly indurated; the thoracic and remaining abdominal viscera healthy.

The case of Thomas Laws, æt. 35, admitted August 27th, 1835, was a remarkable instance of the success of the hepatic treatment. The general appearance of the patient was most striking: although only 35 years of age his hair was grey, and he had all the appearance of a man of 60, and but for his repeated assertions to the contrary, it would have been difficult to believe otherwise; his countenance was indicative of extreme suffering; he was greatly emaciated; both knees were in a state of contraction and enlargement from synovitis, and so painful that he could not bear the pressure of the bed-clothes; there was a tumor of some considerable size over the left tibia; he was labouring under constant cough, with copious bronchial expectorations; the abdomen was hard, unyielding, and very painful on pressure, especially at the flexures of the colon; the epigastrium was highly sensitive and acutely painful to the touch; bowels obstinately costive; great febrile action; profuse night sweats; he had been confined to his bed twelve months, and could only lie on his back. He had been ill altogether five years. By the occasional application of leeches and blisters in the region of the liver, combined with an alterative treatment of mercury, sarsaparilla, &c., and with careful attention to the bowels by aperients and enemata of warm water, he was sufficiently recovered at the end of about seven weeks to quit his bed, and though feeble could walk with the aid of crutches; the tumor over the tibia was fast suppurating: he left the infirmary, October 13th. He returned as an out-door patient, May 19th, 1836: his appearance at this time was wonderfully altered for the better: he informed me that the abscess over the tibia had not broken, but had been absorbed; he could walk several miles without difficulty, and had experienced no return of the local disorder. His general health was, however, somewhat deranged, and a similar but less active treatment to that of 1835 was now pursued, and he left September 13th, perfectly recovered. The manner of examining the liver requires some attention; it is best done with the patient in the erect position, by placing

the right hand on the loins of the left side for the purpose of support, whilst tolerably firm pressure should be made with the points of the fingers or thumb of the left hand on the pit of the stomach, a little to the right of the mesial line : in this way it is far easier to appreciate the degree of tenderness that may exist. It may seem unnecessary to dwell so particularly upon this point ; nevertheless it is very important.   Patients themselves are scarcely ever aware that any pain exists in the hepatic region, unless their attention is drawn to it by an examination so conducted.   I shall only adduce two out of the numerous cases that have passed under my obser- vation in support of this assertion. The first was that of an in-door patient, ad mitted at the infirmary in the year 1832: he was suffering from hydrops articuli of the right knee joint ; the cap- sular ligament was greatly distended with what seemed to be a thin fluid, for, when under examination, it gave the sensation of a bladder filled with water, the parietes scarcely feeling thicker than that membrane in a state of dis- tension ; he walked with great difficulty by the aid of a stick.   During a period of six weeks, a variety of remedies were employed, counter-irritants, such as blisters, tartar emetic ointments, &c. ; subsequently warm salt water bathing, the douche bath, warm and cold, the iodine preparations* in the form of lotions, the ointments of iodide of lead and mercury ; alteratives were exhibited, iodine, sarsaparilla, &c., but all without producing the slighest amelioration in the symptoms.   Being dissatisfied with the slight progress he had made, I determined to investigate more care- fully the state of his general health, which he constantly affirmed to be ex- cellent.   Accordingly at a subsequent visit I found the pulse rather quicker than natural, and slightly jerking ; his tongue very far back was covered with a thick fur of a dirty buff colour ; the alvine excretions were rather dark coloured, but not deficient in quantity . I now determined to examine the liver ; the pressure exerted in so doing was not great, but he started back and in- sisted that he had been used very roughly, and complained of great pain.

This determined the subsequent treat- ment ; eight leeches were applied to the epigastrium, followed by a blister ; a pill of calomel and opium was ordered every night at bed time, followed by an occasional saline aperient in the morning.   The patient declared him- self averse to the treatment, and insisted that he was quite well ; nevertheless he submitted to it.   The next morning I found the capsular ligament was much less distended ; he expressed himself greatly relieved.   In the course of a fortnight the fluid was entirely absorbed, and he left the infirmary at the end of that time perfectly recovered.   In the summer of 1835 I was consulted by an intimate friend about his son, a youth of sixteen or seventeen years of age, on account of slight enlargement of the cervical glands, which he said were occasionally painful.   Upon ex- amination I found several of them on either side of the neck enlarged to about the size of a pigeon's egg.   On ques- tioning him as to the state of his health, he said that it was excellent.   Notwith- standing I found the pulse small, and ranging from 80 to 90 beats in a minute ; the tongue was slightly furred at the back.   On making pressure in the hepatic region he shrunk from the touch, but insisted that it did not give him pain ; on repeating it he suddenly turned very sick, and fainted.   I ad- vised a similar local treatment as in the former case, and prescribed an alte- rative course of medicine : the glandular swellings were immediately relieved. The further treatment, however, was not persevered in, as he persisted that he was quite well.   He died of phthisis about eighteen months since.

It may seem that I have laid too much stress upon the hepatic symptoms ; yet if it be acknowledged that the liver is congested during scarlatina (as pointed out by Dr. Graves), and that scrofulous cachexia does frequently en- sue as a consequence of this fever, surely its importance as an exciting cause cannot be overlooked.   The clear and minute account afforded by Louis of the organic changes which take place in the digestive organs of those who die of phthisis, can leave no reasonable doubt on the minds of any one as to the vast importance of constant atten- tion to the state of them when treating such cases.   Finally, it seems to me highly probable, that a deranged state

of the digestive functions must, in all cases, precede the deposition of tubercular matter, in whatever structure of the body it may be localized. Whenever we are called upon to treat tuberculous affections, we must regard them as the termination of a disease, and not as its commencement; for all the phenomena which follow are only so many means adopted by nature to rid the system of a foreign body. That tuberculous matter may be deposited in almost every part of the human frame is sufficiently demonstrated, and that wherever loose tissue exists there will it be found in the greatest abundance; accordingly the lungs are ever the most frequent seat of it. Much more might be said on this highly interesting subject, but, as I have already stated, I do not intend to pursue it further than is necessary to my present subject, I shall conclude by observing, that the circumstances which give rise to scrofulous diseases are seldom if ever apparent to the patients themselves, or to those who have charge of them; and that we are rarely called upon to treat them, until evidence is given of their existence through the medium of one or more of the various local affections to which they give rise. The slight constitutional disturbance accompanying many strumous cases has often been the source of comment, but it is far more serious than is generally imagined. As children are more affected with tubercles than adults, we should never omit to impress on the minds of those who have charge of them the great necessity of attention to the excretions. It might excite the incredulity of some persons to be told, that clay-coloured evacuations alone were sufficient to indicate the presence of the tuberculous diathesis, yet nevertheless such is the fact. I shall now pass on to the consideration of the symptoms of hip disease.

[To be continued.]

DEATH AFTER NATURAL LABOUR.

To the Editor of the Medical Gazette.

SIR,

IF you think the enclosed case likely to interest any of your readers, you will oblige me by its insertion.—I am, sir,
Your obedient servant,
JOHN CHATTO.

23, Great Coram Street,
Feb. 13, 1841.

A. B., æt. about 25. This patient's health was formerly very good, but, during the latter period of her pregnancy it became much shattered by a severe attack of rheumatism, and poignant mental distress, occasioned by the misconduct of her husband. I saw her a few weeks prior to her confinement, when there only remained, of the rheumatism, a stiffness of one of the wrists, and great debility, attributed by her, in a great measure, to the severe antiphlogistic treatment to which she had been subjected. However, as her time approached, by the aid of tonics, she got much better, although always very "nervous."

I was summoned to her on account of her labour on the 27th of November; and found her suffering pain of a rather peculiar kind. At intervals she was seized with a violent pang, referred to the lowest part of the spine, and accompanied with a temporary but most severe dyspnœa. When this passed off she felt very feeble; but her pulse was by no means low: she also vomited frequently in a distressing manner. Circumstances prevented me making an examination per vaginam at that period; and, prescribing an anodyne in an effervescing draught, I left her. In a few hours I was again sent for, when I found the above suffering replaced by true labour pains, and good dilatation of the os uteri, the liq. amnii being already discharged. The pains continued vigorous, she (to use the old woman's phrase) " bore" them well, and the labour was completed in an hour. The placenta was detached by the same pain which terminated the delivery of the child, and was at once removed; the uterine contraction was good. In the intervals of the pains she complained urgently of feeling so very weak and feeble; although neither her pulse nor voluntary exertions indicated a state of debility.

After the birth of the child she exclaimed, with marked fervency, " May God be praised!" and soon after sank into a listless state, her face resembling that of one exhausted, and her respiration being much hurried. Her pulse, however, though quick, possessed some power, and the contraction of the uterus continued good. A bandage was applied firmly, and some brandy and laudanum were administered. I waited with her two or three hours longer, until she had considerably rallied, when, having ascer-

tained that no flooding had occurred, and the uterine contraction continued firm, I left her. I was, however, in two hours after again called to her, her friends supposing that she was on the point of death. I found her in the same position on the bed I had left her in, almost pulseless, and, indeed, manifesting every symptom of the extremest prostration. This state I learned came on shortly after I quitted the house. I at once suspected uterine hæmorrhage, and was surprised to find that no more than the usual discharge had occurred, and that the contraction of the uterus continued complete. Stimuli were very freely administered, and I availed myself of the benefit of Dr. Lee's advice. A slight degree of rallying took place, but this was soon followed by a relapse, and she died about eighteen hours after delivery.

Her body was examined by Dr. Lee and myself next day, when all the viscera were found quite healthy, and no cause of death could be discovered. The uterus was well contracted, and quite healthy, containing a large coagulum in its cavity.

I attribute this catastrophe chiefly to the almost heart-broken state in which the patient passed the latter period of her pregnancy; as her physical debility prior to labour was by no means excessive (it is well known how favourably women often go through the process even when exhausted by long-standing disease), nor her sufferings during it prolonged.

EXTENSIVE ABSCESS

SITUATED BETWEEN THE CRICO- AND THYRO-ARYTENOIDEI MUSCLES AND THE LINING MUCOUS MEMBRANE.

To the Editor of the Medical Gazette.

Sir,

THE case enclosed presents some interesting points in its pathology and diagnosis: should it appear to you worthy of a place in your valuable journal, you will oblige me by inserting it.—I am, sir,

Your obedient servant,

SAMUEL B. COWAN, M.R.C.S.

Harrow, Feb. 16, 1841.

Josiah Adams, æt. 19, a labourer, of a sanguineous temperament, temperate habits, having enjoyed generally a good state of health, came under my care November 30th, 1840, labouring under symptoms of continued fever.

The attack, at first sthenic in its character, soon assumed the typhoid type, induced chiefly by copious and repeated bleedings from the left nostril, which for two days continued in spite of remedies, and could only be restrained at last by plugging the posterior nares.

The whole course of the attack was attended by slight pectoral symptoms, and partial loss of voice, which his friends have since told me existed some months previously, but which I then attributed to a congested condition of the pulmonary mucous membrane, so common in these cases. I cannot ascertain if he ever had syphilis.

He gradually recovered from the more severe symptoms, daily acquiring flesh and strength under a tonic regimen; and up to January 27th continued in a course of steady and progressive improvement.

27th.—This afternoon he was very much frightened by a cat, which flew at him, but did not bite him, and which, in his extremely debilitated state, caused great agitation and excitement; at the same time inducing considerable exertion of the voice in calling loudly for help. He did not recover the fright for some hours, and during this time, his wife told me, the respiration continued hurried, irregular, inspiration being attended by a great effort and a shrill croupy sound; expiration more free, but accompanied at intervals by a dry, short, hoarse cough, which she likened to the barking of a dog. I was not sent for until the next morning.

28th.—I found him this morning looking extremely anxious, nostrils dilated, shoulders elevated, respiration hurried; irregular spasmodic inspiration, attended by a crowing croupy sound; expiration short, and frequently interrupted by a hoarse barking noise. Voice husky, thick, weak; expectoration copious, very viscid. There is no apparent swelling or local pain about the larynx. Tongue coated: pulse very irregular, varying from 90 to 120, extremely soft and compressible.

R Emplast. Lyttæ gutturi applic.
R Hydrarg. Chloridi; Sacchari, aa. gr. ij. ft. pulv. 3tia quaque hora sumend. An emetic of Ipecac. immediately. Hot pediluvia.

29th.— He found great relief from the emetic bringing up a quantity of

viscid mucus; no appearance of a false membrane. The crowing still continues, with the peculiar cough: the symptoms improved towards evening, there being distinct intervals of aggravation.

> Continues the remedies as before, and was ordered an embrocation of croton oil to the larynx.

30th.—Says he is better. Croupy symptoms continue; expectoration thinner, less copious; symptoms increased towards evening.

31st.—Passed a better night; voice weaker; restlessness; anxiety; countenance duller.

> Continues his remedies; mouth not sore.

Feb. 1st. — Symptoms unchanged; pulse quicker, 130, extremely compressible; complains of slight dysphagia; restlessness and anxiety continue, increased towards evening.

2d.—Passed a bad night; respiration attended by increased effort; croupy symptoms continue unchanged.

3d.—All the symptoms continue much the same; countenance duller; complains of drowsiness; strength much impaired. He was ordered to continue his remedies, with the addition of an antispasmodic mixture every six hours. Contrary to orders he eat a hearty dinner of meat, and died suddenly in raising himself in bed about an hour afterwards.

I was not sent for until more than half an hour afterwards, when I found life quite extinct.

Sectio cadaveris thirty-eight hours after death.—Externally, very slight if any swelling about the larynx; parts around the base of the tongue tumefied; papillæ at the base of the tongue very much enlarged. On removing the larynx and trachea, together with the œsophagus, and slitting it up posteriorly, the lining membrane of the trachea was found more than usually vascular, being œdematous towards its upper part; free mucus on its surface: no appearance of fibrinous deposit. On cutting through the cricoid cartilage, about three drachms of greenish yellow, apparently healthy, pus escaped, exposing an extensive abscess, whose centre had been cut through, situated between the crico- and thyro-arytenoidei muscles and the lining mucous membrane. Walls of the abscess thickened; cartilaginous in parts. The whole of the central posterior part of the cricoid cartilage was absorbed; the edges of the cartilage being seen on the left side in the centre of the abscess rough and irregular. Rima glottidis extremely small, not admitting a crow's quill; mucous membrane thickened, œdematous, corrugated, more than usually vascular. Corda vocales scarcely perceptible; ventricles of the larynx obliterated from the œdema. Glottis erect; mucous membrane somewhat thickened, vascular: œdematous at its base; œsophagus contracted immediately behind the abscess.

From the history of this case, and the sudden appearance of the more severe symptoms, we confess we found great difficulty at the time in arriving at any satisfactory diagnosis. The disease was evidently in the larynx; but its exact nature appeared extremely doubtful, from the sudden accession of symptoms, and the evident increase and decrease in the severity of the dyspnœa; the expectoration at the same time giving evidence of a certain degree of inflammatory action. From his extremely debilitated condition, state of the pulse, &c. we refrained from either general or local bleeding, and put him on the treatment of chronic laryngitis, for want of a better conception of his case. Had we been summoned sooner at the last, we should have opened the trachea, which we did not feel justified in doing in the previous stages, and in this way prolonged life: whether permanently or not, it is difficult to say.

DAMAGED TEA.

To the Editor of the Medical Gazette.

Sir,

I was last night at the house of a highly respectable tea-dealer, who shewed me a sample of the damaged tea from the ship "Westminster;" which, as is well known, after having been sunk in the sea, has been washed, kiln-dried, and offered for sale. The tea is of a dirty black colour, with specks of white or grey; it is soft, flexible, and dampish; not dry and crisp like good tea, and it has a faint sickly odour. The infusion has a nauseous smell, very much like that of senna; it has not the least vestige of the aromatic flavour of good tea, but tastes faint, sickly, and

somewhat saline and styptic, with a trace of putridity : in fact, just as one may imagine that half-decayed sea weed would taste.

Of course no one would drink such detestable stuff to gratify the palate. But as some very economical people might think its cheapness more than a compensation for its bad taste, it may be as well to hint to the public that decomposing vegetable matter is, in several forms, exceedingly noxious, and that this damaged tea cannot fail to be unwholesome.—I am, sir,

Your obedient servant,
ROBERT DRUITT.

6, Bruton Street, Feb. 12, 1840.

MEDICAL GAZETTE.

Friday, February 26, 1841.

PROPOSED ALTERATIONS IN THE UNIVERSITY OF CAMBRIDGE.

IF practitioners of physic are to rank as professors of a liberal art—if their name is to conjure up all that science and literature have to bestow on human life—it is clear that whatever concerns general education touches us most nearly, and that we must look with the highest interest on every progressive step made by our great schools and universities. In this age of rapid change, however, quiet men may be excused, if not praised, should they feel something like alarm at the sweeping improvements which are proposed, and something like distrust of the persons who, too often, propose them. Disappointment has been known to call itself patriotism, and spleen would pass for justice. In proportion to the frequency of these natural alarms must be the gratification of every right-minded man, when he finds reforms reasonable in themselves proposed by one whose name renders eulogium superfluous,

and who necessarily looks with affection on the time-hallowed institutions from which he borrowed the glory which he returns. Such is the case in a splendid instance now before us. Several important changes in the University of Cambridge are advocated by Dr. Peacock, the Dean of Ely, one who has been favourably known to every Cambridge man, we might add to every British mathematician, for the last quarter of a century. The work in which he has so ably set forth the grounds of these reforms is one which cannot avoid making a sensation in high places *. Dr. Peacock treats his subject with uncompromising firmness; and has the rare art of uniting arguments which must convince, with a delicacy which will necessarily please. In short, he mingles the useful and the sweet; and though we cannot suppose that he will carry off every vote, yet he will obtain a good many, and will, assuredly, gain his point at last ; for truth is great, and shall prevail. We are now speaking of his proposal to abolish University oaths; as to the alterations which he proposes in the system of study, there is, of course, more room for difference of opinion ; and we shall venture to record our dissent on certain points, though we are aware that, in disputing with the Dean of Ely on subjects of University education, we expose ourselves to have the adage ὑς Ἀθηνῃ quoted against us.

Dr. Peacock commences his learned and entertaining essay with an account of the ancient and statutable constitution of the University, and the alterations which it has undergone. Such has been the change which has taken place both in manners and studies since the age of Elizabeth, that though the statutes which she imposed upon the University still remain unrepealed,

---

* Observations on the Statutes of the University of Cambridge. By George Peacock. D.D., V.P.R.S., &c., Dean of Ely.

scarce a vestige remains of them in practice. The undergraduates of those days went to the University at the age of fourteen or fifteen. The collegiate discipline was suited to their years, and the rod was the punishment of their offences up to eighteen. Two, three, or four, chummed in the same room; and even in Trinity College no one under the degree of doctor of divinity seems to have had a chamber to himself. Among other severities of that disciplinarian age, no student below the standard of a bachelor of arts of his second year was allowed to go into the town, unless accompanied by a master of arts; and the use of the English language among gownsmen was utterly prohibited. At five o'clock in the morning they assembled in the College Chapel for prayers; at six they proceeded to the Hall to perform the College exercises; at nine they went to the public schools of the University, either to hear the lectures of the professors, or to attend the disputations required for the degrees of bachelor and masters of arts. " They dined at eleven o'clock, and at one o'clock they returned to their attendance on the declamations and exercises of the masters and bachelors of arts. From three o'clock until six they were at liberty to pursue their amusements, or their private studies; at six o'clock they supped in the College-Hall, and immediately afterwards they retired to their chambers." (Peacock, p. 8).

The bachelors of arts were intended still to reside at the university; and the three years which elapsed before they were admitted to the degree of master of arts were to be devoted to the study of the Aristotelian philosophy, astronomy, cosmography, music, and Greek. They were likewise compelled to be present at all public disputations of masters of arts. They also had to make three responsions, in addition to two by way

of practice, in *suo grege*, and a declamation. Every master of arts, on being created, was admitted to the *regency*, *i. e.* to the office of presiding over the disputations in the public schools, and this regency he was sworn to continue for five years. He was also to be a daily and diligent hearer of the lectures of the professors of theology and Hebrew, during the five years of his regency; and during this period was also to respond once (*i. e.* to maintain an argument against the objections of opponents), and twice to oppose a bachelor of divinity, "and after preaching once in Latin and once in English, at St. Mary's Church, and once likewise at St. Paul's Cross, he was, at the end of seven years, admitted bachelor of divinity." His labours, however, were not yet finished; for a similar course of studies and exercises was enjoined for five years more, at the end of which he was admitted a doctor in theology. The sum total was nineteen years of residence and study.

It is almost needless to dwell on the innumerable points of discipline and instruction which have gradually fallen into neglect, and almost into oblivion, since the days of Queen Bess. The name of Aristotle, which then swayed the schools with despotic authority, is now scarcely pronounced; and the scholastic logic, once thought the perfection of human wisdom, is now utterly forgotten. Nobody regrets this; no one would give up Newton for Aristotle, or Porson for "the grammatical institutions of Clenardus, Ceporinus, or Gaza;" every one has admired, and must admire, the University of Cambridge for the cautious zeal with which it has embraced every improvement in science, and every refinement of literature: yet still there remains one amendment to be adopted, which Dr. Peacock urges in the best possible tone, and in which every friend to the common-

wealth will agree with him. The system of education is wholly different from that which is enjoined by the statutes : no one desires to see the practice brought back to the theory ; then alter the theory to suit the practice—repeal the statutes. But this, it seems, cannot formally be done, at least with a great number of them. The code of statutes of the twelfth year of Elizabeth, as well as some other enactments, cannot be repealed by the authority of the senate alone ; then let them be abrogated by Parliament, or by the Queen in Council, as may seem most expedient, and let others be substituted which are recommended by the actual practice of the University. The most painful point, however, concerning these statutes, both university and collegiate, is, that the custom of swearing to observe them is still continued. In two instances, indeed, Dr. Ainslie, the Master of Pembroke College, (honour be to his name!) has succeeded in converting the oaths into equivalent affirmations, under the authority of the Duke of Richmond's bill. These are, the matriculation oath, and the one on taking the degree of bachelor of arts ; the others remain as they were. On these Dr. Peacock says—

" We have now considered the principal oaths which are required upon admission to degrees and to the regency; and every person who deprecates the attestation of the name of God, and the appeal to his vengeance, except upon the most serious and most solemn occasions, when important obligations are about to be incurred, and most responsible duties are required to be performed, will agree in wishing for their abolition or amendment. For we have found that they relate to observances which have become obsolete or impossible; to statutes which, to a great degree at least, have ceased to be obeyed; to studies and exercises which have ceased to be followed or performed; to payments which have ceased to be paid ; to official duties which have ceased to be discharged; to continued residences within the University which have ceased

to be demanded: whilst the few fragments of the real obligations which they impose are not generally of such a character as would appear to require the security of so solemn an act."

Mr. Tyler, whose treatise on oaths is quoted by the Dean of Ely, wishes for an entire abolition of the oaths administered by the University of Oxford. Dr. Peacock would seem to wish to retain the oaths taken by masters and fellows of colleges, after the statutes which they promise to obey have been reformed * ; but we confess that we do not agree with him.

The oaths of admission to degrees and creation have a *cautela* attached to them, by which the University declares that those who break the statutes, but submit to the consequent punishments, are not guilty of perjury ; and the juror always takes the oath *secundum tenorem senatus-consulti in cautelam jurantium facti.*

This *cautela* was framed in 1647, when the ruling party saw the danger of the oaths, but had not boldness enough to throw them overboard altogether : let us hope that the higher tone of the religious and moral feeling of this age may enable the present reform to be a thorough one † !

It is clear that sooner or later this improvement must come : we could wish it to be immediate. In considering the subject of College statutes (as distinct from University ones) Dr. Peacock comments on the restrictions to be found in the statutes of several Colleges relating to the counties in which fellows are born. In the fifteenth, and beginning of the sixteenth century, party feuds ran so high, and the factions of the *Boreales* and *Australes* fought so internecine a war, that it was thought necessary to enact in the Colleges founded at that

* Op. cit. p. 92-3.
† This *cautela*, we believe, is not annexed to Collegiate oaths, nor, indeed, to all University ones.

period, that not more than two fellows should be elected from the same county; or, in other instances, that natives of counties north and south of the Trent should be elected alternately. Should such statutes be retained? The Dean of Ely answers this question by an able distinction. The statutes of a College are often of two kinds; some being adopted from the laws of more ancient bodies, while others are the founder's own. The former may be considered as more especially characteristic of local and temporary circumstances; the latter, of the original and independent design of the founder. Now, when circumstances have entirely changed, when Cistrentani and Transtrentani live in peace and amity, the statutes which were merely based on their feuds may be repealed without violating the founder's will; but there are many instances of the limitation of fellowships to peculiar counties, or schools, where this rule does not apply, and where the preference evidently proceeded from some partiality of the founder; and in these cases the founder's wishes are to be respected, " even though by so doing we may not always consult the highest interests of the society to which such restrictions apply." Surely, this is carrying conservatism too far. All other entails can be broken, and why not these? If the possessor of an estate and his heir-at-law can disturb the course of succession intended by their ancestors, why should the will of some benefactor of the fifteenth century give an eternal and irrevocable preference to the minor merit of one county over the major merit of another? What the Dean says in another place of the inexpediency of unchangeable laws, holds good of legacies of unchangeable application; and the supreme power in the state can never have its hands tied by laws passed in the days of the Henries and the

Edwards. The University of Cambridge, however, on this as on other points, has set an excellent example; and the principal Colleges have thrown open their fellowships without distinction of counties.

SIR ASTLEY COOPER.

WE understand that Sir Astley has left his books and preparations, together with a small sum of money (£2000), to Mr. Bransby Cooper. He has also bequeathed £4000 for the purpose of founding an annual prize, to be competed for by the medical pupils of Guy's Hospital. The bulk of his fortune goes with the title.

A meeting is to take place on Thursday, March 4th, at 8 P.M., in the Freemasons' Tavern, " for the purpose of considering the propriety of raising a fund by subscription for the erection of a monument to the memory of this distinguished surgeon;" Mr. Travers to take the chair.

REPORT OF THE CASES
TREATED AT THE
ARDWICK AND ANCOATS DISPENSARY, MANCHESTER,

From the 30th of April, 1839, to the 1st of May, 1840.

BY RICHARD BARON HOWARD, M.D.
Physician to the Institution.

THIS dispensary, at which nearly 4000 patients are admitted annually, is situated in one of the poorest districts in Manchester. The persons to whom it affords relief are, for the most part, employed in the various branches of the cotton manufacture, and may, therefore, serve to afford some indication of the diseases most prevalent amongst this class of operatives. The majority of the patients are in a state of great indigence and destitution; they seldom have a regular adequate supply of wholesome food; are insufficiently clothed, and, from the nature of their employments, are often exposed to great and sudden variations of temperature. They reside in densely populated, filthy, and confined localities; their dwellings are damp, dilapidated, scantily furnished, and extremely comfortless—many of them cellars of the worst description—where they herd together in almost incredible numbers, without the least regard to order, cleanliness, or venti-

lation. Intemperance is very prevalent amongst them, and to this vice many of their diseases, and much of their poverty, is undoubtedly attributable ; though it has probably been too much the custom of late to ascribe their distressed condition too indiscriminately to this cause, whereas it has appeared to me to arise more generally from their frequent want of employment, and inability to work in consequence of bad health.

In a population suffering from so many causes of physical depression, it is not surprising that there always exists a large amount of disease, or that their complaints are generally of an asthenic type, and little under the control of medicines, or such other remedies as a physician to a dispensary has within his reach.

In the following report (which merely comprises the cases under the care of one of the physicians) the diseases have been classified, with few exceptions, according to the arrangement proposed by Mr. Farr. It is not professed that the name of the disease assigned to each case has always been strictly correct ;—such accuracy, in the present state of medical science, is impossible, and least of all is it attainable in dispensary practice. The irregular attendance of the patients, and the difficulty of obtaining post-mortem examinations, are here great obstacles. In the more trivial cases, it often happens that after two or three attendances the patient gets well and resumes his work, without ever taking the trouble of returning to be regularly discharged, and the physician has then no opportunity of confirming or correcting his first diagnosis. In the chronic or incurable cases, again, the patient not unfrequently becomes dissatisfied with his slow progress, and if there is a choice of charities, perhaps applies to another for advice, or more probably places himself under the care of a quack, who generally contrives, by a system of artifice or deception, to delude the poor sufferer into a belief of his power to cure his disease, until he has robbed him of his last penny.

When, from peculiar obscurity, there was a difficulty in referring the case to any strictly idiopathic affection, the most urgent symptom was assumed to be the disease, and has been registered as such in the table.

Yet, even with the liability to error from all these sources, such reports, if sufficiently numerous, cannot fail to afford useful statistical data.

CLASSIFICATION OF THE CASES.

Epidemic and Contagious Diseases.

Fever	80
Infantile remittent fever . . .	10
Variola	7
Rubeola	14

Scarlatina	40
Anasarca following scarlatina . .	20
Pertussis	9
Catarrhus epidemicus	7
	187

Diseases of the Brain and Nervous System.

Hydrocephalus	3

                                  80

Total number of patients, 914.

The cases of *fever* were generally of a mild character, and not marked by any peculiarity requiring particular comment. The disease prevailed chiefly in the most confined and filthiest parts of the district, especially in close courts and cellars, where great numbers were crowded together, and amongst the poorest and most destitute portion of the inhabitants. It was often distinctly traceable to contagion, and the occurrence of more than one case in the same house was very frequent.

Among the diseases of the epidemic class, the circumstance most worthy of notice was the great prevalence of *scarlatina.* I attended, altogether, sixty cases. Forty of these were admitted during the febrile stage, and twenty at a subsequent period, after the supervention of dropsy. Of the whole number, nine proved fatal, and fifty-one recovered.

The greatest variety prevailed in regard to the type of the disease : in many instances it was extremely mild ; in others it was of a very malignant character, proving rapidly fatal ; and I had frequently occasion to remark, that when one child in a family suffered from the complaint in the latter form, the others who were attacked had it severely also. This was not without exceptions, though the fact was usually as I have stated. In those cases where death occurred early, there were generally great swelling and inflammation of the parotid and sub-maxillary glands, which appeared, in many instances, to be the immediate cause of the fatal termination. Extensive sloughing of the throat was not so frequent an occurrence as I have known it in some other epidemics. In infancy the proportion of deaths was very large, and the younger the child the less was the chance of recovery. The period at which the eruption showed itself, its duration, and its shade of colour, were extremely various ; and its recession and reappearance in the course of the disease were by no means uncommon.

The most remarkable feature, however, in the history of the epidemic, was the singular frequency with which the disease was followed by dropsy. In no other epidemic of scarlatina have I witnessed so uniform a tendency to this formidable sequela of the complaint.

Nothing could be more uncertain than the period at which this symptom came on. In some instances its existence was perceptible almost immediately after the decline of the efflorescence, and in one case there was an interval of six months ; but the most usual time of its appearance was from ten or twelve days to three weeks after the commencement of the fever.

The œdema usually first shewed itself in the face, then in the inferior extremities, and, if not arrested by remedies, gradually extended over the whole body. In severe

cases, the general anasarca was followed by effusion into the serous cavities of the head, chest, or abdomen.

The urine, very scanty in quantity, re- sembled dirty water, or an infusion of coffee, in appearance, and was often as dark coloured as porter. In every instance in which I tested it, traces of albumen were exhibited on the application of heat or the bichloride of mercury, though sometimes only slightly so. The tongue was gene- rally white, and the pulse quickened, but there was seldom much febrile disturbance ; and, indeed, I have often been surprised at the remarkable absence of any particular feeling of indisposition on the part of the patients, who were not uncommonly inclined to play about and continue their juvenile amusements as usual. The appetite was often good, and sometimes positively vora- cious, during the whole course of this secon- dary disease. Frequently no great uneasi- ness or distress was experienced until the effusion in the chest became so copious as to interfere with the function of respiration. In some of the aggravated cases, where hydrocephalus threatened, obstinate vomiting was present, and constituted a formidable obstacle to the internal administration of remedies.

The rapidity with which this dropsical effusion occasionally accumulates, and the suddenness with which fatal symptoms sometimes supervene, when the patient appears to be going on well, requires especial attention, and points out the necessity of caution in giving a prognosis.

I have known more than one instance where a child, apparently in no danger, was seized without warning with convulsions, and died in a few minutes, in consequence of effusion within the head ; and I have wit- nessed death produced under similar circum- stances by rapid and unexpected effusion in the chest.

A favourable prognosis can never with safety be given until the secretion from the kidneys has been restored and become natural in appearance. As long as the scantiness and high colour of the urine continue, the case must be considered one of danger, even though all the other symptoms are improving. By the action of purgatives or of vomiting, or from some less obvious cause, the anasarca is often temporarily diminished ; but, unless the urinary secretion be at the same time re-established, the dis- ease always returns, or the patient often becomes suddenly and alarmingly worse. Relapses, indeed, were very frequent among the dispensary patients.

The severity of the original disease cer- tainly did not increase the tendency to dropsy ; on the contrary, it was, according to my observations, decidedly more frequent

after mild than severe cases. In some instances (where anasarca followed) the eruptive stage was so slight as scarcely to attract the notice of the child's attendants ; and presumptive evidence of its general mild- ness exists in the simple fact, that, in twenty of the cases, medical aid was not sought until the dropsy had supervened. Neither did a state of debility appear to predispose to it, for its occurrence was not more com- mon in children who were much reduced, than in those who were robust.

The cause which above all others seemed to be most powerful in giving rise to this formidable sequela of scarlatina, was ex- posure to cold ; and in this fact we have a ready explanation of its greater frequency after mild than severe attacks. In the former (in consequence of the trifling feeling of indisposition remaining, and the apparent little necessity for precaution), the children, of the lower orders at least, are generally allowed to go out of doors immediately on the subsidence of the fever ; whereas, the debilitated state of children who have suffered from the disease in a severer form, compels them to remain in bed, or, at any rate, confines them to the house for a considerable time ; and to this circumstance I cannot doubt that their comparative exemption from dropsy is attributable.

The extremely cold weather, and par- ticularly the chilling easterly winds which prevailed for a long period in the spring, when scarlatina was rife, appeared to be particularly active as an exciting cause of the anasarca. The frequent occurrence of other cases of acute dropsy at this time, where no predisposition to the disease had been ac- quired by an attack of scarlatina, indicated something in the state of the weather peculiarly favourable to its development. One of the cases of measles under my care was followed by anasarca ; an occurrence which, though rare, compared with its fre- quency after scarlatina, is mentioned as an occasional sequela by several authors.

With respect to the pathology of this species of dropsy, I think no doubt can be entertained as to the correctness of the generally received opinion, that it is of an active character, and not the consequence of debility. This is proved by many of the facts already stated, as well as by the success attending the employment of remedies of the antiphlogistic kind.

That disturbance in the functions of the skin should be a frequent consequence of an attack of scarlatina might naturally be ex- pected. The weakened state of the cuticular capillaries (the effect of their previous inordinate action during the eruptive stage), and their unusually unprotected situation, arising from the loss of the cuticle by desquamation, render them peculiarly sus-

ceptible of external impressions ; and any exposure to cold air at this time quickly checks the perspiration. In order to compensate for this suspended exhalation from the skin, and obviate the injurious effects of undue distension of the blood-vessels by its detention in the circulation, serum is effused into the cellular tissue, or the cavities lined with serous membranes. I am not inclined to consider the effusion as the result of inflammatory action : the absence of all febrile symptoms in many of the cases shows that this is not the case. The process appears to be merely the substitution of one kind of exhalation for another ; the natural excretion from the skin being checked, the system relieves itself by establishing a vicarious one.

I have no doubt that the utility of venæsection arises from its effect in relieving internal congestion and augmenting the activity of absorption, by lessening the mass of blood, according to the well-known principle first propounded by Magendie. When ascites, hydrothorax, or hydrocephalus, takes place, there are no symptoms indicating inflammation of the peritoneum, pleura, or the meninges of the brain ; nor has the fluid found in these cavities after death the appearance of inflammatory effusion. In the few cases in which I have had an opportunity of making post-mortem examinations, it was clear, and without any flakes of lymph. Neither did the serous membranes themselves exhibit any traces of inflammatory action. I have never observed any unusual appearance in the kidneys, further than slight congestion. It is important to bear in mind, however, that, in patients recovering from scarlatina, there is often a remarkable tendency to inflammatory attacks, and that these may, and often do, co-exist with dropsy.

In the *treatment* of this affection, by far the most efficacious remedies were the abstraction of blood, and purgatives. Except when an extremely enfeebled state of the circulation forbade it, bleeding was seldom omitted. The tender age of many of the patients of course precluded the adoption of general bleeding ; but in plethoric children, about the age of five years, I never hesitated to order a few ounces of blood to be taken from the arm, and was seldom disappointed with the result. When either of the two circumstances just mentioned seemed to render the propriety of general bleeding questionable, leeches were often applied with great advantage. In this mode, blood may be extracted so slowly as to avoid any dangerous shock to the system, and yet so copiously as effectually to relieve the loaded circulation. It will be observed, that we take away blood in this disease with a very different view from that which influences us in inflammation ; in the one case, our

object is merely to reduce the volume of blood circulating in the vessels, in order to remove congestion, and increase the activity of absorption ; whilst, in the other, our endeavour is to diminish the force of the heart's action ; and it is generally important to effect this with as little loss of the vital fluid as possible.

The embarrassed state of the respiration, and evident congestion of the lungs, naturally point out the chest as the most eligible place to which to apply the leeches. If danger is threatened from cerebral symptoms, of course they will be more appropriately applied to the head.

Next to the abstraction of blood, *purgation* is the most efficient remedy in this species of dropsy. It is not sufficient merely to remove the constipation which may exist : in order to obtain the full benefit of this class of medicines, it is necessary to produce copious watery evacuations, and, for this purpose drastic, or what are called hydragogue cathartics, are required. That which I have chiefly used is jalap, in combination with calomel, or the bitartrate of potash. Elaterium proved very efficacious in the few cases in which I gave it, but the extreme youth of most of my patients prevented me from prescribing it frequently. When, from the tendency to vomiting which often existed, powders were rejected, I generally prescribed pills composed of calomel, compound extract of colocynth, and scammony ; and these were often retained. In such embarrassing cases, enemata become a useful and necessary auxiliary.

Of *diuretics*, digitalis was the most beneficial. Colchicum was also certainly useful in several cases, sometimes acting on the bowels, and sometimes on the kidneys, and I am inclined to think will be found a remedy of considerable value in this disease ; but caution and watching are necessary in exhibiting it to children.

Tonics did not appear to me to have any effect in removing the effusion, and were only useful in relieving the subsequent debility. There was good evidence in some instances of the utility of the warm bath.

I shall confine myself to a few very brief remarks respecting the remaining diseases.

The case of ramollissement cerebri occurred in a man 34 years of age. His symptoms, on admission, were pain in the loins and all his limbs, but especially severe in the former place. It was not until he had been nearly three weeks under treatment, and about a fortnight before his death, that any marked indication of cerebral disease manifested itself. At that time he began to complain of violent pain in the head also, was occasionally delirious, had some tetanic spasms of the extremities, and experienced much distress and difficulty in

voiding his urine. On examination after death, the fornix thalami, and parts surrounding the lateral ventricles, were very greatly softened. In several points the cerebral substance was completely broken down, and reduced to a pulp, like thick cream.

The subject of tic douloureux was a delicate young woman, 23 years of age. Her disease, though severe, was not of long standing, and gave way to quinine, in combination with morphia, after iron had been tried without benefit.

Under the head of bronchitis and chronic cough, are comprehended several varieties of pulmonary disease — catarrhus senilis, chronic pneumonia, and probably some cases of incipient phthisis, in which the disease was not sufficiently far advanced to be detected either by the general symptoms or by the stethoscope. Many of the dispensary patients are spinners, cotton batters, or are employed in other manufacturing operations, by which the air is loaded with dust, and other irritating particles, and they are in consequence especially liable to diseases of the bronchial membrane.

The two cases of *vomiting* were somewhat singular. In neither patient could the symptoms be traced to any cognizable cause ; there was no evidence of disease either in the stomach, head, or spine. Yet the vomiting recurred regularly after every meal. Both cases were extremely obstinate, but both ultimately recovered. One was cured by creosote, after a variety of remedies had been tried in vain.

The morbid symptoms referred to *undue lactation*, occurred in delicate women, who were harassed by long-continued toil or depressing anxieties, and had not a sufficient supply of wholesome nutritious food. Such persons often suffer at the same time from leucorrhœa, or have a continuance of the menstrual discharge whilst suckling : a combination of weakening actions which quickly produces an alarming degree of exhaustion. Though often aware themselves of the cause of their illness, they are generally reluctant to wean their children, from a fear they should sooner become pregnant again.

Though only three cases are registered as *scrofula*, it must not be inferred that this disease is rare amongst the dispensary patients. On the contrary, it is extremely common, and the seeming inconsistency arises from the cases being classified according to the organ particularly affected : as the lungs, mesenteric glands, &c. When the joints or external parts were the seats of the disease, the patients were placed under the surgeons' care. It was only where the system generally was affected, without localization of the disease in any particular organ, that the complaint was registered as scrofula.

A very erroneous inference would also be

drawn, if it were supposed that only six instances of disease from deficiency of food occurred, as it was only where the unequivocal and direct effects of starvation were the sole symptoms, that the case was classed under this head. If an enumeration were made of all the patients, the origin of whose diseases could fairly and legitimately be traced to defective nutrition, the amount would be lamentably increased ; and if to this number were added those whose illness was attributable to want of the other common necessaries of life, clothing, fuel, and shelter, the result would exhibit such a melancholy and astounding picture of the wretched and destitute condition of the labouring classes, that by those who had never investigated the subject its truth would not be credited.

The winter of 1839-40 was one of peculiar suffering and distress amongst the poor in this district, owing to the high price of provisions, and the scarcity of employment ; and for not a small proportion of the cases admitted at the dispensary during that period, nutritious food, and not medicines, would have been the appropriate remedy.

ROYAL COLLEGE OF PHYSICIANS, EDINBURGH.

MEDICAL REFORM.

AT a meeting of the Royal College of Physicians of Edinburgh, called to consider the Report of a Committee of their body, on the Bills for Medical Reform, which have been introduced into the House of Commons by Mr. Warburton and Mr. Hawes, the following Resolutions were unanimously adopted:—

1st. That the College derive much pleasure from finding that the subject of Medical Reform, which has so often been under their consideration, and in which they have repeatedly endeavoured to interest the legislature, has at last been brought, in a tangible form, under the notice of the House of Commons ; and trust, that the full discussion which the subject has received, and is receiving, from the profession at large, and the attention now about to be bestowed on it by Parliament, will lead to the removal of some of the evils of which the College have frequently had occasion to complain.

2d. That, in the opinion of this College, the great evil arising from the want of an uniform system of medical legislation throughout the united kingdom, is the possession, by particular corporations, of local privileges, which render their Licentiates alone legally capable of acting as general practitioners in particular districts and portions of the country, to the exclusion of persons of equal, and it may even be, of superior qualifications.

3d. That, so far as the College is aware, the only plausible objection which has been urged against the abolition of these local

privileges, and against the adoption of a system for placing the Licentiates of all the Medical Corporations on an equal footing in respect of the right of practice, is the inequality alleged to exist, or actually existing, in the amount of Medical Education required of candidates for their licenses by the several Boards, and in the degrees of strictness with which the examinations of such candidates are conducted.

4th. That whilst, therefore, with a view to the interests both of the public and the profession, community of privilege should, in the opinion of this College, be the primary object of any legislative enactment relative to the medical profession, sufficient education and examination must, at the same time, be duly provided for.

5th. That from the communications which have taken place, and the understanding that has been come to, between a number of the different Boards with which the superintendence of medical education at present rests, little difficulty can now exist in fixing a minimum course of study, general and professional, without evidence of having passed through which, no one should be allowed to present himself as a candidate for a medical license. On this point the College will only farther refer to the joint resolutions agreed on by the Medical Faculty of the University, and by the Royal Colleges of Physicians and Surgeons, of Edinburgh, of date October 1838.

6th. That to produce some approach to uniformity in the system on which the examinations of candidates for licenses are conducted by the several Boards, and to secure the public against the admission of incompetent persons into the medical profession, it appears to this College that it would be desirable that some superintending body should be constituted, having authority to take cognizance of the manner in which the duty of examination is executed.

7th. That the persons of whom this Board should consist might probably be most advantageously selected by the Crown from lists furnished by this and the other boards at present entrusted with the government of the medical profession.

8th. That, in the opinion of this College, no measure of medical reform will be satisfactory which does not confer on a person who has once received a certificate of his fitness to exercise the medical profession from any of the established Boards, the right of practising in any district of the country, or in any particular department of the profession, without the necessity of submitting himself to a second examination before another board.

9th. That whilst the College readily acknowledge that the proposal of creating a representative body or bodies, elected periodically by the profession at large, by which the affairs of the medical profession might be superinteded and directed—(a proposal which forms so prominent a feature in the two measures which have been submitted to Parliament)—is desired by many most respectable members of the profession, they are disposed to believe that this desire has in a great measure originated in accidental and removable causes; and they are satisfied that any attempt to carry it into effect would be attended with serious inconveniences, if not insuperable difficulties.

10th. That, in particular, the College conceive that this proposal has in a great measure grown out of the dissatisfaction very generally prevailing among the members of the medical profession, not only with the local privileges of practice attached to the licentiates of particular corporations, as already noticed, but also with the narrow and exclusive system on which admission into the governing body of some of the medical incorporations has hitherto been regulated ; and that the adoption by, or enforcement on, these corporations of conditions of admission of a more reasonable and liberal character, in obtaining for them the confidence of their licentiates, would in a great measure supersede the desire at present existing for a representative system of superintendence.

11th. That among the obvious inconveniences with which the election of a representative body, by the medical profession at large, would be attended, the College conceive that it would have the effect of producing and continually renewing agitation and dissension among the members of the profession, and of directing their attention from far more important duties ; whilst those who are best qualified for performing the duties that should be committed to a superintending body, would be least likely and least able to take those steps which are essential to the gaining of popular suffrages. And, as a farther objection to the Boards proposed, in the bills before Parliament, to be established for the regulation of the profession, it may be remarked, that, from the multifarious duties intended to be committed to their members, and the necessity which would be imposed upon them from time to time, of leaving their homes for execution of these duties, it would be impossible to obtain the services of persons of eminence and station in the profession ; and that the appointments would therefore fall into the hands of an inferior grade of individuals, in whom neither the public nor the profession would have confidence.

12th. That whilst the College readily acknowledge that the actual constitution of

some of the medical corporations in the united kingdom requires to be rendered more conformable to the spirit of the age, they are not disposed to admit that these institutions are so useless, or so incapable of amendment, as to make it advisable either to abolish them by direct, or to supersede them by indirect legislation, the acknowledged fact being that, notwithstanding any defects under which they may labour, the country is, through their agency, provided, at the present time, far beyond all precedent, with well-educated and judicious practitioners.

13th. That it would be desirable that the duty of examination should be remunerated in such a manner as to remove the possibility of a suspicion, that the examiners have a pecuniary interest in the number on whom they confer the license to practise.

14th. That, considering the large amount of services gratuitously rendered to the public by the medical profession, the very inadequate compensation received by a large proportion of its members for the long and expensive course of education necessary to qualify them to practise, and for the performance of its very laborious duties ; and considering also the direct interest which the public has in being able easily to distinguish between qualified and unqualified practitioners of the healing art, the College are decidedly of opinion, that any additional expenses which might be occasioned by an improved system of medical legislation should be defrayed out of the public purse, and not by an annual tax upon the profession, as seems to be contemplated in the measures which have been submitted to Parliament.

15th. That the College consider that it would be highly desirable that a scheme should be arranged for the registration of licensed practitioners. That, in their opinion, none but registered practitioners should be legally eligible for any public professional situation ; that the assumption of a professional designation by a person not entitled to it, should be declared an offence punishable at common law ; and that the right of suing in Courts of law for professional remuneration should be secured to licensed, and denied to unlicensed practitioners. But, in recommending enactments to these effects, for the encouragement of the licensed, and the discouragement of the unlicensed, the College is convinced that the suppression of unlicensed practitioners is beyond the reach of legislative interference, so long as there exists a taste for this species of practice in the public mind.

Edinburgh, Feb. 12, 1841.

WINDOW TAX ON HOSPITALS.

To the Editor of the Medical Gazette.

Sir,

You will observe that the Commissioners of Taxes have declared, in the enclosed paper*, that work-houses are, in certain cases, discharged from window-duty, notwithstanding which I find they have declared, on the supposed authority of the Westminster Hospital, printed case No. 1154, that under similar circumstances to work-houses, hospitals are not exempt, although "hospitals" are expressly named in the very exemption clause alluded to.

I find that many hospitals are not charged with window duty at all. That other hospitals are charged for the rooms of officers and servants 1s. 9d. a window; others are charged on the scale of progressive duty, 2s. 1d. a window; others 5s. 2d. a window, 3s. 9d. a window, 2s. 10d. a window, and 6s. 2d. a window.

An order has been made by the House of Commons for a return of window duty charged on hospitals, and when that shall have been done, these and many more inconsistencies will appear officially. But, in the meantime, the governors of hospitals which are charged should give notice of appeal, as the current tax year will expire on the 5th April. See 48 Geo. III. c. 55, schedule A. Rule 8, and Exemption 2 ; 4 Geo. IV. cap. 2, sect. 2, and 3 Geo. IV. c. 7, sect. 1.

Observe, Rule 8 speaks of public hospitals ranging with universities, &c. (and meaning, I conceive, Haslar, Chelsea, Greenwich, and such like), but Exemption 2 speaks of hospitals (not using the word public) ranging with charity schools, &c. and meaning, as I conceive, such as are maintained by voluntary contribution. The attention of the judges not having been led to this distinction may have induced them to give an erroneous decision in the Westminster Hospital Case ; and, at all events, I cannot discover how the windows in that case were reduced under the 4 Geo. IV. c. 11, to 1s. 9d. each window, without being wholly discharged by the 3 Geo. IV. cap. 7, sect. 1.

Should the windows of hospitals be charged at all ?

I hope you will deem this information of sufficient value to be made public.

I am, sir,
Your obedient servant,
A Governor.

Feb. 23, 1841.

* We have not thought it necessary to insert the paper alluded to.—Ed. Gaz.

THE RIGHTS OF THE UNIVERSITY OF ABERDEEN.

To the Editor of the Medical Gazette.

SIR,

HAVING had my attention called by several professional friends to an attack on the University to which I have the honour to belong, I feel it my duty to request of you to give place to the following reply, which I enter upon with reluctance, but without humiliation, conscious as I am, although one of the accused, that whatever is disgraceful in this attack belongs only to the accuser. I could have wished that I had been in circumstances that would enable me to refer to documents, and to particularize dates; yet I hope that no material inaccuracy will occur to affect the subject of discussion.

You have represented the University of Aberdeen as a College " empowered to confer degrees in Arts," but which " never received any shadow of authority to confer any degree except in Arts;" that in 1728, as, you say, " is believed," Marischal College " was pleased to confer on itself the power of conferring on others the degree of Doctor in theology, law, or medicine." Her degrees, you say, " are not degrees at all, and are worth no more than the parchment and wax of the diploma." You say, that " if Marischal College had created Baronets as well as Doctors," it would be " a step equally justified by their Charter;" and you conclude by alleging " that any ten gentlemen who choose to seat themselves round a table have exactly the same power. The College, then, in its new scale of fees, has unconsciously estimated its degrees at their real value—*nothing*."

In this manner, sir, have you selected a period when, if I remember well, the University of Aberdeen became illustrious in scientific history, as the place where Newton's Philosophy was taught first from the lips of Colin Maclaurin, as the earliest date of a fraud that has been continued for longer than a century.

You say, " we speak advisedly. We have now lying before us all the charters, acts, and muniments, of Marischal College, printed by the Royal Commissioners, for visiting the Scottish Universities." Therefore, sir, you cannot be ignorant that there have been several reports made by successive Commissions. These reports are very elaborate. A general report relating to *all* the Universities of Scotland was drawn up by some of the most eminent lawyers and clergymen in Scotland, in conjunction with several of the leading nobility of the country. Allow me, then, to ask, is there in that general report, or is there in any of the subsequent more special reports of other commissions to visit the *Universities* of Aberdeen, a single word stated by the Commissioners to indicate that they regarded the Marischal College and University as less a University than any of the others in Scotland ? Pray, sir, do us the justice to answer " advisedly."

I am no lawyer, sir, and therefore am ill qualified to do justice to a discussion of this kind; but I have had sufficient interest in the history of the University to which I have the honour to belong, to be able to state as much, in a plain way, as will enable your readers to appreciate the character of your attack.

Prior to the Reformation there were three Universities in Scotland—St. Andrew's, Glasgow, and Old Aberdeen. These, having been all founded by the Papal authority, and under the management of the bishops, became almost altogether extinct on the national change in religion, until the zeal of some of the distinguished reformers caused them to be remodelled, so as to be in accordance with the altered circumstances of the country. The modifications in question were all made by the sanction of the Scotch Estates in Parliament. About the same time two new Universities were instituted by Protestant enterprise; the University of Edinburgh, by King James, and the present University of Aberdeen, by the Earl Marischal. The charters of both Universities were confirmed by parliamentary authority.

Under the poverty and in the distracted state of Scotland at the Reformation, extended Universities, such as exist in our own happier times, could not be looked for. Small schools of Arts made up the principal portion of every University in Scotland in those days; but, according to opportunity, some provision for theological education was also made by the reformers; and you are under a mistake when you say that in Marischal College no provision was made for theological instruction, for, from the first, nearly the same provision was made in Marischal College as was made in the Glasgow College in the University of that city.

In a national chartered institution, it is not at all unusual that, as occasions arise for its enlargement, the original Charters should be found narrow enough to give occasion to questions as to their interpretation under new circumstances. In the University of Aberdeen, there has to the present day, so far as I am aware, never been occasion to justify its rights to grant the degree of Doctor; but, incidentally, in the transactions of another University, these rights were brought under the review of the supreme Court of Appeal in the case of a disputed election to the office of professor.

The case happened about a hundred years

ago ; and the particulars, so far as material to the present question, and as may be gathered from printed papers in the cause, are these :—To hold the office of Professor of Civil Law in the University of Old Aberdeen, it is necessary to be a Doctor of Laws. A certain candidate was elected to this office, being LL.D. in the Marischal University. His qualifications were disputed by an opposing candidate, who held the votes of a minority of the electors. I need not say, that, in such a case, it was no discredit to the University that an interested party chose to dispute its authority. The circumstance, however, caused the charters and the constitution of the University to be considered by the House of Lords, by whom, through Lord Chancellor Hardwicke, the case came to be decided, and the disputed qualification sustained. I am entitled to call your attention particularly to this decision. It was given within twenty years after the time when you say the University " conferred on itself" the power of granting the degree of Doctor ; and, I can assure you, the rights of the University were vindicated, not from a reference to immemorial practice, but upon rights conferred by charter, and sanctioned by Parliament. " Advisedly" as you say you profess to have considered the same subject in a legal point of view, I may yet be permitted to remind you, that a decision of the House of Lords, undisputed for a century, constitutes what is regarded to be the law of Scotland. So undisputed, indeed, is this decision, that the present holder of the office alluded to, holds upon no other qualification than precisely the same degree, conferred by precisely the same University. It is remarkable enough that the office of principal of King's College, likewise in the University of Old Aberdeen, which can be held only by a Doctor of Divinity, is at present held by a Graduate of the Marischal University ; and as to the degree of Doctor of Medicine, when the University of Old Aberdeen, for want of sufficient medical examiners in its own body, selected an extra University Examiner in Medicine, that University judiciously made choice of a well qualified gentleman whose only right to teach or practise medicine lies in his diploma of M.D. from the Marischal University.

It is little more than a year ago that Her Majesty was pleased to institute a Regius Professorship in Anatomy, and another in Surgery, in *her University of Aberdeen*. By a like authority a Professorship of Medicine was instituted more than a century ago. Sir, you say *it concerns the honour of the profession* to represent, as you have done, the gentlemen holding such offices and myself— fulfilling according to the best of our ability the high functions entrusted by the country to our charge—acting under the authority of

ancient charters ratified by Parliament, and sanctioned by the decision of the highest court of law ; members of a University, whose existence, in all its privileges, is guaranteed by the treaty of national union—as no better than a gang of impostors. Malign us as you may, and possibly you may succeed, in your " concern for the honour of the profession," to degrade us in the eyes of such as know us not ; it is yet some consolation to think that the students, among whom we move—to whom our characters and principles are known—will look with scorn upon your attack upon our motives ; and that these have not been mistaken, and have been appreciated by our fellow citizens, insomuch as to make it expedient for our traducers to seek an audience among strangers.—I have the honour to be, sir,

Your obedient servant,

THOMAS CLARK, M.D.
Professor of Chemistry, Marischal
College, University of Aberdeen.
Tavistock Hotel, Covent Garden,
Feb. 23, 1841.

[The above was. received as the sheet was passing the press, and we have no time to make any remark upon it, but if on reperusal it appear to require any answer, we shall give it next week.—ED. GAZ.]

ELIXIR OF VITRIOL.

AMONG the relics of old pharmacy retained in the French Codex, is the preparation known by the several names of *Teinture aromatique, Elixir vitriolique de Mynsicht*, and *Tinctura aromatica sulphurica*. Lest any of our young readers should confound it with the aromatic spirit of ether of the Pharm. Lond., 1824, we will observe that the Parisian elixir is made without distillation. The French receipt is as follows :—

Take of the root of sweet flag, an ounce ; galangale *(Galanga officinalis)*, an ounce ; chamomile flowers, half an ounce ; sage leaves, half an ounce ; wormwood leaves *(Absinthium officinale)*, half an ounce ; curled-leaved mint *(Mentha crispa)*, half an ounce ; cloves, three drachms ; cinnamon, three drachms ; cubebs, three drachms ; nutmegs, three drachms ; ginger, three drachms ; aloes wood *(Aloexylum agallochum)*, one drachm ; lemon peel, one drachm ; white sugar, three ounces ; alcohol, two pounds ; sulphuric acid, four ounces.

The solid substances are to be reduced to a course powder, then put into a matras, and eight ounces of alcohol poured over them. After forty-eight hours' maceration, the sulphuric acid is to be gradually mixed with them, and the mixture is to stand for twenty-four hours ; the rest of the alcohol is then to be added.

SUBCLAVIAN ANEURISM.

On Saturday, the 20th instant, Mr. Partridge, at the King's College Hospital, tied the subclavian artery in the first part of its course, for an aneurism which had existed in the vessel for about twelve months. After the operation pulsation was no longer perceptible in the tumor ; and for the first two days, the patient, who bore the operation very well, went on as favourably as could be expected. We believe this is the sixth time that the operation has been performed, and in no case has the individual ultimately recovered ; for we regret to say that Mr. Partridge's patient died on the 24th.

MEDICAL APPOINTMENT.

Dr. Forbes (late of Chichester), has been appointed Physician to her Majesty's Household. [This appointment has been held by Sir James Clark, in addition to that of Physician in Ordinary to the Queen, since the decease of William IV. up to the present time, and is now relinquished in favour of Dr. Forbes.]

RECEIVED FOR REVIEW.

Dr. Williams on the Pathology and Diagnosis of Diseases of the Chest.

Illustrations of the Practical Operation of the Scottish System of Management of the Poor. By W. P. Alison, M.D. (Read before the Statistical Section of the British Association, September 1840.)

Organic Chemistry, in its applications to Agriculture and Physiology. By Justus Liebig, M.D., &c. Edited from the MSS. of the Author, by Lyon Playfair, Ph. D.

NOTICE.

Dr. Hocken begs to state, that, by some unaccountable oversight, the combined actions of the obliqui, and also of the recti muscles, in his paper of last week, were misplaced. The obliqui cause elongation of the axis of the globe, and are therefore used in near vision, and *vice versâ*. The contrary was stated in his paper.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

By Dr. Watson.

Lecture XXIV.

Delirium tremens, concluded. Chronic inflammation of the brain. Softening, suppuration, abscess, induration. Tumors in the brain.

I DREW a rude outline, yesterday, of that singular and interesting malady usually denominated *delirium tremens.* The disease is very common in this country; for its causes are in common and powerful operation. You will meet with it in every walk of life: and you will be almost sure to witness several examples of it during the course of every year, in any of our metropolitan hospitals. It is not a chronic or vague complaint likely to be treated with *placebos,* or by waiting upon nature. Active measures are pretty certain to be adopted; and, in many cases, one plan of treatment, vigorously pursued, will hurry the patient to his grave; another plan will restore him to health with an almost magical celerity. It certainly bears a strong resemblance to that most formidable disease, inflammation of the brain and its membranes: but the great remedy for encephalitis acts like a poison in pure delirium tremens; and the drug, by the timely and careful administration of which we can often promise a speedy cure in delirium tremens, is one which we must carefully avoid, in the earlier treatment at least, of encephalitis. Accuracy of diagnosis, therefore, between these different disorders, with similar outward signals, becomes of the very highest importance.

Delirium—tremens.—There is delirium always; and there is generally, but not always, tremor. The name is a good enough name, in my humble opinion; yet it has been found fault with, because the trembling is not always present; and some have, therefore, christened it *delirium è potu,* or *delirium ebriositatis*: but these terms are open to just the same objection as the other; for though the disorder is most commonly connected with intemperate habits, that is not always the case. One very curious fault has been discovered in the name: it is said that the delirium cannot *tremble;* and, therefore, that it is better to say, *delirium cum tremore,* or *tremefaciens:* and you would hardly suppose it, but there has been a sort of contention for the honour of thus mending the nomenclature of this disease. But they who object to *delirium tremens* appear to see no harm in *delirium ferox:* whereas it is just as incorrect to say *delirium* is fierce, as to say that it trembles: it is the patient who is furious, even as it is the patient who trembles; and all this dispute about a name is mere trifling. It matters not what we call a disease, so that the name conveys no erroneous theory as to its nature or treatment. No such source of error attaches itself to the term delirium tremens: and, therefore, if it be only to avoid the inconvenience of change, we will adhere to that term.

Recollect that the strong features of the complaint are sleeplessness; a busy, but not angry or violent delirium; constant chattering; trembling of the hands, and an eager and fidgety employment of them. To these are added other symptoms which, though they are not so calculated to strike a looker on, are of not less importance, inasmuch as they help to establish the diagnosis. The tongue is moist and creamy; the pulse, though frequent, is soft; the skin is perspiring, and most commonly the patient is drenched in sweat. The sweat is usually described as having an offensive or a peculiar

smell : I cannot say that I have observed it to be so. The face also is said to be pale ; but that, I know, is not always the case, and therefore this point cannot be relied upon as a distinguishing circumstance. In one of the instances which I related in the last lecture, the face was flushed, and the eyes red and ferrety.

Let me remind you, in a few words, of the peculiar characters of the delirium. If you question the patient about his disease, he answers quite to the purpose ; describes, in an agitated manner, his feelings, puts out his tongue, and does whatever you bid him : but immediately afterwards he is wandering from the scene around him to some other that exists only in his imagination. Generally his thoughts appear to be distressful and anxious ; he is giving orders that relate to his business to persons who are absent ; or he is devising plans to escape from some imaginary enemy : he fancies that rats, mice, or other reptiles, are running over his bed, or that strangers are in his room. He is perpetually wanting to get out of bed, but he is readily induced to lie down again. It is very seldom that he meditates harm, either to himself or to others ; there is rather a mixture of cowardice and dread in the delirium.

All the points that I have been mentioning require to be investigated in every case of this nature : and an inquiry into the previous history of the patient, into what the French call the commemorative symptoms, is equally important. In a large majority of instances you will find that he has been an habitual drunkard ; and very frequently that from some reason or other this habitual stimulus has been diminished or taken away. Some accidental illness has befallen him, and he has been restricted to low diet, and as a sailor would say, " His grog has been stopped." When, with symptoms such as I have mentioned just now, you hear a history of this kind, you may be satisfied that the disease is not inflammation of the brain, but delirium tremens. I believe that habitual intoxication of any kind may lead to this disorder ; but distilled spirits more so than wine ; wine more than beer. I make no doubt either, that what is alleged of the habitual use of opium, in preparing a person to suffer in the same way upon its being withheld, is quite true, although I have had but few opportunities of noticing such cases.

But the disease is not confined to drunkards, although it is so commonly connected with that pitiable vice, as to have been called *mania è potu*. You meet with it occasionally in men who have overstrained their nervous system by other modes of strong excitement. Long-continued mental anxiety, that state of mind in which gamblers and great speculators (who indeed are gamblers) are accustomed to live, may cause it ; any thing by

which the mind is over wrought. A well-informed medical man, of temperate habits, told me a few days ago that he was on the brink of delirium tremens in the year 1825. He had foolishly entangled himself in some of the speculations which prevailed here like an epidemic at that period, and his mind was on the tenter-hooks of suspense and apprehension for some time. He could not sleep, and he found himself everlastingly chattering. It comes on in the course of certain diseases, as sometimes, for example, in apoplexy : and it is a very common result of bodily injuries and accidents, and of surgical operations ; or, I should rather say, that it often *follows* such diseases and casualties ; for it is, even then, the consequence of the treatment and regimen to which the patients are subjected, rather than of the surgical or medical complaint. And it is certainly *more* apt to occur, under these circumstances, in old people ; and in those who are younger, but have been known to be intemperate. So frequently does the delirium manifest itself upon the cessation of the accustomed spur, that the continually recurring stimulus has been regarded as the *predisposing*, and the privation of that stimulus the *exciting* cause of the affection. Sometimes, however, it comes on in men who are perpetually fuddled, even although they have not intermitted their usual indulgence in drink. We had a porter (an old soldier he had been) at the Middlesex Hospital, who was of great use to us as a subject to practise upon, and to shew to the pupils. I never saw him drunk, so as to be unable to perform his duty : but I cannot conscientiously say that I ever saw him sober. Every three or four months we were sure to have him in the wards with delirium tremens. Sometimes he fell into the hands of one physician, and sometimes of another ; but in one of his attacks he slipped through our fingers : I am not certain that he was not nominally my patient on that last and fatal occasion : but assuredly he was never an example of the disease coming on from the adoption of more temperate habits. We often find that the malady shews itself immediately after an unusually severe debauch, which has disturbed the stomach and bowels, and left behind it a proportional degree of exhaustion and languor.

Without knowing why it should be so, my own experience would lead me to the belief that delirium tremens is very uncommon among women. The number of beds for females in the physicians' wards of the Middlesex Hospital is somewhat greater than for males. On the men's side of the house cases of delirium tremens are very frequent ; whereas I scarcely remember any on the women's. Yet each sex is obnoxious to its main causes. The gin-shops of this town

are said to draw a fearful crowd of vota-
resses. And we might expect that the more
sensitive character of the female constitution
would render them especially liable to this
peculiar consequence of the abuse of alcohol.
My experience, however, is such as I tell you.
On the other hand, Dr. Roots thinks he has
seen quite as many instances of delirium tre-
mens attacking females as males. The result
of M. Rayer's observation is more in accord-
ance with my own. Of 176 patients seen by
him, 7 only (not 1 in 25) were women. A
still smaller ratio is recorded by Bang, 10 in
456; less than 1 in 45. The disorder ap-
pears to be more common in the summer
than in the winter months.

The peculiar nature of the complaint, and
the proper method of treating it, were first
brought into general notice in 1813 by a
new work of Dr. Sutton's, of Greenwich.
He saw a good deal of the diseases of the smug-
glers, and the customers of the smugglers,
that frequent the coast of Kent; and he
was struck by the different event of this dis-
order in the hands of different practitioners,
according as bleeding or narcotics were
adopted. It is the same disease which Dr.
Abercrombie speaks of as " a dangerous mo-
dification of meningitis, which shews only
increased vascularity." Dr. Bright also
includes it among his cases of " Arachnitis."
Both these eminent physicians had learned,
however, that the complaint requires a par-
ticular method of treatment. Of late years
many essays and papers on the same malady
have appeared in this country, in France, and
in the United States, where the disorder is
common. But even now it is not so well
understood, throughout the profession, as it
ought to be.

You may ask me, what is the essential
nature of the disease: and I can only state
in reply that it consists in *nervous irritation*.
Some persons hold that this is tantamount
to no answer at all; but I do not agree with
them. They seem to think that if you assign
a state of the brain or nervous system which
is not visible or tangible, you lose yourself in
mere hypothesis. But we see a number of
striking phænomena in this and in many
other forms of disease, for which phænomena
we can trace by our senses, in the organ af-
fected, no physical cause; yet we are sure
that they have a cause; and we call that cause
irritation: if we had given it some Chinese
name it would have been all the same.
From certain symptoms we infer irritation;
just as from certain phænomena we infer
gravitation. I do not mean to put the two
upon an equal footing; or to pretend to say
that the laws of irritation are established
with any thing like the certainty which be-
longs to the ascertained laws of gravity: but
we pursue the investigation of these laws in
the same way in the one case as in the other:

and it is quite idle to object to an arbitrary
term, like irritation, because it is meant to
represent something which makes itself known
to us only by its effects.

Now I apprehend that we are borne out,
by authentic facts, in believing that certain
changes in the blood-vessels will lead to
irritation, and at length to inflammation, of a
part. But there are other sources of irritation;
and irritation in its turn will lead to changes
in the blood-vessels. In the one case we
bring back the blood-vessels to their healthy
condition, and the symptoms of irritation
cease. In the other we calm the irritation,
and the previous effect of it upon the blood-
vessels stops. In other words, deviations
from the natural and healthy state of the
nervous system are sometimes the cause, and
sometimes the consequence, of disturbances
in the sanguiferous system. Whether this
be good philosophy, or whether it seem to
you rational and intelligible, I do not know;
but it is the best explanation that I can offer
you upon this subject.

I apprized you, in the last lecture, that
the great remedy in delirium tremens is *sleep*;
and that our most powerful means of induc-
ing sleep are to be found in opium. The
opium must be given in full doses; and it
must be fearlessly repeated if its desired effect
does not follow. If the patients pass many
nights without sleep, they will die. I have
tried various forms of opium; and I am quite
satisfied with morphia. Some persons, how-
ever, have not found it so successful as solid
opium, or as the common tincture, laudanum.
You may try the one or the other, or the
one after the other, if you please. No par-
ticular rules can be laid down that will suit
all cases. After clearing out the bowels by a
moderate purgative, you may give three
grains of solid opium; and if the patient
shew no inclination to sleep after two or
three hours have elapsed, you may begin to
give one grain every hour till he does sleep.
Or you may prescribe corresponding quan-
tities of the acetate or muriate of morphia;
or of laudanum; or of the black drop; or
of Battley's liquor opii sedativus. At
the same time his room should be kept dark
and quiet. If he sleeps for some time he will
awake calmer and more sensible; perhaps
perfectly so: and you must withhold the
remedy, or continue it in smaller or less
frequent doses, according to the circum-
stances of the case.

Dupuytren found opiate enemata of great
efficacy in the cases of traumatic delirium
that came under his care. That mode of
administering the narcotic may properly be
adopted, if there be any impediment to its
reception or retention by the stomach.

Now sometimes this opiate treatment
alone is quite enough. Sometimes it is not.
You will meet with patients who resist very

DR. WATSON ON THE PRINCIPLES AND PRACTICE OF PHYSIC.

large doses of the drug ; but who presently sleep, or become composed, if you give some of their accustomed stimulus with it : " a hair (as the vulgar saying goes) of the dog that bit them :" if you put their opiate dose into a glass of gin, or a pint of porter. This I have continually experienced with hospital patients. And I rather think that you may get some clue to the particular cases that require this treatment, by examining into the state of the digestive functions. If you learn that, notwithstanding the intemperate habits of the patient, his appetite for food has continued unimpaired, and his digestion sound, you will, I believe, generally find that good nourishing diet, strong broths for example, and the opium, will suffice for the cure. But if the powers and natural sensations of the stomach have been injured and perverted, as is too often the fact, then a temporary recurrence to the habitual stimulus will frequently be necessary : and it is well to ascertain, in such cases, what the stimulus has been, whether spirits, or beer, or wine, and to order it accordingly. Of course this is not to be continued after the patient has recovered from his delirium ; but the stimulus under these circumstances must be cautiously withdrawn. When the stomach retains its power of digestion, the bad habit of drinking ought to be broken off at once : and if, after sleep, you can get the patient to eat heartily of a beef-steak, or mutton-chop, I should always advise it.

There are some things which I find it necessary to mention, for the sake of discommending them. I know persons who in treating these cases combine calomel with the opium. And they say that they cure their patients so ; and I make no doubt that they do ; neither can I doubt that the same success would have followed the same quantity of opium without the calomel. In *pure* cases of delirium tremens I advise you *not* to give calomel. I know no possible good it can answer : it is itself a source of great irritation to the nervous system in many persons : and if it comes to affect the mouth, you inflict upon your patient a superfluous discomfort ; and, I believe, in many cases, a downright injury. You will be told also of digitalis, as a specific remedy for the disease ; or you may read of it : but do not be led away from the standard remedies which reason recommends, and large experience has sanctioned. Knowing what we do of the power of opium generally, and of its efficacy in this complaint in particular, I should consider myself guilty of a criminal trifling with human life if I made experiments with digitalis upon the loose reports of some one or two persons, of whose credit or information I knew nothing ; and whose dicta had been transferred perhaps from some foreign journal to fill a vacant corner in one of our own.

Of the combination of opium and antimony, which has been much praised by good and competent judges, I am unable to tell you any thing from my own experience.

In hospital practice it sometimes becomes necessary to confine the patient to his bed by straps, or to muffle his limbs in a straitwaistcoat : but this is a most unfortunate necessity. Physical coercion, whether manual or mechanical, should never be resorted to, in delirium tremens, when by any means it can be avoided. The angry feeling and mental fret which it produces, and the exhausting bodily struggles to escape or resist the thraldom, are always highly injurious and full of danger to the patient. A couple of strong and good-tempered attendants will not have much difficulty in persuading and managing the sick man, who is seldom either boisterous or obstinate : and if he be intractable by soft words, he will yield more patiently to their gentle restraint than to the force of manacles ; while the appearance of coercion need not be continued a moment after his acquiescence.

I have drawn the line between encephalitis and delirium tremens with sufficient clearness, because I have taken well-marked forms of each. But I am sorry to add that there are mixed cases, which are very puzzling when they occur, and exceedingly difficult to treat ; and which require opiates on the one hand, and moderate depletion on the other. When the indications are uncertain, or equivocal, we must carefully weigh the different symptoms, and we must cautiously *try* the remedies. The circumstances that most distinguish the one form of disease from the other are to be found in the *pulse ;* which is hard and resisting in the earlier stages of inflammation of the encephalon, soft and compressible in delirium tremens : in the *tongue ;* which is mostly parched and rough in the former, moist and creamy in the latter : in the *skin ;* which is hot and dry in the one case, covered with sweat in the other : in the *countenance ;* which is flushed in inflammation, and mostly (though not always) pale in delirium tremens : in the *tremors ;* which are not common in the primary periods of inflammation of the brain : in the usual absence of *headache* in delirium tremens : and in the peculiar characters of the *delirium* in the two cases, which I need not repeat. If these symptoms contradict each other, as they sometimes will, you had better act on the *worst* supposition, and presume that there is inflammation, and employ antiphlogistic remedies : but you must not do so with a strong hand ; you must use them cautiously, and watch their effects, and guide thereby your subsequent treatment. Take a moderate quantity of blood from the arm : observe whether it has the buffy coat ; and note the condition of the patient afterwards. In mixed or ambiguous cases it will be proper

to combine calomel with the opium. You will sometimes find a state resembling delirium tremens left after the subsidence of acute inflammation of the parts within the cranium, and requiring the treatment of delirium tremens.

I do not know that there is much good to be expected from counter-irritation in this disease. But after the more decided symptoms were gone by, I have sometimes thought that the recovery has been accelerated by the application of a blister to the nape of the neck.

Inflammation of the brain, and delirium tremens, are distinct diseases. Hence, in the mixed cases, of which I just now spoke, we may expect after death to find, and we often do find, unquestionable traces of inflammatory action within the skull. But pure delirium tremens frequently leaves behind it no morbid appearance whatever in the brain or its membranes. In other cases there is serous liquid collected in the interstices of the pia mater, or in the cerebral ventricles ; and I have on several occasions seen the arachnoid thicker and less transparent than is natural, and sprinkled over with little spots or streaks of a milk-white colour. Changes of this kind we believe to be owing to chronic inflammation of the membrane. But, even in these cases, I see no reason for thinking that the fatal disorder had any connection with the morbid state of the arachnoid. We meet continually with like appearances when there has been no delirium tremens ; and we have delirium tremens without any such appearances. The habitual abuse of ardent spirits leads to chronic inflammation in various parts and tissues of the body : in the blood-vessels, in the liver, in the kidneys, and in the arachnoid. We need not be surprised at finding that membrane thickened and partially opaque in the victims of delirium tremens ; since they are chiefly men who have run a long course of intemperance. I believe that disease to bear the same relation, and no other, to the chronic arachnitis in such persons, as to the chronic hepatitis to which they are equally subject. There is but one morbid condition which, since my attention was first directed to it, I have found constant in persons dead of delirium tremens, and that is, a remarkably soft, pale, and flabby state of the muscular tissue of the heart.

The chemist may be more likely to detect altered conditions in the brain, in these cases, than the anatomist. Very lately Dr. Percy has obtained alcohol from the brain of a person who died from excessive drinking ; and from those of various animals which had been killed by that poison. These facts are interesting, but they do not help us much in our attempts to explain the phænomena of the disorder.

Cases such as I related in the last lecture, where violent symptoms are calmed at once, and the patient is rescued in a few hours from great apparent peril, make a strong impression upon those who witness them ; and the practitioner gains amazing credit, and is spoken of to all their acquaintances as a wonderfully clever man. It is unfortunate that we are obliged to set off, against this advantage, a corresponding danger, when the disease ends ill, of being blamed without our deserving it. When these patients die (and they usually persist in their evil habits and die at last in one of the attacks of the disease), when they so die, they are apt to die much in the same way as patients who are poisoned by opium ; and if their friends are aware that we have been giving large and repeated doses of that drug, they sometimes have the charity to lay the death at our door : and you ought to be prepared for this : and I will conclude what I have to say upon the subject of delirium tremens by relating a case, in which I have no doubt that I suffered (though quite unjustly) under that kind of imputation.

Six or seven years ago I was asked, one morning, by a general practitioner at the west end of the town, to see a patient with him ; of whom he gave me this account :— The man was about forty years old : he had been attacked some days before with sore throat, common cynanche tonsillaris ; the tonsils and fauces were so much swelled that his deglutition was greatly impeded, and for four or five days he had not been able to swallow any thing. The night before I saw him he had become delirious, and then had been largely bled, and he was worse in the morning. His bowels had also been very much purged.

I found him propped up in his bed, with a coronet of leeches round his head. He was pale ; there was no headache, nor affection of his breathing ; his pulse was not very frequent, and it was quite soft and compressible. He was sweating profusely. He answered the few questions I put to him readily and pertinently, and then went talking on in a rambling way about his business. He was a hackney-man, or stable-keeper, in a large way. He said (I remember) that the boys were all ready to start ; that there were two pair of horses going down the road, and that he must go and see after them ; and much more on the same subject. His mind was busy about the execution of imaginary orders. He had not slept at all for some nights.

Upon my inquiring into his previous condition, his wife told me that without any turn for dissipation he had for some time been an habitual hard drinker ; that he had continual dealings with the coachmen to the various families which he furnished with

horses ; and that he was obliged to drink something with each of them ; so that every day he had many glasses of spirits, and a good deal of porter. She told me also that his mind had been anxious and uneasy ; that the business was a large and harassing one ; that he had embarked a considerable sum of money in it ; and that it had not turned out so prosperously as he had expected.

Putting all these things together, there could be no doubt, either as to the character of the complaint, or as to the treatment proper to be adopted. Here was a man who had been living a life of continued mental and physical excitement : suddenly the sti- mulus to which he had been accustomed was taken away ; he could not swallow even such nourishment as his case required or admitted : then came on delirium—a symptom not be- longing to his disease in the throat—and pro- tracted watchfulness. He is largely bled, and profusely purged, and he gets worse instead of better under these remedies. At the same time his skin is moist and per- spiring, and there is no hardness in his pulse.

I recommended that the leeches should be removed from his head ; that he should take immediately (for he could swallow now) two grains of opium, and afterwards twenty drops of laudanum every three hours, till he fell asleep.

Somewhat unluckily his wife's brother — a very young man—was the apprentice or assistant of a surgeon in the neighbourhood of town, and he came in to see his relative. After hearing what I had said, he went home, and probably consulted his books, and then came back again with doubts whether the com- plaint really was delirium tremens after all. Whether in consequence of these doubts I cannot tell, but for some reason or other only one or two doses of the medicine were taken. I had offered to see the patient again in the evening ; but his friends said they would send for me if he did not get better. They did not send ; and the patient did not sleep. At night, therefore, at ten o'clock, three grains of opium were admi- nistered. The result of this was, that he passed a quiet but a sleepless night. Per- haps (but I cannot be sure of that) if the opium had been persisted with, the case might have terminated otherwise. About eight o'clock the next morning I was summoned to him in a great hurry : when I got there he was dying, perfectly comatose, breathing stertorously, with blue lips and contracted pupils. He had appeared so much better at seven, that he was, for the first time, left alone for a quarter of an hour ; and when they went back to him he was changed in the manner I have described.

The general practitioner with whom I had first seen the patient—a very sensible man— was much concerned at this issue of the case, and observed to me that doubtless our patient had been poisoned by the three grains of opium. I was able, however, to relieve his mind from this notion ; and I have mentioned the case chiefly for the sake of guarding you against similar misgivings, under similar circumstances. The manner of dying was just such as opium will pro- duce ; but, then, death by coma is also fre- quently the termination of delirium tremens : effusion at length is apt to take place into the ventricles, or into the meshes of the pia mater, and stupor comes on, and the patient sinks. But in this instance I was certain that his death had nothing to do with the opium he had taken, for this reason : that so long a space of time had elapsed—nine hours—between his taking the opium and the coming on of the comatose symptoms. Dr. Christison, in his elaborate and valuable work on Toxicology, states it as the result of extensive inquiry into this subject, that when opium has been swallowed in a poi- sonous dose, it almost always begins to act as a poison within an hour ; that very rarely indeed has its specific operation been post- poned much beyond the hour, except, occa- sionally, when the person taking it has been intoxicated at the time. In one remarkable instance a drunken man took two ounces of laudanum, and no material stupor followed for five hours. I guess that I incurred the reproach of recommending a fatal plan of treatment in the particular case I have now related ; but I am quite satisfied that the opium was innocent of the patient's death, and I even think that his chance might have been much mended if the opiate, in smaller doses perhaps, had been steadily continued.

We may be content to bear, occasionally, these unfounded imputations, when we con- sider the other side of the account, and call to mind the far greater number of instances in which spontaneous recoveries are credited to us as cures ; and the Doctor, like Belinda's Betty, is " praised for labours not his own."

I should next wish to put you in posses- sion of what has been ascertained in respect to *partial* and to *chronic* inflammation of the brain, as these are met with in adults ; for I must speak of the head affections of children separately. But I really do not know how to bring this part of the subject before you in a practical manner. If I were first to describe symptoms, and then to state what organic changes had been discovered after death preceded by them, I should have to tell you of different symptoms with the same morbid conditions, and of the same symptoms with different mor- bid conditions, in various individuals. I believe the best method, upon the whole, will be to describe the several morbid appear-

ances which the brain is found to present; and then to mention the symptoms that have *most commonly* been observed to occur in association with such morbid conditions. I must premise, however, that the whole subject is full of uncertainty and apparent irregularity. Doubtless there *is* some constant and uniform connexion of cause and effect between the altered physical states of the brain and the altered manifestation of its functions; but we have not yet been successful in our search after those settled relations; or we have but partial and imperfect glimpses of them.

Ramollissement.— One very remarkable condition of the brain has been several times mentioned in these lectures; viz. *softening.* A great deal of attention has been paid to this condition of late years, both in France and in this country : and some points in its pathology have been fairly made out. I will bring them together as concisely as I can. In the first place, the softening varies greatly in degree, from the consistence which naturally belongs to the cerebral substance, to that of thin cream. In its minor degrees it may be easily overlooked; and is more perceptible by the touch than by the eye. The cerebral matter is less coherent, but it is not yet discontinuous or broken down. It may be washed away, however, by letting a slender stream of water fall upon it; and the softened parts are thus easily distinguishable from those which retain their natural consistence. In the next stage of softening we recognize the complaint at once, for the softened parts undergo a change of form by their own weight : parts that are prominent in the healthy state, as the optic thalami, corpora striata, and convolutions, sink down, as it were, and are more or less flattened. If you make a horizontal section through a part thus diseased, a portion of the softened brain adheres to the knife, and is removed by it, and a depression is left. In a still more advanced degree, the natural texture of the organ in the softened part is entirely destroyed and confused by the change, diffluent : you may pour the softened matter out.

The *colour* of the softened portions varies also considerably. Sometimes they are unchanged in colour : sometimes they are quite white, and present a strong contrast with the tint of the neighbouring parts: sometimes they are marked with various shades of redness, from a rosy pink to an orange, or deep red, or even a mahogany brown. Often there are red spots mixed irregularly with the softened cerebral pulp, and giving it very much the appearance of a mixture of raspberries and cream. In other cases we find the softened mass of a pale yellow, or straw colour, infiltrated, as it were, with purulent matter : and sometimes it is mixed with serous fluid.

Softening of the brain is usually partial. It may occupy any part; but it is said to be more frequently met with in the grey than in the white matter : and more often in the grey matter of the convolutions than of the more central parts of the brain.

You will find softening of the septum lucidum, and of the fornix, occurring very frequently in connection with an accumulation of serous fluid in the lateral ventricles.

Now, it is well established that softening of the brain is a common result of two very different morbid conditions. It is often caused by inflammation of the softened part: it is often caused, also, if I may say so, by its starvation; by the diminished supply of arterial blood, in consequence of diseased blood-vessels.

Can we distinguish these two forms of softening from each other by their physical characters? Why, sometimes we can : and sometimes, it must be confessed, we cannot.

The same parts that are most liable to have their consistence diminished, through an inflammatory process, are also most liable to be softened from defect of nutrition. The most vascular parts of the brain, in short : the grey matter of the convolutions, and the grey matter of the thalami, and corpora striata.

It is stated, however, that softening of the corpus callosum, septum lucidum, and fornix, from obliteration of the arteries, is extremely rare.

If there be pus mixed with the softened brain, we know that there has been preceding inflammation. Again, if we find the arteries impervious, we conclude that the softening has not been inflammatory. Dr. Carswell states that the obliterated arteries may occupy the softened cerebral substance, and may often be seen ramifying through it; and that when this substance is removed by pouring water upon it, the solidified vessels retain their situation, and feel sometimes as hard as fine wires. But we come to the same conclusion if we find the larger vessels, the carotid or vertebral arteries, obstructed by ossification; and a large portion of the brain unnaturally soft.

We have no certain test of the nature of the softening in its being red. The redness may be the result of inflammatory congestion; but cerebral hæmorrhage may occasion softening; and, on the other hand, softening may give rise to cerebral hæmorrhage. *This* may be said, however : that the redness is seldom *considerable* when the softening proceeds from an obliteration of the arteries. When the softening extends much beyond the redness, or the effused blood; or when the redness occupies several small portions only of the softened pulp; we may presume that the blood was extravasated subsequently to, and in consequence of, the softening

On the other hand, when redness and vascularity can be traced into the brain, some way beyond the softened part, we may regard the softening as the consequence of inflammation. And we adopt the same belief, with still greater confidence, when around the softened and disorganized pulp we find the cerebral substance *hardened*, and of a uniform reddish colour.

In attempting to make the diagnosis between these two forms of softening, we get some assistance by noticing the *age* of the patient. The ossification, which gives rise to the obliteration of the arteries, is almost peculiar to the advanced periods of life; whereas inflammatory softening may occur at any age; in children, in adults, or in old persons.

Some of the French pathologists have laid down this rule as the result of their experience in regard to softening of the brain— that it is attended, during the earlier part of its progress, with a permanently contracted state of the flexor muscles of one or more of the limbs. " In some cases the contraction of these muscles amounts only to a slight degree of stiffness; in others it reaches such an extent, that if the arm be the part affected, the hand is clenched, and remains pressed against the shoulder; or, if the leg, the heel is carried up to the hip." Sometimes this tonic spasm is so strong that you cannot extend the limb; and the attempt to do so gives the patient pain. After a certain time the rigidity is succeeded by complete relaxation; the contracted limb has become palsied.

I believe that this is a valuable diagnostic symptom of softening, and especially of inflammatory softening—*when it occurs*. But it is often wanting. I wish I could tell you something more certain and constant in respect to the symptoms of this interesting change; but the facts that I have myself observed, and which have been recorded by others, will not permit me to do so. Dr. Abercrombie even goes so far as to say, that judging from the cases that have fallen under his own notice, there is no foundation for the statement that *ramollissement* is distinguished by tonic contraction of one or more limbs: that the same thing is met with in connection with affections of the membranes, without any disease of the cerebral substance; and with the encysted abscess of the brain; and that it is frequently observed in cases of typhus fever, where there is much cerebral disturbance, but which terminate favourably. 1 will give you the general result of his experience in this matter, as being untinctured with any wish to reduce his facts into compliance with a preconceived opinion, or hasty generalization. He states that " the cases which terminate by ramollissement seem in general to be characterized by convulsion, more or less extensive, followed by paralysis and coma; the convulsion ceasing for some time before death, and being succeeded by the coma." But he saw one case in which " the convulsion continued with the utmost violence till the very time of death." In another instance " there was no convulsion at all, but a sudden attack of palsy, exactly resembling the ordinary attack of hemiplegia from other causes." In two cases he found " ramollissement of very limited extent, in connection with symptoms of long standing, both cases being at last rapidly fatal by a sudden attack of convulsion." In other cases " there was extensive destruction of the cerebral substance, without either paralysis or convulsion, and even without coma."

Suppuration and abscess of the brain.— When you find the softened substance infiltrated with purulent matter, you may call the case one of suppuration of the brain. But suppuration also occurs in another form; viz. in the form of abscess. The pus is contained in a regular well-defined cavity, surrounded by cerebral matter in a healthy or in a hardened state. Now in suppuration occurring in the brain, there is the same puzzling diversity of symptoms as in cases of simple softening. Still, in the main, there seems an approach to the same order of symptoms; convulsions in the earlier period constituting the most prominent feature of the disease; paralysis in the latter. I will take one of Dr. Abercrombie's cases in illustration of the formation of encysted abscess in the brain.

A girl, aged eleven, thin and delicate, after having complained for some days of headache, was seized, on the 11th of January, with convulsions, which continued about half an hour: paralysis of the right arm followed the attack of convulsion. She was bled from the arm, and purged, and cold was applied to her head; and she was much benefited by this treatment. On the 13th the headache was much abated, and she had recovered a considerable degree of motion of the arm. On the 15th the headache increased again, and the arm became more paralytic, and she was again bled: and on the 16th and 17th the power of moving the arm was greatly improved. On the 18th, after being affected with increase of headache, and some vomiting, she became convulsed, the convulsion being confined entirely to the head, and to the right arm; the head was drawn towards the right side, with a rolling motion of the eyes; the arm was in constant and violent motion. She was sensible, and complained of headache. Being bled to eight ounces, the convulsion ceased instantly, and the headache was relieved; but the right arm remained in a state of complete paralysis. Her pulse, during the five following days, fell from 100 to 60; some

headache continued; she had occasional vomiting; and the convulsive attacks returned several times: they were entirely confined to the right arm, which, after the 23d, was left in a state of permanent paralysis. Hitherto no other parts of the body had been affected by the convulsion; but on the 24th it attacked the right thigh and leg, and left them in a state of paralysis. The former remedies were repeated without any effect. The thigh and leg went through a course precisely similar to that described in regard to the arm, and on the 29th remained in a state of permanent paralysis.

She was now, therefore, paralytic of the whole right side; she had no return of convulsion, was perfectly sensible, and made little complaint. Gradually she became dull and oppressed, and at length fell into a state of perfect coma, and died on the 14th of February, a little more than a month after the commencement of her illness.

In the upper part of the left hemisphere of the brain there were two distinct defined abscesses, containing together from six to eight ounces of very fœtid pus. They were lined by a firm white membrane; and a thin septum of firm white matter separated them from each other. The one was in the anterior part of the hemisphere, very near the surface; and the other immediately behind it. In the posterior part of the right hemisphere there was a small abscess containing about half an ounce of pus. There was no serous effusion in any part of the brain, and no other morbid appearance.

In this very interesting case it is worth remarking how the convulsion preceded the paralysis, and how the palsy was more than once diminished by antiphlogistic measures.

It is reasonable to conclude—it can hardly be called a conjecture—that in such cases of partial disease of the brain as I have hitherto mentioned, the occurrence of convulsion, or of rigidity, marks the inflammatory stage; and the supervention of permanent paralysis denotes the period of softening or suppuration, of complete disorganization, that is, of the texture of the brain in that part.

Induration of the brain.—Partial inflammation of the brain, especially when it is chronic, sometimes produces a totally different change from any that have yet been described. Instead of becoming softer, or being converted into pus, the inflamed part is indurated; comes to resemble in consistence portions of brain that have been for a short time immersed in weak nitric acid. In this state it is often unusually vascular and injected. When the induration is greater in degree, the hardened part assumes the appearance of wax, or of boiled white of egg, or (as Andral says) of Gruyère cheese, and contains but little blood, but is, on the contrary, distinguished by its pearly whiteness. That these changes are the result of slow inflammatory action is the more probable, because they are sometimes found to exist around an old apoplectic clot or cell; the blood effused having acted as a cause of inflammation of the neighbouring part, just as any foreign substance might do. In the progress of cases in which partial induration is effected, convulsive movements are common, but paralysis does not appear to be so frequently present. The symptoms may go on for months, and often remit, and are again aggravated by paroxysms. These cases are the more interesting, because they offer a greater probability of cure than those that are attended with an opposite condition of the cerebral mass.

Tumors of the brain. — Besides these varieties of inflammation, and their consequences, the brain is often infested with tumors, which also give rise to a great diversity of symptoms. There are fibrous tumors which grow rather *around* the nervous matter than within it, and are connected with the dura mater. They have been found at almost all parts of the surface of the brain; at its base, at its sides, and towards its summit. Scrofulous tubercles are also not uncommon: these are embedded in the nervous substance, and assume a round form, for the reason I formerly mentioned, viz. because the tubercular matter that is separated from the blood is not cast into any particular mould (as it is when it is effused into the small bronchial tubes), but poured forth into the homogeneous pulp, which exerts an equal degree of pressure upon it on all sides. These scrofulous tubercles of the brain are infinitely more frequent in children than in adults; and they are more commonly met with in the cerebral hemispheres than in any other part of the brain, occupying the cortical and medullary substance indifferently. They sometimes appear to originate in the pia mater. They differ from pulmonary tubercles in this respect, that they are seldom numerous in the same brain. Sometimes one only is found. They vary in magnitude from the size of a large pin's head to that of a hen's egg; and they are sometimes even bigger than that. The substance of the brain immediately surrounding these tubercles may be unchanged, in which case it is probable that the tubercles themselves give rise to no particular symptoms, the cerebral matter of the spots they occupy having been gradually absorbed to make room for them; but at length important alterations take place in the neighbouring texture; congestions of blood, or softening, or suppuration; and then the ordinary consequences of these changes declare themselves outwardly.

Cancerous tumors occur also in the sub-stance of the brain. They usually occupy a large portion of it before they extinguish life. Hydatids are sometimes found there.

Now of the occurrence of these various local maladies of the brain it is necessary that you should be aware, for you may expect to meet with them frequently in practice. And it is right also that you should be aware that they do not disclose their precise nature by any peculiar symptoms, or succession of symptoms. They all, sooner or later, dis-turb the functions of the organ in which they are situated; and they may all disturb them exactly after the same fashion. We may judge, sometimes, *from other circum-stances*, that the disease is of this or of that character. If we see scrofulous or cancerous disease in other parts of the body, we infer that the symptoms which denote disease of the brain are caused by scrofulous or can-cerous tumors there situated; but from the symptoms themselves, we can only learn that there is some morbid condition of the brain.

I attended, recently, with Dr. Latham, a youth, whose symptoms led us to believe that he had tubercular disease of the perito-neum; a very formidable complaint, which I shall more particularly describe hereafter. We thought it probable also, although there were no *physical signs* of pulmonary disease, that his lungs contained crude tubercles. After some time, he went down to the coast; and was there attacked with a fit of general convulsions. Up to that period he had shewn no symptoms whatever indicative of organic disease within the head. On being apprized of this seizure, we expressed to the physician then attending him, our opinion that it had resulted from the presence of scrofulous tumors in the patient's brain. The convul-sions returned a few days afterwards with great violence, and he died. It was as we had conjectured. The peritoneum was found studded with innumerable miliary tubercles: there were a few crude tubercles, of some size, around the roots of the lungs; and two large masses of the same sort in the brain. Here, you see, we were directed to a correct special diagnosis of the cerebral disease, simply by the evidence which had satisfied us that scrofulous tubercles existed in other parts of the body.

In the case of specific tumors there is really nothing to be done by way of cure; and we must then treat symptoms, and seek to alleviate them as they arise. When it appears likely, or not unlikely, that the cere-bral symptoms may be the result of cerebral inflammation, we must give the patient the chance of being benefited by some of the remedies of inflammation: we must treat the case in this instance upon the *most favourable* supposition. The class of remedies from

which most may be hoped in equivocal cases, are local bleeding, counter-irritation, and especially the cautious and regulated employ-ment of mercury. I have stated to you before, that I have known several obscure but threatening symptoms of brain disease clear entirely away, when the gums were made sore by mercury, and kept slightly tender for some little time. It is possible that we may sometimes do our patients harm by this mercurial treatment. We may, now and then, accelerate the arrival of death in cases which nothing could save : but we must not be deterred from giving them this chance of being rescued from a disorder which may be susceptible of cure, but which, if unchecked, will be inevitably fatal.

LECTURES
ON THE
FUNCTIONS OF THE NERVOUS SYSTEM.

By W. B. Carpenter, M.D.

Lecturer on Physiology in the Bristol Medical School.

Lecture II.

General Sketch of the Comparative Anatomy and Physiology of the Nervous System.

Although the structure and distribution of the nervous system in the different classes of animals have been, until recently, but little appealed to in the determination of its func-tions, they are capable of supplying evidence regarding some of these, not less important in its character than that which comparative anatomy affords to other departments of physiology. Some of the principal of these contributions will now be pointed out.

In the lowest tribes of the *Radiated* division of the animal kingdom, no nervous system has yet been discovered. These have, there-fore, been separated by some naturalists into a new primary group, to which the designa-tion of *Acrita* has been given, on account of the (supposed) "*indistinct*, diffused, or mole-cular character of their nervous system." This idea of a "diffused nervous system" seems to be regarded by many—physiologists as well as naturalists — as the necessary alternative, resulting from the want of any definite indications of its presence. It ap-pears to me, however, to be based on very erroneous notions as to the true offices of the nervous apparatus. Its influence is not required to endow the tissues with *contrac-tility*; a property possessed in a high degree by the structures of many plants, to which these beings present a much greater *general* resemblance than they bear to the higher

animals ; and, even in the latter, this property is independent of "nervous agency," although generally called into exercise by it. That a nervous system is not required by them for the performance of the functions of nutrition and reproduction, otherwise than to supply, by its locomotive actions, the conditions of those functions, would also appear from its absence in plants. It is on the sensible movements of these beings that our belief in their possession of a nervous system must be founded, when we cannot render it cognizable by our senses. But we must be careful not to draw hasty inferences from such phenomena. Sensible movements are, as we have seen, performed by the Dionæa and sensitive plant, in respondence to external stimuli acting on distant organs ; and here the channel of communication is probably the vascular system. We observe, however, that in the polypes an impression made upon one part (one of the tentacula, for example) is propagated to distant parts, and excites respondent movements in them, more rapidly than we could imagine to occur without such a channel of communication as as a nervous system *only* is known to afford. Moreover, some of their actions appear to show a certain degree of *voluntary* power, and therefore of consciousness ; being independent, so far as can be ascertained, of the operation of external stimuli. These phenomena, then, would lead us to suspect the existence of a nervous system in the beings which exhibit them ; not, however, in a " *diffused* " condition, but in the form of connected filaments. For, what consentaneousness of action can be looked for in a being whose nervous matter is incorporated in the state of isolated globules with its tissues ? How should an impression made on one part be propagated by these to a distance ? And how can that consciousness and will, which are *one* in each individual, exist in so many unconnected particles ? If, then, we allow any sensibility, consciousness, and voluntary power, to the beings of this group of Acrita—to deny which would be in effect to exclude them from the animal kingdom—we must regard these faculties as associated with nervous filaments, of such delicacy as to elude our means of research. When the general softness of their textures, and the laxity of structure which characterizes the nervous fibres in the lowest animals in which they *can* be traced, are kept in view, little difficulty need be felt in accounting for their apparent absence. The case is very different from that of vegetable structure, the greater consistency of which enables us to place much more reliance upon the negative evidence afforded by anatomical research.

The correctness of this view (on which I have dwelt the longer, because it appears to me to involve a fundamental question in nervous physiology,) is borne out by the fact, that, in those members of the group whose size and consistency allow their structures to be sufficiently examined, a definite nervous system has been detected, in the position which it might, *à priori*, be expected to occupy, according to the type of the individual. Thus, in the large fleshy isolated polype, commonly known as the sea-anemone *(actinia)*, a nervous ring has been discovered, surrounding the mouth as in other radiata, and sending off branches to the tentacula, with a minute ganglionic enlargement at the base of each. Similar nervous circles have been stated to exist in various species of the *Medusa* tribe. Amongst several of these tribes, too, minute red spots are to be observed, which, from the analogy of similar but more perfect organs in the higher classes, are believed to be eyes. It is obvious that these could be of no service to the animal in directing it to the choice of food, or in warning it of danger, unless they were connected with some central sensorium. It is curious that these should present themselves in many animals in which no nervous filaments have been detected. Thus, we find them as well marked in the Planariæ (which so much resemble the Entozoa in general structure) as in the Medusa and Pecten, in which nervous filaments can be traced running towards them, if not absolutely into them. Dugès found that, if strong solar light be directed to the head of the Planaria, on which two of the eye-specks are seen, it escapes from its influence by a sudden movement,—a fact which seems almost indisputably to prove the existence of a connected nervous system in this gelatinous animal, although the most careful research has not discovered it.

Regarding the *Polypifera*, then, as the lowest of the radiated classes in which there is a regularly organized digestive apparatus, and which perform movements of a character ascribable only to a nervous system, I shall inquire a little more particularly into the phenomena they exhibit, and the degree in which these necessarily involve the possession of the higher mental endowments. In this inquiry I shall refer principally to the little *hydra*, or fresh-water polype, the habits of which are better known than those of any other species. Although no nervous filaments have been detected in this, we have a right to infer their presence for the reasons already given ; and they probably form a ring around the mouth, as in the actinia, sending filaments to the tentacula. There has been much vagueness in the comparisons frequently drawn between the springs of action in this creature, and the agents which operate in higher animals. And this may be attributed to the tendency which has prevailed among many physiologists, to grasp at a superficial resemblance, instead of seeking for a funda-

mental analogy. Thus, some naturalists seem by their language to imply that the hydra possesses as much sensibility, and is as completely under the guidance of volition, as man himself. But what is the character of this interesting little being ? It is a *stomach*, the orifice of which is provided with tentacula, that contract when irritated by the touch of any adjacent body, and endeavour to draw it towards the entrance. Now, to what action in the human body is this most allied ? Evidently to that of the muscles of deglutition, which lay hold, as it were, of the food which has been conveyed to the fauces, and carry it into the stomach. These muscles are called into action, not by an effort of the will, but by the contact of the food with the lining membrane of the pharynx. This *impression* is propagated by the glosso-pharyngeal nerve to the medulla oblongata, where a respondent motor impulse is excited, which is transmitted through the pharyngeal branches of the par vagum to the muscles of deglutition, and causes their contraction. This phenomenon will be more fully examined in a future lecture; it is adduced here simply as an instance of the important class of *reflex* movements, which are independent of the brain (though, to a certain extent, controlled by it), which are altogether involuntary, and which do not *necessarily* involve the production of sensation. There would appear to be little difference in the character of this movement, between the simple hydra and the most perfect vertebrated animal. In the latter, however, another set of muscles are superadded to these, for the purpose of preparing the aliment by mastication for the operations of the stomach, and of bringing it within reach of the pharyngeal constriction. But, it has been urged, the inactivity of the tentacula when the hydra is gorged with food, proves that they are excited to action by the will of the animal. This inference, however, may be easily disproved. The muscles of deglutition in man are not called into action with nearly the same readiness and energy when the stomach is distended as when it is empty ; a fact of which any one may convince himself, by observing the relative facility of swallowing at the commencement, and termination of a full meal. No one will assert that *this* variation is an effect of the will ; indeed, it is often opposed to it, being one of those beautiful adaptations by which the welfare of the economy is provided for, but which the indulgence of the sensual appetites opposes. Most of the movements of this animal, and of others of the class, appear to be equally the result of external stimuli with that already described; and it is only in a few instances, principally those of absolute locomotion or change of place, that any evidence of *voluntary* action can be discerned.

It may be occasionally remarked, however, that one or more of the tentacula are retracted or extended, without the slightest appreciable change in any of those external circumstances which seem ordinarily to affect the motions of the animal ; and this action we can scarcely regard as otherwise than voluntary.

As my present object is to obtain from comparative anatomy such illustrations as it is capable of affording, in the study of the complex phenomena of the nervous system in the higher animals, rather than to detail systematically the varieties of form which this system presents in each group, I shall pass over the less important classes, and proceed at once to the highest of the radiated division—the *Echinodermata*. With considerable diversity of external form, there is nevertheless a close correspondence in the disposition of the principal organs among the different members of this extensive group ; and this is especially the case in regard to the nervous system, which we shall describe as it exists in the common star-fish (*asterias*). In this animal there is a fila-

Fig. 1.
Fig. 1 —Nervous system of *Asterias*: the dotted line shows the outline of the body ; *a*, position of the mouth.

mentous ring surrounding the mouth, which presents a regular series of ganglionic enlargements, of which one corresponds with each segment of the body. From every one of these a branch is transmitted to the corresponding ray ; and this may be traced along its whole length. In some species of asterias a small red spot may be seen at the end of each ray, which is probably a rudimentary eye ; and this is connected with a minute ganglionic enlargement at the extremity of the nervous filament, near which it is situated. A curious disposition of the spines around these spots has been lately pointed out by Mr. E. Forbes, by which these organs may be protected ; and the same gentleman has remarked that the animal seems by their means to take cognizance of food placed at a little distance. Besides these diverging branches, two smaller ones pass downwards from each ganglion, to be distributed to the stomach and other viscera

included in the centre of the star. If, as seems probable, these may be regarded as the rudiments of the sympathetic or visceral system of the higher animals, we have here an instance of that community of function which is so remarkable in the organism of the lower tribes, when contrasted with the separation which is perceptible in those at the opposite extremity of the scale. The visceral nerves of the asterias are not isolated at their central terminations from those which are connected with the sensorial and loco-motive functions; nor are those which minister to the instinctive actions separable from those which convey the influence of the will. Every segment of the body appears equal in its character and endowments to the remainder; each has a ganglion appropriated to it; and, as the ganglia, like the segments, are all alike, neither of them can be regarded as having any *presiding* character.

From the radiated we now pass to the *Molluscous* classes; the general character of which, as a natural group, is the remarkable predominance of the nutritive system over that of animal life. In fact, although the organs which minister to their vegetative functions attain a very high degree of de-velopment, the animal powers of sensation and locomotion are, in general, so feebly manifested, as to show that they are entirely subservient to the exercise of the former. There is not in the Mollusca, as in the Radiata, any repetition of parts around a common centre; and we do not therefore meet in them with a number of ganglia nearly or altogether alike in endowments. In some of the higher species there is a conformity between the two sides of the body, or a lateral symmetry, which involves a subdivision of some of the ganglia that are single in the inferior tribes into two masses, which always remain in connection with each other. With this exception, it may be ob-served, that all the ganglia, to the number of four or five, which we meet with in the higher Mollusca, appear to have distinct functions; as may be determined by tracing the distribution of their nerves. Thus we find a pair of *cephalic ganglia*, situated above the œsophagus, connected with the organs of special sensation, and sending motor nerves (as we shall see reason to believe) to all parts of the body. This is obviously analogous to the brain of Verte-brata. Below the œsophagus there is gene-rally a small ganglion, connected with the apparatus of deglutition, which may be called the *stomato-gastric* ganglion. In connection with the gills we have always one ganglion, sometimes a pair, which may be termed the *branchial* ganglion. Another is found at the base of the foot, which may be called the *pedal* ganglion. And there is sometimes another, which especially supplies the mantle

with nerves; and this may be called the *palleal* ganglion. The distribution of their nerves to the different organs would alone indicate their respective functions; but these are placed beyond doubt, by that very great variety in the disposition of these organs, which is characteristic of the Mollusca. The development of the sensory organs, the situa-tion of the gills, the structure and position of the foot, the conformation and uses of the mantle, are well known to differ in the most obvious manner, in genera which are closely allied to each other. Hence the anatomist is able, by the discovery of corresponding changes in the nervous system, to satisfy himself of the particular functions of its different centres.

It is only in the higher tribes, however, that this separation of function is evident; and it will be worth while to trace briefly the steps by which it is attained. Feeble as are the animal powers in a great proportion of the Mollusca, they would seem to be almost extinct among the members of the class *Tunicata*, or *Acephala nuda*. These animals are enveloped in a tough elastic tunic (the analogue of the *valves* of the Conchifera); and within this is found a muscular coat, con-sisting of fibres crossing each other in various directions, by which compression may be exercised on the contents of the cavity it surrounds. Two openings penetrate these sacs; one, termed the *branchial*, admits water to the general cavity, partly for the purpose of aerating the blood, and partly to bring food to the digestive orifice; the other, termed the *anal*, gives exit to the current which has passed over the respiratory sur-face, and also to the contents of the intestine and ovaria. These openings are bounded by distinct circular sphincters, the fibres of which are connected with those of the general muscular integument of the sac. By means of this apparatus the animal is capable of diminishing the capacity of the branchial sac, and thus of ejecting, with considerable force, a part of the water it contains; whilst the elasticity of the external tunic spontaneously restores its usual dimensions, when the con-tracting force is inactive. No movements of this kind, however, are commonly em-ployed, either for the respiratory process, or for the prehension of food. A continuous and equable current of fluid enters the branchial orifice, and is propelled from the anal, without any other visible agency than the movement of the cilia which cover the aerating surfaces. The mouth, or entrance to the stomach, is situated at the bottom of the branchial sac, and is unprovided with any special sensory apparatus. It seems to derive its supplies from the respiratory current alone, and not to depend upon any prehen-sile movements; but particles unfit to enter it are probably stopped at the branchial

orifice. Moreover, as each animal possesses within itself all the organs necessary for the propagation of its race, no powers of active motion are called into exercise by the per- formance of this function.

So far, therefore, as the regular vital operations are concerned, we see no indication of *voluntary* action in these singular animals; or even of that kind of respondence to im- pressions which would lead us to suspect the existence of a connected nervous system. But in the simultaneous contraction of the whole muscular sac, which is occasionally witnessed, we can scarcely fail to acknow- ledge the operation of nervous agency. If one of these animals be touched, when its cavity is full of water, a jet of fluid is thrown out to some distance ; and a similar expulsion sometimes takes place without any external irritation. The only organs peculiarly adapted for receiving sensory impressions, which these animals can be regarded as possessing, are the tentacular filaments which fringe the interior of the branchial orifice. Although nothing is absolutely known of their function, it would not seem improbable that they are susceptible of impressions from substances entering with the respiratory current ; and that these may excite, through the nervous system, the closure of the sphincter, and may thus prevent the admission of injurious bodies. We find, on examining into the character of this nervous system, that it is

Fig. 2.
Fig. 2.—Nervous system of *Ascidia*: *a*, bran- chial orifice; *b*, anal orifice; *c*, ganglion; *d*, sac of the mantle.

most simple in its structure and distribution. One ganglion, situated between the two orifices, serves as the centre of all the actions to which it ministers. From this, filaments are sent towards each aperture ; and others ramify over the muscular sac, to which they seem almost exclusively confined. If the closure of the branchial orifice really takes place under the circumstances just described, it is evident that we may attribute it to a reflex action ; since it is performed in direct respondence to an external stimulus ; and

since the closure of the sphincters in the higher animals is, in like manner, inde- pendent of the impulse of volition, although capable of being influenced by it. It would seem probable, too, that by the same sphincter is regulated the quantity of water which shall enter for the supply of the respiratory and digestive systems, in accordance with their requirements, communicated in like manner, through the ganglion ; and the ciliary move- ments would appear to be under the same control, (although not so in higher animals,) since in those beings which make use of them for the acquirement of food, such as the common wheel-animalcule, they stop and recommence in a such a manner as to pre- vent the observer from assigning any other cause to their variations.

In the *Conchiferous* Mollusca, we find the nervous system presenting a more elevated form, in accordance with the greater variety of the actions performed by the animals. In some of the lowest, however, as the oyster, the locomotive and sensorial powers do not seem much greater than those of *Tunicata*. The nervous system possesses but three gan- glionic centres, of which the principal one is evidently the analogue of the single gan- glion in the former class, being situated be-

Fig. 3.
Fig. 3.—Nervous system of the *Oyster*: A, A, anterior or œsophageal ganglia ; B, branchial gan- glion ; *a, a*, branches to mantle ; *c, c*, branches to gills ; *d, d*, connecting trunks ; *e*, transverse fila- ment uniting anterior ganglia ; *f*, arch over œso- phagus, ε.

tween the branchiæ, and supplying the whole respiratory apparatus. The other two gan- glia are situated anteriorly. They lie beneath the entrance to the œsophagus ; and, being connected by a transverse filament, which passes beneath it, as well as by an arch which passes over it, they may be regarded as con- stituting but one centre of action. The principal branches from these ganglia are distributed upon the sensitive tentacula, and upon the anterior portion of the mantle. They send two large trunks backwards towards the branchial ganglion ; these, how-

ever, do not seem to enter the substance of the ganglion, but rather to subdivide into branches, which accompany in their distribution those proceeding from the ganglion itself. The anterior ganglia, being alone connected with the special sensory organs, will obviously have a superior influence on the movements of the animal; and this they seem to possess by the distribution of their branches through the whole structure, whilst those of the branchial ganglion are confined to one set of organs. This last may be considered, however, from its size and connections, as the centre of the actions performed by the organs which it supplies, when these are stimulated by impressions made on, or originating in, themselves. Such would probably be the case with respect to the respiratory actions, which constitute a large proportion of the sensible movements of these animals. The whole course of their lives shews them to be so little elevated in the scale of psychical endowment, that we can scarcely regard the motions executed by them as often possessing a voluntary character; they may rather be compared with the involuntary or sympathetic actions of the higher classes. The closure of the shell, for example, which has been observed to take place when the shadow of a boat passes over an oyster-bed, resembles, in its *protective* tendency, the contraction of the pupil under the stimulus of light, or the closure of the glottis against irritating matters.

In the higher species of this class, we find a peculiar locomotive organ developed, which serves a variety of important purposes. This organ, which is termed the *foot*, has a firm muscular structure, and is capable of very energetic action. Sometimes it is employed in burrowing in sand or mud; and sometimes in executing sudden and rapid motions—true leaps, by which the animal is enabled to change its place with great celerity. These motions are frequently executed in such a

Fig. 4.

Fig. 4.—Nervous system of *Pecten*: A, A, anterior ganglia; B, posterior or branchial ganglion, bilobed; c, pedal ganglion.

manner as to imply consciousness of the most advantageous direction for them, and therefore the operation of a guiding *will*. With this organ, an additional ganglion always exists in close relation, being usually situated at its base, and following its changes of position, as well as corresponding with it in degree of development. This *pedal* ganglion is always connected, like the branchial, with the single or double cephalic ganglion; but the pedal and branchial ganglia are not connected with each other. This would seem to indicate that their functions are distinct,

Fig. 5.
Fig. 5.—Nervous system of *Mactra*: A, A, anterior ganglia nearly meeting over œsophagus, є; B, branchial ganglion; c, pedal ganglion.

although partly under the control of the anterior ganglia. The influence of the pedal ganglion on the foot not improbably resembles that of the branchial ganglion upon the parts which it supplies. The general movements of this organ may be directed by the cephalic ganglia; whilst the particular adaptations by which it fixes itself upon a given surface, and adapts its disk to the inequalities which it encounters, may be produced simply by impressions reflected through this ganglion by its own circle of afferent and efferent nerves. Although such a view must be admitted to be hypothetical only, as regards this class of animals, it will be hereafter seen to derive remarkable confirmation from the actions of the suckers of the Cephalopoda in relation to their ganglia, and from similar experiments on the independent functions of the pedal ganglia in insects and other Articulata.

In the next class of Mollusca, the *Gasteropoda*, we find a nervous system still formed upon the same type, but presenting a yet greater number of isolated centres. Although none of this class possess very active powers of locomotion, few are entirely
fixed; all are more or less dependent upon the exercise of these powers for their supply of food; and the higher tribes employ them also in the perpetuation of the race, since the connection of two individuals is in them an essential part of this function.   Although the foot is, as in the Conchifera, the chief instrument of locomotion, some of the naked aquatic species have other means of propelling themselves.   These move through the water by the undulations of their whole bodies, like the leech, or the vermiform fishes; and a few appear materially assisted by an expansion of the mantle on the anterior part of the body, which contains muscular fibres, and seems to act as a fin.   In every division of the animal kingdom, we find the development of special sensory organs to bear a close relation with that of the locomotive apparatus.   In the present instance, we observe an evident example of this general rule.   The organs of vision, which, when existing at all among the Conchifera, were very imperfect, are here almost constant and more highly developed; the tentacula are more sensitive, and are sometimes increased in number to six or eight; and there is reason to believe that some of them occasionally minister to the sense of smell. These senses, as well as the locomotive powers of the animals, have an obvious relation with the supply of the digestive system, which is not here, as in the inferior classes, dependent upon the miscellaneous aliments conveyed to the mouth by the movement of the surrounding fluid medium, but is more limited as to the character of the food to which it is adapted, and, consequently, requires the means of becoming acquainted with the proximity of what it can digest. It is not a little curious, however, that, although the general surface appears highly susceptible of impressions which excite responsive movements adapted to fulfil some important office in the economy, it does not seem to be susceptible of *painful* impressions in any thing like the same degree.   This, which cannot but be regarded as a beneficent provision for the happiness of animals so incapable of offering any active resistance to injury, would appear from the observations of various experimenters, and especially from the testimony of M. Ferussac, who says, " I have seen the terrestrial gasteropods allow their skin to be eaten by others, and, in spite of large wounds thus produced, show no pain."   This fact has an important bearing on our general views of the operations of the nervous system; since it would seem to confirm an opinion founded upon other phenomena, that the *impressions*, which produce reflex actions through the nervous system, do not always involve the production of *sensation*.   Thus, cases of paralysis of the lower extremities have occurred in the human sub-

ject, in which no sensibility existed in the limbs, nor had the will any power to move them; yet irritation applied to the soles of the feet, of which the patient was not conscious, produced retractile movements in the legs.   This question will be more fully discussed, however, in a future lecture.

The nervous system of the Gasteropoda consists of at least three distinct centres, the relative position of which varies with that of the organs which they supply.   The *anterior* or *cephalic* ganglia are longer in proportion to the rest than in the Conchifera; and they exhibit a tendency to gain a position anterior to the œsophagus, and to approximate towards each other, so as to meet and form a single ganglionic mass on the median line. The *branchial* ganglion is constantly to be met with; but its position is extremely variable.   This centre, however, always bears a close relation with the gills, both in situation and degree of development; and even where conjoined, as it frequently is, with the *pedal* ganglion, it may be distinguished from it by the distribution of its nerves, as well as by its separate connection with the cephalic ganglia, which is always noticed in such cases.   This may be observed in the *patella* (limpet) and *limax* (slug).   Sometimes the functions of this ganglion are subdivided between two, of which one is still appropriated to the branchia, whilst the other is connected with the general surface of the mantle, and with the respiratory passages which are prolongations of it, and hence may be called the *palleal* ganglion.   The position of the *pedal* ganglion (which is generally double in the Gasteropoda, though the foot is single), also varies, but in a less degree since it is generally in the neighbourhood of the head.   Besides these nervous centres, we find in many of the Gasteropoda, a separate system connected with a very important set of organs the gustatory and manducatory, which are bu slightly shadowed out among the Conchifera In these higher tribes we find the œsophagus dilated at its commencement into a muscular cavity, with a curious rasp-like tongue, which serves to reduce the food, often supported upon cartilages, and sometimes furnished with horny maxilla.   The nerves which supply these do not proceed directly from the cephalic ganglia, but they are a part of a distinct system, which sends its ramifications along the œsophagus and stomach, and which is occasionally connected with the first by inosculating filaments. This set of ganglia and nerves, which is even more important from its relative development in some other classes, and into the analogies of which in the nervous system of Vertebrata we shall hereafter inquire, may be called, from its distribution, the *stomato-gastric* system.

The manner in which the cineritious

matter of the ganglia of the Mollusca is disposed, in reference to the nervous fibres which stand in relation to it, at once distinguish these centres from the ganglia of the sympathetic nerve of Vertebrata, or of the posterior roots of the spinal nerves, with which they have been sometimes compared. In the latter we observe the fibres *continued through* the ganglia, and the grey matter interposed amongst them. In the former, the grey matter is confined to the centre, and is *not traversed* by fibres; and the roots of the nerves which terminate in the ganglion are observed to penetrate to it, and then to diverge, becoming, as it were, lost in its substance; and this is alike the case with what are believed to be, from their connections, both sensory and motor nerves. This structure obviously resembles, therefore, that of the centres of the cerebro-spinal system in Vertebrata; and these ganglia may be regarded as corresponding with those parts of the nervous centres in the Vertebrata, the distribution of whose nerves is analogous. Thus the *branchial* ganglion obviously corresponds with that portion of the medulla oblongata which is the centre of the respiratory actions in Vertebrata. The *pedal* ganglion is analogous to that division of the spinal cord from which the nerves of the anterior or posterior extremity pass off. It is well known that such portions of the spinal cord may be completely isolated, without destroying the functions to which they minister. Thus, the brain and lower part of the spinal cord may be removed,— that portion only of the cerebro-spinal axis being left, which connects the principal respiratory nerves, in fact the *respiratory ganglion*,—and yet the animal may continue to exist for some time. It is then reduced to a condition similar to that of the Tunicata, whose single ganglion, though combining in some degree the functions of those which exist separately in the higher tribes, has evidently the regulation of the respiratory movements for its chief object. In the same manner, the integrity of the segment of the cord with which the nerves of the extremities are connected, will enable them to execute those movements of a reflex character, which depend upon its power as their centre, even though it is isolated from every other part of the nervous apparatus. The *cephalic* ganglia must be regarded as analogous, not to any single portion of the encephalon in Vertebrata, but in some degree to the whole. We find nerves of special sensation proceeding from them, certainly to eyes, perhaps also to olfactive organs; as well as others of special sensation, supplying the tentacula and mouth. Hence we must admit, that they perform the functions of the optic ganglia of Vertebrata, and perhaps also of the olfactory lobes; as well as of the

portion of the medulla oblongata in which the sensory portion of the fifth pair terminates. Moreover, they certainly give origin also to motor nerves, and must thus perform the functions of the medulla oblongata, from which the corresponding nerves arise in Vertebrata, as well as, perhaps, of the cerebellum. And, if we regard these animals as enjoying the perceptive, reasoning, and volitional faculties, in however low a degree, we must attribute to their cephalic ganglia some portion of the attributes of the cerebral hemispheres in the highest classes. This combination of function will not appear so extraordinary, when it is recollected that *all* the central operations of the nervous system are performed in the Tunicata by *one* ganglion, and in the Radiata by a series, of which each is but a repetition of the rest; and it is quite conformable to the general principle of the *gradual specialisation* of function, which may be observed in ascending the scale of organisation.

It is obvious that the portion of the nervous system of the Gasteropod Mollusca, into the analogies of which we have thus inquired, cannot in the least be compared *as a whole* with the *sympathetic* system of the Vertebrata, which it was formerly imagined to resemble. The distribution of some of its nerves to the viscera, however, may indicate that it partly performs the functions of that system, with which it is structurally intermixed, even in Vertebrata, as the late inquiries of Müller and others (of which the results will hereafter be stated) have shewn. But the stomato-gastric system may, perhaps, with more probability be considered as executing its offices. Into the peculiar character of that system we shall be more competent to inquire when we have traced it through other classes of Invertebrata.

Having thus separately considered the nervous centres of the Gasteropoda, and determined their special functions by their structural relations, we shall inquire into the mode in which these functions are combined, so as to enable them to act in harmony. This is an inquiry of much interest in reference to the determination of the offices of the different parts of the nervous centres in vertebrated animals. If we examine the mode in which the different ganglia are united by connecting trunks, we are led to perceive the important fact that, while they have little or no communication with each other, they are all directly connected with the cephalic ganglia, which seems thus to harmonize and control their individual actions. Frequently such a communication with one another appears to exist, where there is really none. Thus, in *Aplysia*, a cord passes from the branchial ganglion, which is situated in a posterior part of the body, to the pedal ganglion. Where such is

Fig. 6.
Fig. 6.—Nervous system of *Aplysia*: A, cephalic ganglion; B, branchial ganglion; c, c, lateral ganglia, combining the functions of pedal and palleal ganglia; D, pharyngeal ganglion.

the case, the trunk is not united with that which proceeds from the ganglion through which it passes; but the two remain distinct, though running in the same direction. Moreover, the double function of a ganglion may be sometimes recognized by its being connected with the cephalic mass by a double trunk. Thus, in the Aplysia, that which has been termed the *pedal* ganglion is really made up of a pedal and palleal ganglion, as is proved by the distribution of its branches; and in conformity with this double function, we find it communicating with the cephalic mass by two cords, besides the one which has been just mentioned as passing through it, and which appears as a third. In *Bullæa*, whose nervous system is disposed on the same general plan, the pedal and palleal ganglia are separately connected with the cephalic; the cord from the branchial ganglion passing through the palleal. These facts have been noticed by anatomists; but it has not been until recently that the physiological explanation of them has been given.

Further, a careful examination of these ganglia, and of their connecting cords, discloses this important fact, which is peculiarly evident in the case of the pedal ganglia—that the cord does not lose itself in the grey matter of the ganglion, but divides itself into filaments, which mix with those proceeding from it, to form the nervous trunks which it distributes. We can scarcely, then, fail to infer that the pedal ganglion, with the nervous fibrils proceeding from it, is the source of the reflex actions of this organ; whilst the filaments which are continuous with those of the connecting trunk, and which are thus in

relation with the nucleus of the cephalic ganglia, are the channels of sensory impressions, and of the motor impulses of volition. This is well illustrated in the very curious disposition of parts which we find in the arms of the cuttle-fish. These are provided, as is well known, with a series of suckers, which are important instruments of locomotion and prehension to the animal. It has been observed by Dr. Sharpey, that the nerves which supply these arms are provided with ganglionic enlargements, of which one corresponds with each sucker; and that each trunk consists of two tracts, in one of which the ganglionic enlargements exist; whilst the other passes continuously over these, but sends off nervous filaments, which help to form the branch going to each sucker. It has been supposed that the white or fibrous tract is the motor portion, and the ganglionic the sensory; but this is inconsistent with the facts known regarding the influence of the nerves upon the movements of the suckers. When the animal wishes to embrace any object firmly with its arm, it brings all the suckers simultaneously to bear upon it. There can be little doubt that this action is occasioned by a motor impulse, propagated from the cephalic masses by the non-ganglionic portion of the cord, which supplies all the suckers alike. On the other hand, any individual sucker may be made to attack itself by placing the substance in contact with it alone; this action is independent of the cephalic ganglia, as is evident from the fact that it will take place when the arm is severed from the body, or even in a small piece of the arm, if recently separated; and it can scarcely be doubted that it is due to the reflexion of the impression made upon the sucker, through the small ganglion in its neighbourhood, where it excites a motor impulse. The operation of these independent centres appears, in the entire living animal, to be controlled, directed, and combined, by the cephalic ganglia, through the medium of the fibrous band that passes over them, and mixes its branches with theirs. A very similar arrangement will be hereafter shown to exist in the double nervous column of the Articulata.

From the Gasteropod Mollusca we might pass to the class Cephalopoda, which is a most interesting one, in many respects; exhibiting to us the modification of the molluscous type (which is, perhaps most characteristically presented in the Gasteropoda), occasioned by their proximity to the Vertebrated division of the animal kingdom. In no organs is this modification more evident than in the nervous system; for, whilst in the lowest members of the group we find it approximating closely to the form it presents in the higher Gasteropods, its whole character and relations in the more elevated

species are so like those which exist in the lowest Fishes, that the analogies between their several parts may be traced with little hesitation. Into details on this subject, however, it does not suit our present purpose to enter, as little new information can be derived from it in illustration of the general functions of the nervous system.

CASE OF
RUPTURE OF THE FALLOPIAN TUBE
FROM ACCUMULATION OF THE CATAMENIAL FLUID.

To the Editor of the Medical Gazette.
    Sir,
The following are my notes of the case of rupture of the fallopian tube from accumulation of the catamenial fluid within the cavity of the uterus, to which reference was made by my friend Dr. Moore, in the conversation which ensued upon the reading of Sir Benjamin Brodie's "Account of two Cases of Imperforate Hymen," before the Royal Medical and Chirurgical Society, on the evening of the 9th of the present month. (See MED. GAZ. vol. xxvii. p. 810.)

Early on the morning of Tuesday, Oct. 24, 1837, I was requested to visit R. S. æt. 18, who, on my arrival (about an hour subsequently), was evidently *in articulo mortis.* Her pulse was barely perceptible, but extremely rapid; the skin was covered with a cold and clammy perspiration; there were low muttering delirium; tracheal rattle; the facies Hippocratica; and a continual involuntary discharge of the alvine contents. She died in a few hours.

Upon making some inquiries into the history of the case, I was informed that she had never menstruated; that about eighteen months previously, when the evolution of the external organs of generation and of the mammæ rendered probable the speedy appearance of the catamenia, she suffered from headache, pains in the back and limbs, cold extremities, and a heavy dragging sensation in the pelvic region, with some bearing down pains. These symptoms, after a brief continuance, subsided, but returned in five or six weeks; again ceased, and then returned after a shorter interval. This state of things continued for three or

four months, the symptoms upon each recurrence remaining longer, and becoming more urgent, whilst the intermissions became shorter in duration, and less perfect; so that at last there was no intermission, but manifest exacerbations occurring every fourth or fifth week.

In January, the lower part of the abdomen began to swell; a deep-seated tensive pain was felt in the pelvis; all her symptoms were aggravated, and there was in addition occasional vomiting. She still, however, kept about her usual employment, and took, by the direction of a neighbouring practitioner, some medicines, which, from the description given, I presume consisted either wholly or in part of iron. Under this treatment she got rapidly worse. On Friday the 20th, when stooping, she felt, to use her own expression, something give way within her, and the swelling of the abdomen appeared to subside, as did likewise the dragging and tensive pain above mentioned. Towards evening she complained of diffused pain of the abdomen, which, by Saturday, had so far increased that she was unable to bear the slightest pressure. There was great heat of skin, headache, knees flexed upon the abdomen, some difficulty of breathing, contracted state of the features, nausea and vomiting, with difficulty of, and intense pain over the abdomen, on emptying the bladder. This condition continued until Monday, when she passed gradually into the state in which I found her on the Tuesday morning.

Autopsy twenty-six hours after death.— On laying open the abdomen, I was surprised to find a large quantity of a dark red and thickish fluid (somewhat similar in appearance to blood, which had been for some considerable time effused) lying in the cavity of the peritoneum, and amounting, I should imagine, to twelve or fourteen ounces. The peritoneum, which was every where in contact with it, was stained of a reddish colour. On wiping away the fluid with which it was covered, there was an evident increase of vascularity, and in some parts the membrane was covered with a thin layer of coagulable lymph. I searched for the source of this sanguiniform fluid, but for a considerable time without effect. The uterus at length attracted attention; it was considerably larger than the

ordinary size of a man's fist, but, nevertheless, flaccid. Upon opening it, I found four or five ounces of a similar fluid to that in the abdomen, contained within its cavity. The fallopian tubes were enormously distended; so much so that I could with ease pass the little finger into them. Close to the fimbriated extremity of the left tube there was a fissure about two lines in length, with ragged edges, thus forming a free communication from the cavity of the uterus to that of the peritoneum : through this the fluid in question had evidently passed. The lining membrane of the uterus was of a slightly reddish colour, depending, as I imagine, on its contact with the contained fluid. On pursuing the examination, I found an obstruction to the passage of the finger or probe through the vagina. This was caused by the apposition of the walls of the canal, and their junction by firm cicatrization. This cicatrix was from half an inch to an inch in length, and contained a hard tough substance in many respects resembling cartilage. I could find nothing at all resembling the hymen.

Of the many interesting points presented in this case, there is but one upon which I shall here make any comment, viz. the period which elapsed between the rupture of the tube and the death of the patient. It is stated by the most esteemed practical writers on the diseases of the abdominal viscera, that peritonitis from extravasation of foreign matters into the cavity of the peritoneum proves generally fatal in a period varying from eighteen to thirty-six hours. That this statement is applicable to the great majority of cases will not, I think, admit of doubt; and if so, how is the diversity observed in the above instance to be explained? May it not have reference, in some measure, to the nature of the effused fluid; or does it receive a more probable explanation from the situation whence the foreign matter proceeded? The few cases of peritonitis consequent upon irritating substances in its cavity, which have come under my observation, either as student or practitioner, seem to show that death results more rapidly according as the exit of the foreign matter be higher up in the abdomen. The effects of opium in procrastinating or averting death—and in cases like these they are great—could not here have

contributed to the result; for a blister to the abdomen, and saline mixture, constituted the entire of the treatment which had been adopted.—I am, sir,
        Your obedient servant,
                WILLIAM MUNK, M.D.
        Physician to the Tower Hamlets Dispensary.

2, Finsbury Place South,
    Feb. 20, 1841.

ON THE USE OF OILED SILK.

SIR,

I WISH to register in your valuable columns my testimony in favour of oiled silk in surgery, and to acknowledge my gratitude to Dr. Macartney, for having first recommended to me an expedient, the value of which I have since proved, both in military and civil practice.

As it would be endless to enumerate cases, I shall briefly state the mode of application, and the result in ulcerated legs. When the skin surrounding the ulcer is inflamed, I immediately use the polytome, and encourage the bleeding by warm water, and afterwards apply dry lint, which I accurately cover with oiled silk, kept in its position by a bandage nine yards in length, from the toes to above the calf. The next day, on removing it, the lint is found moist with discharge and vapour from the ulcer; the inflammation appears much abated; the patient generally expresses relief from pain, and walks better. If the sleep be disturbed, I prescribe calomel and opium at bed-time, aperients the following day, a solution of cream of tartar for ordinary drink.

In most instances I have found it better to use the dry lint than the water dressing.

When the graduated pressure of the bandage, and the discharge of blood and matter, have reduced the swelling, with a feather I apply astringents, *e. g.* varied solutions of nitrate of silver, to the ulcer and adjacent skin. The detaching of sloughs is to be excited by the solution of one drachm to an ounce of distilled water; the lint and oiled silk to be continued. In a few days the skin and subcutaneous tissue become indurated from deposited lymph, when the absorbents should be excited by iodine ointment, which I have also

found beneficial in allaying the itching pustules infesting the skin after the ulcer is healed.

I substitute compound tincture of iodine for nitrate of silver, when the ulcer is of impetiginous origin. It is almost unnecessary to remark, that if varicose veins be the exciting cause, constant support is indicated; and should there be any internal derangement, counter-irritation is to be applied over the diseased organ. Should the ulcer be attributable to scrofula, I have prescribed hyd. c. cretâ, with pulv. cinchonæ, followed by a course of iodine.

When a sinus exists, it is often obliterated by the application of caustic to the skin over it.

I may here remark, that, in cases of ophthalmia, the blue or green oiled silk forms a good covering for the eye, keeping it moist and warm, admitting an agreeable light, and excluding dust, &c.

The French oiled silk is preferable to the English, as it is finer.

I am, sir,
Your obedient servant,
ALEX. LEIGH, A.B. M.B.

CASE OF

SIMPLE DISLOCATION FORWARDS OF THE HEADS OF THE TIBIA AND FIBULA.

To the Editor of the Medical Gazette.

SIR,

AMONG several useful purposes which such a journal as that which you edit serves, one is to provide an opportunity of publishing authenticated reports of single cases of rare occurrence. Permit me to send you an additional contribution of this kind.

— Enright, aged 65, of a spare habit, but hale and ruddy complexioned, by employment a stone-mason's labourer, was stooping to clear away some rubbish beneath a portico that was just completed, when the stone forming the architrave, weighing towards seven hundred weight, broke in two, and falling upon him bore him to the ground. His right hand was jammed under one fragment, which it was necessary to lift to extricate it. He could not stand for the shock, and some in-

jury to the left knee. The accident happened about half-past five P.M., on the 23d of February; he was shortly after brought to the Middlesex Hospital. I saw him between six and seven.

The first impression, on looking at the injured knee, was that the femur was broken immediately above the condyles, where there was a considerable depression, and there seemed to be motion. But upon a closer examination the femur proved to be entire, the depression being caused by the head of the tibia overlaying that bone. The condyles of the femur, the outer stretching the skin very tensely, were to be felt behind the upper ends of the tibia and fibula, the extremity of the condyles being fully four inches below the level of the articular surface of the tibia. The position which the displaced bones assumed was that of slight flexion. The pulsation of the anterior tibial artery on the instep could not be felt.

Two brief and ineffectual attempts were made by hand to reduce the dislocation, keeping the bones slightly flexed. Then a round towel was passed within the limb, to get a purchase upon the ischium and pubes; this was fastened to the irons of the head of the bed. Another round towel was secured by a clove hitch upon the malleoli and instep. Using these means, direct extension was made upon the leg, and in about a minute the reduction of the dislocation was accomplished. The limb was then laid straight upon a pillow, and supported laterally by junks.

Upon examining the hand, finding three of the fingers crushed, the flesh of the thumb deeply lacerated, and the skin torn off the whole dorsal surface, I amputated it above the wrist. The patient's progress has been in every way favourable. Some swelling and pain there was of the knee-joint forty-eight hours after the accident, for which twenty leeches were applied; but there is no pain now unless the joint is moved; and the swelling has disappeared.

This is the only case of simple dislocation of the head of the tibia forwards that I have witnessed. I saw, some years ago, with Mr. Andrews, of Stanmore, a young gentleman who, a few days before, had suffered simple dislocation of the head of the tibia

backwards, which Mr. Andrews had reduced. He had used direct extension, and had found considerable force necessary. The accident had happened in the following manner. The young gentleman was riding a pony on the common, and meaning to pass a tree that stood in his way on one side, when the pony swerved, and carried him by on the other side of the tree, which took the tibia, and forced it backwards, dislocating it behind the femur.

In the case which I have narrated, it is to be supposed that when the unfortunate man was borne down by the mass of stone, his leg, with the knee straight must have been stretched obliquely forwards, and the foot have been fixed against some object, when the strain falling on the crucial ligaments, tore them through, when the condyles of the femur would have been forcibly driven behind the tibia and fibula.

I am disposed to mention, as connected with the subject of dislocation, a simple contrivance, perfecting the commonest apparatus for reducing dislocations of the hip, which I have recently had put up at the Middlesex Hospital.

There was in the room destined for this purpose a ring let into the floor; and opposite to it, at twenty feet distance, was an upright iron bar, fixed by its ends into the wall, having catches at different heights adapted to the hook of a set of pullies. The patient being laid upon a common iron bedstead placed lengthways between the ring and the vertical bar, the two latter furnished points of attachment for making horizontal extension of the thigh. What I have added is an horizontal bar running below the ceiling of the room, the ends being attached to the joists of the floor above. This bar is parallel to a line joining the ring and vertical bar just described. It therefore allows the hook of another set of pullies to hold to it, and so affords the means of making a strain upon the dislocated femur, transverse to the axis of the limb, simultaneously with the longitudinal strain.

I am, sir,
Your obedient servant,
HERBERT MAYO.

March 2, 1841.

OXALIC ACID ACCIDENTALLY SWALLOWED IN AN EFFERVESCING DRAUGHT.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you the accompanying notes of a case of accidental swallowing oxalic acid in an effervescing draught, in mistake for tartaric acid. Should you deem it of sufficient interest to obtain a place in your valuable journal, your inserting it will oblige

Your obedient servant,
T. H. BABINGTON, M.B., T.C.D.
Licentiate of the Royal College of
Surgeons in Ireland.

Coleraine, Ireland, Feb. 17, 1841.

Marg. ——, æt. 24 years, had taken an effervescing draught, composed, as she imagined, of carbonate of soda and tartaric acid. On swallowing the draught in a state of effervescence, she felt a strong acid burning taste in her mouth, which immediately attracted her attention to the ingredients she had used in preparing the draught: she showed the substance which had been used for tartaric acid to her mistress, who immediately suspected that oxalic acid · had been sent her in mistake for tartaric acid*. Acting under this suspicion, she administered a large draught of tepid water (which acted as an emetic) and sent for medical assistance.

May 3d, 1837; noon.—On my arrival, I quickly recognized the suspected substance as being oxalic acid, and ascertained that a tea-spoonful (about two scruples) had been swallowed in combination with the carbonate of soda. I immediately had recourse to a strong solution of tartrate of antimony, which fully evacuated the contents of the stomach, and ordered her to take two table-spoonfuls of chalk mixture every fifteen minutes.

2 o'clock, P.M.—Has taken fourteen ounces of chalk mixture. Feels very cold and weak; pulse quick and feeble; complains of a hot sensation in fauces and œsophagus. Ordered to apply dry

* It is to be remarked that the soda and acid had been purchased from a grocer: hence the occurrence of the nearly fatal mistake. Throughout the north of Ireland, medicines, poisons, &c. are sold by grocers, and other uneducated persons, from whom they are readily purchased; a practice much to be reprobated, and which demands legislative interference.

heat to extremities, epigastrium, and axilla, and to continue the chalk mixture every half hour, with a draught composed of spirit of ammonia, tincture of opium, and cinnamon water, to be taken immediately.

10 o'clock, P.M.—Has had spasmodic pains in her stomach, left side, and along the colon; also numbness and a pricking sensation in her back and along her left thigh. Is thirsty. Burning pain at epigastrium; no tenderness on pressure, nor vomiting; pulse 86, weak and tremulous. Ordered a full opiate, and a castor oil draught early in the morning.

4th, 10 o'clock, P.M.—Rested badly; was delirious in the night; complains of headache; throbbing of temples. Pulse 80; mouth and fauces red and painful; no uneasiness in the stomach or bowels since the operation of the castor oil. Ordered cold lotion to the temples.

10 o'clock, P.M.—Has been very weak, nervous, and excitable, during the day; fainted once; headache better; no pain in stomach. Ordered an opiate draught.

5th, 10 o'clock, A.M.—Slept badly; disturbed by spasmodic pains in bowels, and an unpleasant tingling sensation along the spine and anterior part of thighs. No tenderness of epigastrium, but taking food causes much uneasiness; complains of headache. Ordered an ounce of castor oil.

10 o'clock, P.M.—Feels better since the oil operated. Ordered an opiate draught.

6th.—Slept well last night; pulse 76, regular; bowels free. Ordered gruel for dinner.

7th.—Complains of weakness; slept badly, not having had her opiate.

8th.—Complains of weakness in stomach: want of appetite, and acid eructations, now felt first time. Ordered compound infusion of gentian, with bicarbonate of soda.

10th.—Convalescent. Under the use of the bitter infusion, and an occasional aperient, her appetite and strength gradually returned; but a considerable time elapsed before she was able to resume her duties as a servant.

A few observations may be offered on the above case. All writers on the subject of poisoning by oxalic acid justly condemn the administration of warm water with a view to producing vomiting. In this case it was given by a non-professional person, and very fortunately produced vomiting: on my arrival I followed up this treatment with solution of tartrate of antimony, which more freely emptied the stomach. Some may conceive that this was not the safest emetic medicine I could have used, as its depressing powers might accelerate the absorption of the poison. Others may imagine that the stomach-pump might have been had recourse to with benefit. To the former I can say, tartarized antimony was used as being nearest at hand, and valuable time would have been lost in procuring other substances. In reply to the latter, Dr. Christison says, " I cannot see any use in using the stomach pump in cases of poisoning from oxalic acid." Whilst the emetic was operating I was preparing the chalk mixture, the use of which would neutralize any acid which might remain in the stomach; after which, heat was applied to the extremities, and a stimulating draught exhibited.

Although the symptoms were in this case of a mild nature, still they were strongly enough marked to shew the deleterious effects which even so small a quantity of oxalic acid is capable of causing, even in a case where it remains so short a time in the stomach as in the present case.

In the case before us the most striking symptoms were depressed circulation, followed by considerable and marked derangement of the nervous system*. Dr. Christison, in his valuable work on Poisons, alludes to a case recorded by Dr. Scott, of Cupar, in which nervous symptoms very similar to those I have detailed, occurred, and precisely about the same time. On the morning after swallowing the noxious substance, both, it appears, were similarly affected by weakness, numbness, and peculiar uneasy sensations in the back and legs.

From the symptoms in the case detailed, I think it would appear that this poison (when taken in a dose not sufficient to cause instantaneous death) acts first by depressing the circulating system, into which it is no doubt rapidly absorbed, and then acts through the

---

* The symptoms as detailed in the above case derive additional interest when compared with Mr. Jackson's case of " Poisoning with Binoxolate of Potash," as detailed in the MED. GAZETTE of the 18th of December, 1840.

circulation on the brain and nervous system. I arrive at this conclusion from observing that, at 2 o'clock on the day on which the acid was swallowed, we found weak pulse, cold extremities, &c.; and the next morning we observed the supervention of what may be called decided nervous symptoms, and these symptoms again returned on the 5th, the second day after swallowing the poison; thereby proving that the deleterious substance had exerted a powerful influence on the brain and nervous system generally.

(For the London Medical Gazette.)

AMAUROSIS FROM CEREBRAL AFFECTIONS.

I SHALL not, in the present paper, discuss all that belongs to this head, but narrate two cases, one commencing after fever, the other a well-marked example of organic disease. Various imperfections or losses of vision, conditions of the pupils, of the lids, and eyeball, occur as prominent and highly important symptoms in the progress of many, and even diametrically opposite conditions of the brain or its membranes : in cerebral congestion, or in anæmia ; during the progress, or as a result, of inflammation of the brain or its membranes ; from injuries with or without compression; from organic changes and diseases of the most opposite characters; affections of the brain, &c.; during the progress of other diseases, during and after apoplexy, convulsions, &c.

The following case came on after a severe attack of the petechial or typhus fever, during the progress of which he remained insensible for some days, with a slow and imperfect subsequent convalescence :—

Complete amaurosis of both eyes*; loss of the sense of smell ; impairment of hearing, speech, intelligence, and memory, with severe and continued headache.

William Saunders, admitted at the West of England Eye Infirmary on the 23d of March, 1840. He is 21 years of

age, a shoemaker, short in stature : his countenance pale, deficient in expression, but somewhat anxious, presenting the appearance of suffering from pain. The history we gained from his mother, who attended him, was, that in Nov. 1839, he had suffered from a severe illness, typhus fever, with an eruption of purple spots, during the continuance of which he had suffered severely from his head, and had been insensible for some days, and that his convalescence from the fever had been very slow and imperfect. Previous to this date he had always enjoyed good health. His sight had been impaired ever since his recovery from the coma, when he complained of much impaired vision and dark bodies flitting before the eyes : this had continued to increase to the present time, May 25th, 1840, attended by headache, &c., the vision being then entirely lost.

Symptoms.—Countenance highly vacant, but expressive of suffering ; the eyeballs roll perpetually, and are not directed to any object or person when he is spoken to : this constant rolling or oscillatory motion came on with the amaurosis, and has increased proportionally : the globes themselves appear natural : the pupils of both eyes are widely dilated, and possess no motion whatever in either eye by alternations of light and shade, whether one be closed and the other examined, or both be left open, and each tested alternately.

He states that both eyes are equally blind ; that his vision is so imperfect that he is unable to distinguish night from day. " I can," he says, " see as well with the eyes shut as open." He complains of fixed and severe frontal cephalalgia, pain over the brows, almost always present, but occasionally aggravated in paroxysms, and that during these severe attacks he is affected with nausea; when very excruciating, even

* The plan adopted in taking these cases was, first, to learn as much as possible of the patient's

previous history ; secondly, to inquire into his preceding and incipient symptoms, then to learn all that he knew of the predisposing and exciting causes. The present symptoms were arranged into objective and subjective ; viz. local appearances and changes ; secondly, sensations and functions. The constitutional into febrile and sympathetic conditions—the state of the vascular and nervous systems. Then an attempt was made at diagnosis, and the ascertainment of the pathology. From this was gathered the indications for treatment. The extent and progress of the case was included under the progress, results, and terminations of symptoms, the general and local effects of treatment, and the mode and peculiarities of the employment of remedies.

actual vomiting. His general health is otherwise tolerably good; his appetite regular, his tongue clean, and the secretions and excretions normal. The sense of smell is completely lost, whilst false and disagreeable sensations have supplied its place: thus, he often imagines that he is in the proximity of the most disgusting and fœtid effluvia. The hearing is very imperfect, so that he requires to be spoken loudly to before he is conscious that any one addresses him; and his mother states that he becomes quite deaf when he suffers from sore throat, with which he has been attacked several times of late. His memory is very imperfect; indeed he seems to remember scarcely any thing; he has forgotten the names and application of many things, and his other intellectual faculties are blunted in a similar manner, so that he is not adequate to the slightest bodily or mental exertion. His headache is invariably increased by long sitting, the recumbent posture during the day, stimulants and food, especially dinner; he often complains of vertigo, and weakness in his limbs. His speech is occasionally imperfect from a want of memory. " He has often," says his mother, " a catch in his speech."

The mother attributed the attack of fever (as most persons do where the exciting cause is not obvious) to an accidental chill, which the patient received during his usual employments, since he was quite well before, and became ill almost directly afterwards.

There are no symptoms of fever present: the pulse is quiet and natural, the tongue moist and healthy, with diminished sensibility of the general nervous system.

Diagnosis.—The diagnosis from these symptoms was " amaurotic blindness of both eyes from cerebral disease—probably chronic inflammation and results —deriving its origin from fever, with severe vascular disturbance within the cranium."

Such being the diagnosis, the indications for treatment are evidently here to be directed to the condition of the parts actually diseased — the pathology of the amaurosis. Absolute rest of mind and body, a mild, continued, constitutional action of mercury, slight purgation, rigid attention to diet, continued counter-irritation, coolness

of the head, and warm stimulating pediluvia, were, on these grounds, directed. The mouth was kept slightly sore by five grains of blue pill alternate nights, and the bowels relaxed by an occasional pill of the compound extract of colocynth with one-twelfth of a grain of tartar emetic.

He presented himself again on the 13th and 27th of April, and on the 4th and 25th of May, and was ordered to persevere in the remedies and regimen, as no material alteration occurred in the symptoms; the general health improving slightly, and the sight continuing much in the same condition.

On the 29th of June the blue pill was changed for the Pil. Hyd. Chlorid. Comp.; and the colocynth for the compound rhubarb.

The treatment which had been adopted before this patient applied, according to his own account, was antiphlogistic in the first instance, that this was subsequently changed for the regular employment, first of electricity, and then galvanism, with some apparent benefit at the time, but with aggravation of his symptoms subsequently.

After this period the patient became so ill that he was unable to attend, and I am therefore unable to trace his further history, and, as so commonly happens, unacquainted with the post-mortem appearances connected with these symptoms. It, however, furnishes a good history of the case as far as such cases can be traced usually at public institutions of this kind.

REMARKS.—Here is a case in which the perpetual rolling or oscillatory motions of the globes came on with amaurosis of both eyes so severe that he could not "distinguish night from day," in an adult, from cerebral disease. Such must be very rare; I have never seen or heard of any other similar case. Indeed, the usual explanation of the symptom is that it results from the eager search after light in an individual who has never perfectly enjoyed vision: hence it is almost sure to be present in cases of congenital cataract, or imperfect forms of congenital amaurosis; but the eye-ball does not acquire this restless motion when the sense of vision is completely absent. The cerebral disease was most probably not ramollissement, in which the progressive destruction of the cerebral matter is

marked by a gradual and extending weakness, involuntary spasm, and then paralysis of the muscles, beginning with the lower extremity—not inaptly denominated creeping palsy. There was no fever present; but this is by no means a constant symptom of the progress and results of chronic inflammation within the cranium, affecting portions. Chronic inflammation, affecting a small portion of the brain or its membranes, presents a great diversity in duration, continuance, symptoms, effects, and mode of termination;* in many cases passing into, and not distinguishable from, organic diseases of the same parts. If any reliance is to be placed in symptoms, this was most probably a case of this nature. The intellectual powers and the senses were the functions mainly interfered with, whilst the muscles were neither paralysed, convulsed, nor affected with spasm: he complained only of weakness in the limbs; but no practical deductions of the seat of the disease can be drawn from such data. Nothing peculiar could be made out concerning the amaurosis, save that it had increased gradually, and was accompanied by muscæ volitantes, both eyes suffering equally and conjointly. The continuance, the severity, and the aggravation of the headache, was characteristic.

Headache; amaurosis of both eyes; strabismus of the left; imperfection of hearing, and weakness of the muscular system.

James Newberry is a shoe-maker, twenty-five years of age, of a dark complexion, tall and thin; he professes himself to have been of regular and healthy habits. His present disease came on about two years since, and without, to his knowledge, any obvious exciting cause. At that period he began to experience severe pain in his head, which most frequently affected the back part, but was sometimes situated in the forehead, or seemed to dart from behind forwards; this was wont to continue a considerable part of the day. It came on at irregular intervals, and not at any specified time, was aggravated in very severe paroxysms, and always increased by food and stimulants. When very severe, these parox-

ysms were attended with nausea and vomiting; but the appetite and digestion were usually good, and the functions of the intestinal canal regular. These symptoms, with the omission of the sickness, have continued to the present time (August 1840). Various new indications of cerebral disturbance have lately developed themselves, synchronously with the increase of disease: great weakness of the muscular system generally, so that he states himself "not steady on his legs," but without any other paralytic tendency; the sense of hearing has failed gradually, but is by no means lost, as he understands perfectly when addressed in a loud, clear key; the smell, also, is little if at all affected.

He was quite unconscious of any derangement of vision till about four months since* (May), when, after bleeding nearly to syncope, on opening his eyes he found that of the left entirely lost. The amaurosis of the left organ was complete, and has still continued so: the vision of the right has failed gradually since the left eye became thus affected. Shortly afterwards he discovered that the left eye-ball was not directed normally, and, by degrees, it was turned completely out of the axis of vision.

September 1840. — Strabismus convergens exists at present in both globes, but by far to the greatest degree in the left. The eyes are apparently thrust forwards, rendering them preternaturally prominent; the irides deprived of their healthy brilliancy, of a dark dirty green colour; both pupils dilated, and completely motionless in the left: there is a preternatural vascularity, but the fundus of either eye, as seen through the dilated pupils, appears dull and slightly opaque.

He complains of some degree of tension in the globes, misty distorted vision in the right eye, complete amaurosis of the left, the occasional perception of undefined muscæ or more luminous objects. The vision of the right failed gradually, and at first he was much more troubled with these appearances; objects also being occasionally seen double—one much more

* Vide Abercrombie's Practical Researches, p. 118, edit. 3d.

* Great caution is requisite in entirely crediting the accounts of patients about the sudden occurrence of blindness, since it may have existed long before, and yet not have been discovered from want of observation and comparison.

defined than the false perception, less circumscribed than the true; so that he was always conscious which was true, which false. His general health is tolerably good, but he is nervous and excitable; debilitated, but without paralysis: there is no fever present, and the vascular system is undisturbed. His pulse was rather slow and full.

The usual treatment failed to procure any favourable indications; his symptoms have continued to increase, and no doubt can now exist of an unfavourable termination: should such be the case, and an opportunity be afforded for pathological examination, I trust to give the appearances at some future period.

REMARKS.—This presented the characteristic, continued headache, of organic cerebral disease, and well-marked diagnostic symptoms from cephalalgia dependent on deranged digestion; it exhibits also the great sympathy which exists between the brain and stomach, since when the paroxysms of headache were most intense nausea and vomiting were produced: this is quite usual. Where both eyes are affected, as in this case, we find that one suffers in general before the other, and then its fellow becomes more and more amaurotic in accordance with the extension of disease. Can we deduce the seat of cerebral disease from its effects? I think not. We see disease confined to the cerebellum producing blindness as constantly as when situated in the very part whence the optic nerves take their rise; and blindness is one of the symptoms which, acute and chronic, simple or compound, disease of the spinal cord effects. I trust, in some future paper, to state all that is known concerning the influence of the spinal cord on vision.

The amaurotic symptoms seemed to indicate some mischief going on in the globes themselves, independently of the cerebral affection, whilst the squint seemed to result from the amaurosis rendering the left eye useless, and by its increase likewise interfering with the normal axis of its fellow. The fact of its not occurring until the vision of the left eye was quite lost, leads me to this conclusion in preference to the supposition of its cerebral origin.

DROPSY AS THE
SEQUELA OF SCARLATINA.

To the Editor of the Medical Gazette.

SIR,

IF you consider this letter of sufficient interest, I shall consider its insertion in your valuable journal a great favour.

In reading the highly interesting and instructive report of the Ardwick and Ancoats Dispensary, by Dr. Howard, in your last No., my attention was arrested by his remarks upon dropsy as the sequela of scarlatina; and I would request the favour of inquiring whether it has appeared to him that the occurrence of this sequela has any connection with the treatment adopted during the course of the primary complaint?

The reason I ask this question is, that Dr. Seymour, physician of St. George's Hospital, in his valuable lectures on the Practice of Medicine, in speaking of anasarca following scarlatina, says, " this disease generally follows those cases where purgatives have not been given so freely as is proper, or where the usual diarrhœa that follows eruptive fevers has not occurred; it seldom, or perhaps never, follows a case in which there is great affection of the throat, or which is of a malignant character, as in such cases the purgatives have always received due attention." This would appear, in some measure, to be borne out by the observations of Dr. Howard, who says " it was, according to my observations, decidedly more frequent after mild than severe cases," and that " in twenty of the cases medical aid was not sought until the dropsy had supervened."

If Dr. Howard has the means of ascertaining whether, in the cases of this complaint included in his report, free purgation has been omitted, it would, I fancy, lead to a useful practical deduction; for although it seems probable that exposure to cold is the, or one of the, exciting causes of the disease, yet the neglect of the proper application of purgatives during the course of the primary disease may prove an important predisposing cause.

I may perhaps mention that the authority I have quoted also states that blood is always present in the urine in

this form of anasarca. May not this be the source of the albumen?

I am, sir,
Your obedient servant,
ARTHUR BROWNE STEELE.

Northampton, March 1, 1841.

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à alonger ce que le lecteur se
tue à abréger."—D'ALEMBERT.

Organic Chemistry, in its applications to Agriculture and Physiology. By JUS-TUS LIEBIG, M.D. &c. Edited from the M.S. of the Author, by LYON PLAYFAIR, Ph. D. 1840.

THIS is a work of remarkable interest. Uncertain as the general principles of organic chemistry must at present be acknowledged to be, we find here appli-cations of its facts made to a number of the most interesting and important phenomena of the universe, and this with a boldness and clearness which have rarely been surpassed. Professor Liebig has studied organic chemistry less in his own laboratory than in na-ture's processes on her own great field; and his conclusions are therefore ob-tained less frequently from the products of delicate analysis, than from the na-tural phenomena presented in wide tracts of land, woods, meadows, and corn fields, and in their respective ve-getable products, or from the opera-tions of art on a large scale.

Much of the work is remote from the province of medicine, and we have but insufficient space for that which most nearly concerns us. Of a part of this, however, we cannot resist offering some abstract.

The greater part of the chemical changes that occur in organized bodies under ordinary circumstances are those called chemical *transformations* or *me-tamorphoses;* the peculiar character of which is, that by the action of a decom-posing body, or force, the elements of a compound are disturbed, and made to enter into two or more new compounds, with one or more of which the decom-posing body may or may not combine. From the very slight force by which the elements of organic bodies are held together—the consequence at once of

the number of elementary atoms that enter into the composition of the com-pound, and of the abundant presence of nitrogne nad water—the slightest forces are sufficient to excite the commence-ment of their chemical transformation. And this once commenced, there comes immediately that influence which is the most important in the chemistry of organic substances, and which the author, though he cannot be said to have discovered it, has been the first to exhibit in its true importance—we mean the influence which a body in the act of combination or decomposition exer-cises upon any other body with which it may be in contact. Such a body " en-ables," (or, we would rather say, *may induce*, for the influence is not always effectual, though it is probably always exercised), " another body with which it is contact to enter into the same state."

There are examples of this in inor-ganic chemistry. Platinum does not decompose in nitric acid; it may be boiled with it, even in a state of the finest division, without being oxydized. But an alloy of platinum and silver dissolves with great ease in nitric acid: the oxydation which the silver suffers causes the platinum to undergo the same change; or, in other words, the latter body, from its contact with the oxydizing silver, acquires the property of decomposing nitric acid. Metallic oxydes, in which the whole or a portion of the oxygen is very weakly combined, not only cause the decomposition of peroxyde of hy-drogen, as some of the pure metals do, but are themselves also decomposed and reduced; the act of decomposition of the one oxyde, mechanically (?) pro-duced, having a decomposing influence upon them. " It is evident," therefore, " that the active state of the atoms of one body has an influence upon the atoms of a body in contact with it; and if these atoms are capable of the same change as the former, they likewise undergo that change; and combina-tions and decomposition are the conse-quence." Many organic compounds retain their state only by the *vis inertiæ* of their particles; if this only be de-stroyed, if motion be in any way com-municated to them, they obey other affi-nities, or their own natural attractions, and enter into combinations, which,

under the circumstances, are more stable.

This principle is strikingly exemplified in the processes of fermentation; the ferment is a body undergoing decomposition, and as soon as it is added to the organic solution it exerts a decomposing influence on its particles, which enter into new combinations, or continue passing through a series of changes till the whole of the ferment, the original excitor of the action, is decomposed, and comes to a condition of rest, when again all action will cease. The whole of this process is admirably illustrated; but its details concern the brewer and the wine and vinegar merchant more than the doctor; and we, therefore, prefer to draw our illustration of this decomposing influence of decomposing bodies from those processes which are directly of professional interest, although it must be confessed that such explanations as in the more simple processes bear the manifest stamp of truth, are here comparatively (we are far from thinking them *absolutely*) hypothetical.

When blood, brain, gall, pus, and other substances in a state of putrefaction, are laid upon fresh wounds, vomiting, debility, and at length death, are (sometimes) occasioned. Bodies after death frequently pass into a state of decomposition, which is capable of imparting itself to the living body: a cut with a knife used in dissecting them producing dangerous consequences. Bad sausages have produced death in hundreds of cases; and these have especially happened in Wortemberg, where sausages are prepared from various materials. If well prepared they may be preserved for months, and furnish a nourishing savoury food; but when the spices are deficient, and particularly when they are not smoked till they have been long made up, or not smoked sufficiently, the sausages undergo a peculiar kind of putrefaction which begins at the centre; and in these parts they become paler, soft, and greasy, and are found to contain lactic acid and lactate of ammonia, constant products of putrefaction. No poisonous material can be detected in such sausages, and alcohol and boiling water completely destroy their injurious properties: their influence is the consequence of their being taken into the blood while they are still in a state of decomposition, and of their imparting their peculiar action to the constituents of that fluid.

In the very disease which such sausages produce the author sees the effects of the decomposing influence. There is a gradual wasting of the muscular fibre, and of all the constituents of the body similarly composed; the patient becomes much emaciated, and dries to a complete mummy, and finally dies. The carcass is stiff, as if frozen, and is not subject to putrefaction. All substances in the body that are capable of putrefaction are gradually decomposed, and after death nothing remains except fat (?) tendons, bones, and a few other substances, which are incapable of putrefying in the conditions afforded by the body.

Of course the author adduces other examples of the same kind of influence from syphilis, small-pox, and other contagious and malarious diseases; and he here passes over the ground which has been trodden by many of his predecessors, who have held in all these diseases a theory of fermentation. He points out, also, the analogies between the two processes with all that greater precision which the improved chemistry of modern times, wielded by one of the greatest masters of the science, could not fail to give; but there is nothing in his illustrations that is novel as well as important. It must be confessed, indeed, that in these subjects, pathology is not yet mature for the reception of all the aid that chemistry will one day give it; and if we have a fault to find with the work before us, it is for the boldness with which it asserts things as beyond doubt, of which every practised physician could tell him that that part of their foundation which is set on physiology is utterly fallacious.

In saying this we do not wish to be taken as meaning that chemistry has nothing to do with contagious and other diseases; on the contrary, we believe it highly probable that the act of fermentation, and the influence and apparent reproduction of a contagious virus, will be hereafter proved to be closely and particularly analogous, if not identical. We object only to the method in which these subjects are written on, by those who deal with them as if nothing on either side of the case was doubtful; and who *assert* with more boldness than they are warranted to feel in *thinking*.

Some of the few remarks that the author makes on the action of poisons are important. Speaking of the small quantities of some that are destructive to life, he points out an explanation drawn from the very high equivalent numbers of most animal substances. That of fibrine is 6361 ; and it may, therefore, be assumed that a quantity of fibrine, corresponding to this number, combines with one equivalent of arsenious acid or of corrosive sublimate. When 6361 parts of anhydrous fibrin are combined with 30,000 parts of water, it is in the state in which it is contained in muscular fibre, or in blood in the human body ; 100 grains in this state would form a neutral compound, of equal equivalents with three grains four-tenths of arsenious acid, and five grains of corrosive sublimate. In like manner 100 grains of albumen, containing all the water natural to it in the body, would combine with a grain and a quarter of arsenious acid ; in other words, it would need but five grains of corrosive sublimate, or 3·5 of arsenious acid to poison every 100 grains of fibrine in the body.

The author's notions on the action of medicine are sometimes rather strange. The action of concentrated solutions of salts in purging, depends, he holds, on their abstracting water (after the fashion of the mutual interchange of endosmose) from the vessels of the digestive canal ; and thus diluting the solid substances contained in the intestines. The composition of the salts has nothing to do with their purgative action ! We suspect if a healthy man were to take sulphate of magnesia one day, in the same quantity as he ordinarily, takes chloride of sodium at his meals, he would be able to contradict the professor.

But we must here leave the work. The desire to consider those parts of it which most concern our readers has compelled us to abstract the worst portions of it. The specimens we have given do not do it justice ; on all subjects relating to agriculture, brewing, the management of vines and wines, its contents are far better ; and from all who are interested in chemistry, or in those arts, they deserve a most attentive perusal.

Essays and Heads of Lectures on Anatomy, Physiology, Pathology, and Surgery. By the late ALEXANDER MONRO Secundus, M.D. &c., upwards of fifty years Professor of Anatomy and Surgery in the University of Edinburgh; with a Memoir of his Life, &c. By his SON and Successor. Illustrated by Engravings. Edinburgh, London, and Dublin, 1840. 8vo. pp. clix. and 132.

DR. MONRO, the second physician of that name, was born in the year 1733, and died in 1817, in the 85th year of his age.

"The late Dr. Monro of Edinburgh," says Dr. James Gregory, in a letter to our author, " long and most deservedly enjoyed the highest eminence which any man of the medical profession ever attained in Scotland. * * * * Hardly any life, even of a literary man, can be conceived to afford fewer interesting materials for a biographer than Dr. Monro's. It was distinguished by no striking event—it was chequered by no vicissitudes of good and evil ; it was a life, from early youth to extreme old age, of almost uniform and uninterrupted prosperity. Nay, he seems scarce to have felt any of those discouragements in his splendid career, which most men of literary professions, but especially physicians, experience in their laborious progress to the highest honours and rewards to which they can aspire ; and certainly his progress was never retarded by any such adverse circumstances. His success, on all occasions, like the victories of Timoleon, seemed always to be accomplished with ease ; yet it cannot, on this account, be attributed altogether to good fortune or mere chance. Some favourable, almost accidental, circumstances contributed, no doubt, to his great success in life ; but much more of it must be attributed to his own merits, to his constant unexampled activity in every pursuit in which he engaged, and to his good sense in perceiving and improving those advantages which might be considered as mere favours of fortune."

The memoir embodies short notices of the different works published by Dr. Monro secundus, with extracts from his lectures, and a few additions by our author. The essays are five in number. The first is on the lymphatic system ; the second, on the character, causes,

consequences, and mode of treatment, of inflammation; the third is on the structure of the windpipe and lungs, and some of the organic derangements of the lungs and pleuræ; the fourth treats of the structure and some of the organic diseases of the circulating system; the fifth is entitled, " of the cause of the dangerous inflammation which generally follows the wound of a shut sac, and of the manner of preventing it."

This book contains matter to interest both the physiologist and the practitioner; and ought to find a place in every complete medical library.

A System of Midwifery. By EDWARD RIGBY, M.D. Physician to the General Lying-in Hospital, &c. London, 1841. Small 8vo. pp. 314.

THE work before us is the sixth volume of the Library of Medicine, edited by Dr. Tweedie, of which we took occasion to speak favourably some months ago.

Dr. Rigby has divided his work into five parts; which are, severally, on the anatomy and physiology of utero-gestation; on natural pregnancy, and its deviations; on eutocia, or natural parturition; on midwifery operations; and on dystocia, or abnormal parturition.

Besides English and French writers, our author quotes freely from German ones, such as Naegele, Boer, and Wigand. In speaking of the lock of the forceps, he says, "An ingenious modification was invented by the late Professor Von Siebold, of Berlin; but the most perfect lock is that of Professor Brüninghausen, of Würtzburg, first introduced by ourselves into this country, and known among the instrument-makers under the name of Professor Naegele's forceps. The shank of one blade has a semicircular indentation, which, at the moment of locking, fits into a fixed pivot in the other; this, therefore, combines the advantages of the French and English locks. We can safely affirm, from extensive experience for many years, that there is ever less difficulty in locking it than with the English lock. The blades are capable of instant separation; and yet, when locked, the firmness of their union is equal to that of a pivot joint."—P. 137.

It seems that Madame La Chapelle always shows the forceps to the patient before using it, and we think she is in the right. She also partly explains its

use: " il n'en est aucune que cette démonstration ne tranquillise, et j'en rencontre souvent qui à leur deuxième accouchement sollicitent l'application du forceps qu'elles ont vu mettre en usage pour les débarrasser du premier."

Dr. Rigby's work does him credit; and will maintain the reputation of the useful collection of which it forms a part.

A Practical Treatise on the Cure of Strabismus or Squint, by Operation, and by Milder Treatment; with some new Views of the Anatomy and Physiology of the Muscles of the Human Eye. By P. BENNETT LUCAS. Illustrated by Plates. London, 1840. 8vo. pp. 91.

THIS is a sensible and useful treatise on a subject which has of late much occupied the profession. After a full account of the orbits, the muscles of the eye, and their insertions, the conjunctiva, and the subconjunctival and sub-muscular fasciæ, our author proceeds to consider the causes of squinting. This distortion may arise from excessive development of the rectus internus, dyspepsia, disease of the brain, the exanthemata, from imitation or habit, corneal opacity, &c. In many of these cases it is clear that the operation would be useless, or injurious.

" Two cases presented themselves to me some months ago, to be operated upon for convergent strabismus. On examining the condition of the eyes, one cornea in each was found to be densely opaque; in one case for half its circumference, in the other for a smaller extent. Both squints were consecutive upon the opacities, and evidently took place for the purpose of allowing the rays of light to pass through the transparent portion of the cornea," (p. 55—6). Our author very properly refused to operate in this case; but the operation was performed, he says, by some one else, and the eye was thus rendered straight, but useless,

There are other forms of strabismus which are curable by medicinal treatment, or by mere lapse of time; and which, of course, must not be selected for operation.

The sections on the mode of performing the operation, on the reparative process after it, on the causes of

failure of the operation for convergent strabismus, and on the effects of the operation on vision, are all interesting ; but instead of making extracts from them, we deem it better to refer our readers to Mr. B. Lucas's treatise.

MEDICAL GAZETTE.
Friday, March 5, 1841.

" Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri ; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
                                                            Cicero.

MEDICAL DEGREES.
MARISCHAL COLLEGE, ABERDEEN.

Our readers are aware that we never have attached any very great importance to medical degrees, as was pretty clearly proved by our articles on the subject, when the College of Physicians decided—and in our opinion very wisely decided—on not requiring them from those who were candidates for their license. On the subject of all such honours we are much of the opinion of Falstaff:—

" Can honour set to a leg ? No. Or an arm ?   No.   Or take away the grief of a wound ?   No.   Honour hath no skill in surgery, then ?   No.   What is honour ?   A word.   What is in that word, honour ?   What is that honour ? Air. . . . . . Honour is a mere scutcheon, and so ends my catechism."

When, however, the new regulations of Marischal College, Aberdeen, were sent to us for insertion some three weeks ago, along with a local paper containing an elaborate encomium upon them, we thought the whole subject worthy of attention, and we noticed it in our number of Feb. 12th. Our remarks applied, first, to the plan of education which Marischal College has laid down, and the principles upon which it intends to grant medical degrees ; and secondly, to its right to confer such degrees. Our last number contains a letter from Dr. Clark, who it appears is Professor of Chemistry in

Marischal College, which he has been pleased, for reasons best known to himself, to designate as *the* " University of Aberdeen," and the " Marischal University."

In this letter, the learned professor expresses much anger at the manner in which we have treated the second branch of the subject. He seems to imagine that the proceedings and privileges of his College are altogether beyond the pale of criticism or discussion.   He says we have charged the College with " fraud ;" that we have represented him and his colleagues as a " gang of impostors ;" and he talks with " scorn" of our "disgraceful attack."

Now here is a great deal of virtuous indignation and excellent resentment absolutely thrown away.   We have been in the habit of discussing—and our best title to public confidence is, that we have discussed freely and independently — as well the constitutional powers and duties of the various public bodies connected with the profession, as the manner in which those powers and duties have been exercised and discharged.   In practice we have never shrunk from the examination of matters to which our attention has been specially invited by the parties concerned, and for the circulation of which we have, at their own request, lent our columns. That Marischal College had exceeded its legal authority, seemed a necessary conclusion from the premises which we stated.   But in touching upon the history of its medical degrees, we not only did not apply to the College, and the gentlemen who are associated with Professor Clark in " fulfilling the high functions entrusted by the country to their charge," the offensive expressions which the Professor has thought it becoming to use with regard to them, but we did not so much as insinuate anything at all affecting their honour

or integrity. The question at issue is one in which many professional men are interested, and we shall therefore enter more fully upon it than we should otherwise have done. We feel "scorn," we trust, for no man, and we will endeavour to explain to Professor Clark why his letter has failed to produce in us that conviction which we always yield to sound reasoning, however discourteously expressed.

In the first place, we referred the commencement of the Marischal College degrees in theology, law, and medicine, to the year 1728, or thereabouts. To which Professor Clark replies, that Newton's Philosophy was then and there " taught first from the lips of Colin Maclaurin"—a fact which, however interesting, if authenticated (although, by the way, the Edinburgh Encyclopædia represents him as having been Professor in the University of Edinburgh as early as 1725), has, so far as we have yet been able to discern, no very obvious or important bearing on the question before us : seeing that the interpretation of charters and the definition of legal rights, have never formed the peculiar province of the Newtonian philosophy. Now we would respectfully suggest that the quotation of a few instances of graduation in theology, law, or medicine, prior to the date assigned by us, would have met our statement much more appositely.

Again, it is inaccurate to represent us as having said " that in Marischal College no provision was made for theological instruction." We said that it was created " without any faculty of theology, of law, or of medicine" — a very different statement, and quite consistent with the fact that the principal is required by the charter to lecture on sacred literature for one hour once a week, as also to lecture on the physiology of Aristotle, to which this all-accomplished official is to add a short explication of anatomy, and, moreover, to propound the principles of geography, chronology, and astronomy, besides the Hebrew grammar, in which, as in Syriac, he is required to be skilled ! We wonder whether the principal still possesses these multifarious attainments ? Professor Clark admits that, " in a national chartered institution, it is not at all unusual that, as occasions arise for its enlargement, the original charters should be found narrow enough to give occasion to questions as to their interpretation under new circumstances." So say we ;— and the more's the pity.

In his statement of the case in the House of Lords, our learned opponent has fallen into several important mistakes. The charter of King's College, Aberdeen, requires the professor of civil law to be a Doctor in that faculty, if such persons can *conveniently* (*commodè*) be had ; otherwise, a licentiate *cum rigore examinis*, who is to take the degree of Doctor within a year. The office being vacant, Catanach, an Aberdeen advocate, holding a diploma of LL.D. from Marischal College, had a majority of votes ; Gordon, of the Scotch bar (not claiming to be a graduate in Law), had the remainder. Gordon contended that he, having passed an examination for the bar, came within the description of a licentiate *cum rigore examinis*, and that the votes for his opponent were thrown away :—the latter being no licentiate *cum rigore examinis,* as never having been examined, and no doctor, as possessing only a Marischal College degree:—and, consequently, not duly qualified. The Scotch courts decided in favour of Gordon ; but the House of Lords found that Catanach was qualified, and had been duly elected.

The decision did not touch the question as to the validity of his degree, as that point did not affect the real merits of the case, the preference given to doctors by the charter being quite discretionary—but it proceeded on one of the two following grounds : either that the whole *status* of licentiate in civil law having fallen into desuetude, any one was eligible ; or that Catanach, being a member of the learned body of the advocates of Aberdeen, came within the description of licentiate, and because a year after the appointment is allowed for obtaining the degree. Certain it is that Aberdeen advocates, having no degree of LL.D. from any college whatever, have since been elected to the office without question.

It is not quite accurate to say that the professor of law, or the Principal, of King's College, *must* be doctors in their several faculties. The clause in the charter, which prescribes graduation within a year, is merely directory ; it ought, no doubt, to be complied with, but the election is not made void by non-compliance. But suppose the members of King's College to have acquiesced in what Marischal College has done ; how does that strengthen Professor Clark's position? If, indeed, King's College has suffered Marischal College to do something by which King's College alone was injured, and which it alone had a right to concede or to withhold, the acquiescence of that body might be an important element of discussion. So if Marischal College had wrongfully detained, for the last hundred years, any property — say books—belonging to King's College, then the latter body would lose its legal remedy by acquiescence, however its moral claim to restitution might be regarded. But it is as against the crown and the public, not as against any other college, that Marischal College claims this right. The Reports of

the late Royal Commissioners do, indeed, adopt the phraseology which has of recent years become current on this subject. But a Report cannot confer on any institution a character which did not belong to it before. Against the crown no right can be established by the wording of documents, the reports of commissions, or any thing but direct grant, evidenced by charter or by immemorial custom. As, however, Professor Clark refers to the proceedings of the Royal Commissioners on this subject, let us, for his satisfaction, refer him to the evidence given before them in October 1837, by Dr. Fleming, the distinguished naturalist, a professor in King's College. In that evidence, the very opinion which we lately intimated was most fully and emphatically expressed, and the historical facts, upon which it is grounded, were set forth. The statement was made in the presence of the Principal, the Dean, or late Dean, of Faculty, and the Rector, or late Rector, of Marischal College, all being Royal Commissioners. It has been laid before the Queen, and before Parliament ; it has been printed and published; and yet up to this time it remains unanswered, either by any counter-evidence, or, so far as we are informed, by any attempt at argumentative refutation. How is this? If the statement is inaccurate, and is so offensive to Professor Clark, who shows a warm zeal in the cause of the learned body to which he belongs,—why has he not taken up the gauntlet thrown down by Dr. Fleming ? why, after slumbering upon the wrongs of his College for three years and a half, has he come forth against *us* with so much spirit and alacrity ? Can it be that he, too, has found it " expedient to seek an audience among strangers" ? May Dr. Fleming take from Marischal College the very name of university, and may we not look over its charter ?

We here take leave of Professor Clark; but should it appear that any important charter exists with which we have not been made acquainted, we shall be glad to publish it, and to give it our best consideration.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, February 23, 1840.

EDW. STANLEY, ESQ. VICE-PRESIDENT, IN THE CHAIR.

Cases of Cancerous or Malignant Disease of the Spinal Column: with Remarks. By CÆSAR HAWKINS, Surgeon to St. George's Hospital.

THE author is induced to lay before the society the four cases, the particulars of which are detailed in his paper, from a belief that the fact of malignant disease occasionally affecting the bones of the spine has not been sufficiently dwelt upon by previous writers. There is no other peculiarity in these cases than such as arises from the locality in which the disease occurs, as the alteration manifested by the bony structure is closely analogous to that described by two fellows of the society—Mr. Salter, of Poole, and Mr. Samuel Cooper, in the 15th and 17th volumes of the Society's Transactions, respectively. But though the morbid structure is the same in the several instances, and though the disease first manifested itself in each in the form of cancer of the breast, the train of pathological symptoms in the cases related by the author were extremely peculiar and striking—illustrative of the physiology of the spinal marrow. Thus, in one of these instances, although voluntary power was suspended in every muscle of the limbs, loins, and abdomen, as well as in the sphincters of the bladder and rectum, many of those muscles were, nevertheless, in a constant state of tonic spasm; while there were also, occasionally, convulsive or chronic spasms in the same or other muscles of the limbs or abdomen. The abdominal muscles were so permanently contracted as to curve the body forwards, and present rigid masses to the fingers, the pressure of which increased their hardness. The legs could be extended with very little resistance, and would be flaccid for a few seconds, after which they would suddenly be drawn up again, with a feeling of excruciating pain. Sensibility to external impressions was entirely lost in every point below the back, so that the patient could not feel smart pinching or pricking; while in every part violent pain was caused by spasm, either spontaneous or excited, and sometimes occurred even

when no contraction was present. The temperature was permanently higher, below than above the diseased part, the difference amounting to about four degrees. The urine was permanently alkaline, but free from mucus or albumen. Nutrition was impaired in the usual manner below the disease, so that there was a disposition to the formation of sloughs on any parts exposed to pressure.

In all these cases, as has been before remarked, the malignant disease of the spine was consecutive upon cancer of the breast: and there seems strong reason to believe that, although medullary and fungous tumors not unfrequently originate in bone, ordinary cancer, or scirrhus, is, at least, very rare without preceding cancer of some other tissue.

The author concludes with some highly important general observations upon the appearances elicited by dissection in the cases detailed; and many valuable preparations of the diseased parts were shewn to the meeting.

Dr. Addison remarked, that some of the cases related in the author's paper were confirmatory of the opinion which he had advanced in a discussion on a previous evening, respecting the diagnosis of affections in, and in the neighbourhood of, the spinal cord; namely, that whenever there was actual paralysis, whether loss of sensation, or impaired power of motion below the seat of injury, then it might be anticipated there was disease of the spinal cord itself; but that where the symptoms were chiefly those of spasm or pain in the same parts, then it was probable the disease chiefly or exclusively involved the membranes surrounding the cord, and excited irritation in them. This belief was especially confirmed by that case in which the disease of the vertebral column extending, had produced ulceration of the dura mater of the cord, and in which the patient had suffered from very painful spasms of the lower extremities.

Mr. Hawkins said the case Dr. Addison had alluded to was not to be described as ulceration of the dura mater; it was rather a degeneration and softening of it, by communication of the disease from the adjacent parts, which was followed by perforation of it.

Dr. Addison replied, that whatever were the nature of the disease of the dura mater, it was plain from the appearances (especially the increased vascularity) that were described as accompanying it, that it was connected with some kind of irritation of the membranes, and that the case was therefore confirmatory of the opinion he had already expressed.

Mr. Arnott briefly detailed the histories

of three cases of malignant disease of the vertebral columns, which he had witnessed at the Middlesex Hospital, or in private practice.

Dr. Burns also related a case of tubercular disease of the same kind and seat, and said that his experience did not accord with that of Dr. Addison.

After a few words from Mr. Stanley and Mr. Hawkins the Society adjourned.

Previous to the reading of the paper the President announced that there were nine vacancies in the list of Honorary Members, and that to fill these, the Council proposed to the Society—Sir J. F. W. Herschel, the Rev. W. Whewell, Robert Brown, Esq., W. T. Brande, Esq., M. Andral, M. Louis, M. Magendie, Professor Ehrenberg, and Professor Müller. It was also announced that the anniversary meeting of the Society would be held on Monday, the 1st of March, at 3 o'clock.

OFFICERS AND OTHER MEMBERS OF COUNCIL FOR THE YEAR 1841-2.

President—Robert Williams, M.D.

Vice-Presidents—J. Clendinning, M.D.; Charles Locock, M.D. · James M. Arnott, Esq.; Frederick C. Skey, Esq. F.R.S.

Treasurers—Samuel Merriman, M.D.; Cæsar H. Hawkins, Esq.

Secretaries—Thos. Mayo, M.D. F.R.S.; John G. Perry, Esq.

Librarians—Robert Willis, M.D.; Benjamin Phillips, Esq. F.R.S.

Other Members of Council — George Darling, M.D.; Marshall Hall, M.D. F.R.S.; James Johnson, M.D.: G. Hamilton Roe, M.D.; Thomas Watson, M.D.; Sir Benjamin C. Brodie, Bart. F.R.S.; Benjamin Brookes, Esq.; Robert Liston, Esq.; R. A. Stafford, Esq.; J. C. Taunton, Esq.

EXTRACT FROM SIR B. BRODIE'S SPEECH AT THE ANNIVERSARY MEETING.

Eulogium on Sir Astley Cooper.

Sir Astley Cooper was the fourth son of the Rev. Dr. Cooper, who was rector of Yarmouth, in Norfolk, and otherwise a gentleman of independent fortune. Dr. Cooper conducted the education of his sons in his own house, and Mr. Vince, who was afterwards well known as Professor of Mathematics in the University of Cambridge, was one of those who assisted him in this undertaking in the capacity of private tutor. It appears that his son Astley, at this period, displayed none of that disposition to industry which was afterwards so remarkable a feature in his character; being more distinguished as a lad of spirit and enterprise than he was for his love of learning. When he was about sixteen years of age an accidental circumstance occurred, which determined the lot of

his future life. A boy was thrown from a waggon, and the accident happened in such a way as to cause a laceration of the femoral artery. Some other boys who were present were stricken with horror at the sight of a torrent of blood flowing from the wounded vessel, and ran away. Young Astley alone remained, and had sufficient presence of mind to tie a handkerchief round the thigh, so as to stop the hæmorrhage until the arrival of a more experienced artist. Enjoying the credit which he obtained by this exploit, he declared that he would be a surgeon; and his father, taking him at his word, sent him shortly afterwards to London, placing him under the late Mr. Cline as a private pupil. At that time of day a most absurd custom prevailed of sending boys to begin the study of surgery at the early age of fifteen or sixteen years; as if a good general education was of no value, and as if there was something in the surgical profession which none but a youth could learn. In young Astley's case the usual consequences ensued. His early studies were interrupted, and the first two or three years of his being in London were employed to no good purpose. It appears, however, that Mr. Cline discovered something in his idle pupil which led him to expect that he would turn out well ultimately; for, in the course of time, he gave him to understand that if he could qualify himself for the task, he would give him the opportunity of beginning to teach anatomy as a demonstrator in the dissecting room of St. Thomas's Hospital. From this time the young man became an altered person, and his careless and desultory habits were exchanged for a degree of zeal and industry which could not be surpassed, and which he retained to the latest period of his existence.

In the year 1796, being then twenty-eight years of age, with the sanction of his patron, Mr. Cline, he began to deliver lectures on surgery. He had previously attended those of Mr. John Hunter, and he conceived that he could follow in the steps of that great genius, whose object it was to teach, not so much the details of practice, as what he conceived to be the principles of pathology and surgery. But he mistook his talent, and his class soon began to desert the theatre in which he lectured. This, however, only led to the display of another talent, for which he was remarkable during his whole life. No one could discover sooner than himself what he was fit for, and what he was not. He never allowed his vanity to mislead him on this point; and he never persisted in doing that for which he found that he was not well qualified by nature. On this occasion he was not wanting, and soon corrected the error which he had committed. He altered

his system of instruction. He brought his notes of cases from the hospital, and communicated to his pupils the facts which he had collected and arranged. His discourses, full of important practical knowledge, became valuable and attractive: his class increased, and he soon became one of the most popular and influential lecturers of his day.

In the year 1800, his uncle having resigned the office of Surgeon to Guy's Hospital, he was elected to succeed him. He had now every opportunity of advancement which could be derived from circumstances, independent of his own character and conduct. His career as a hospital surgeon is well known to all of those whom I now address. You also know the important additions which he made to surgical literature, and the success which his very extended reputation obtained for him in private practice: and I feel that it would be idle for me to occupy your time with the details of facts with which you are already well acquainted, and which, in one way or another, have been brought so repeatedly before the public.

If it be generally interesting to study the character of those, who, by the exercise of their own talents, have raised themselves to a conspicuous station in society, it is so more especially on an occasion like the present, where the individual has been one with whom we have ourselves associated; whose early hopes and aspirations were similar to our own; who has been engaged in the same pursuits, and partaken of the same anxieties and gratifications with ourselves.

In reviewing the history of Sir Astley Cooper, the first thing that attracts our notice is the perfect devotion with which he followed the science of his profession from the very beginning to the very end of his career. No other pursuit stood in competition with it, and we cannot doubt that his attachment to it was genuine—that he loved it for its own sake, without reference to it as an instrument for amassing a fortune, or acquiring distinction or importance in the world. Some years ago, when his health was suffering from severe mental and bodily exertions continued during a long series of years, he retired to lead the life of a country gentleman on his own estate, in Hertfordshire; but the experiment failed, and in less than a year he was compelled, by the want of interest in other objects, to return to his old employment. No alteration took place in this respect as he advanced in years, and the additions which he made to his anatomical museum, and his work on the structure of the female breast, bear honourable testimony to the zeal and activity of the latest period of his life. Zeal may exist without industry, as there may be industry where there is little zeal; but in Sir Astley Cooper these two qualities

existed in combination, each tending to exalt the other. Even up to the time of his last illness he was in the habit of rising at half-past six o'clock in the morning, and was generally engaged in some anatomical or pathological dissections for two or three hours before he began what others would have regarded as the first business of the day. He was never without occupation, and having no desultory habits, he persevered steadily in any investigation that he had begun until he had completed it, as far as it was in his power to do so. A strong physical frame afforded him peculiar facilities of labour; yet, notwithstanding this, his exertions were at one period beyond his powers; and he informed me, not long since, that during a great part of the time when he was engaged in extensive practice, he was subject to attacks of vertigo. One of these, more severe than usual, occurred in the year 1824, attended with a slow and intermitting pulse. On one occasion his limbs gave way under him, and he fell to the ground. In the year 1827 he had a fever of an intermitting kind, attended with great general debility, and loss of power over the muscles of one arm, so that he could with difficulty raise any thing to his mouth. This alarmed him greatly; and seems to have been the immediate cause of his temporary retirement from his profession. He afterwards had a fit of the gout, which, combined with the repose of a country life, relieved his other symptoms.

It must be acknowledged that we find in Sir Astley Cooper but little of that inventive and discursive faculty which analyses, combines, and abstracts; which perceives and realises remote relations and analogies; and to which we must attribute the exploits of genius, whether it be in poetry or science. It must also be acknowledged that, for the most part, he thought too rapidly for strict philosophical induction, and that he was apt to draw a general conclusion, even from a single instance, which nothing but an abundant evidence could justify. In truth, the construction of his mind was such that it was less fitted to deal with principles than it was to deal with facts; but in this last respect I have scarcely known his equal. He was a minute and accurate observer, and his perception of facts was so vivid, and the attention which he bestowed on them was so great, that almost every thing of any importance, which he had ever witnessed, remained indelibly impressed in his memory. Many who are now present can testify to the truth of this observation, and will well remember with what facility, when a remarkable case was presented to him, he could draw from the fund of his vast experience, describing some cases exactly like it which he had seen many years before, and others resembling it in some respects, and differing

from it in others. He was scrupulously exact in all his statements, and no one could be more free than he was from that weakness to which even some honest persons are liable, who make themselves believe that facts are different from what they are, when it so happens that they do not precisely suit their preconceived opinions.

At one period of his life Sir Astley Cooper was much engaged in operative surgery, and an opinion has prevailed with many out of the medical profession, that skill in performing operations was the greatest talent which he possessed. Some of the absurd and vulgar, and, for the most part, unfounded anecdotes which have been published since his death, are calculated to give countenance to this opinion. But I need not tell the Fellows of this Society how great an injustice this is to the memory of our late associate. It is very probable that, as a young man, Sir Astley Cooper might have been highly gratified by the merit which he obtained as an operating surgeon, at a time when he had not yet had the opportunity of acquiring a higher and more substantial reputation. Many, however, have been his equals, and even his superiors, in this respect; and the estimation in which he was held among those who had a right to judge of his attainments, is to be attributed to his intimate knowledge of the history and progress of disease, and to his talent in selecting and applying the appropriate remedies; and to nothing else. The time may even arrive when it will be forgotten whether he was or was not expert in the performance of operations; but his published works will remain as long as surgery is cultivated, and especially the treatises on Hernia and Dislocations—replete with important facts, and containing the clearest rules of diagnosis—will transmit his name to posterity with those of Sydenham and Hunter, as a benefactor to the human race.

Sir Astley Cooper enjoyed an unusual degree of popularity for a long series of years, especially among the members of his own profession, and more than his character as a surgeon, however high it may have stood, can easily explain. He owed much of this to his moral qualities. He was considerate towards other practitioners; always ready to communicate whatever information he possessed in a simple and familiar manner; and he never attempted to obtain credit for himself at the expense of a fellow-labourer. In his intercourse with others he was essentially kind-hearted, and he possessed that degree of cheerfulness which made him acceptable to every one whom he met, and without which it is so difficult, and I may say impossible, to obtain an influence over the minds of other men. He possessed another great advantage in having no small degree of practical knowledge of human nature. By this I mean not

that kind of knowledge to which this appellation is so frequently misapplied,—founded on a quick perception of the weak points of the minds of other men, by means of which individuals of small capacity are enabled to gain an ascendancy over those whose intellects are superior to their own,—but a clear and ready insight into the whole of the human character, a knowledge of the qualities of the mind generally, and of the motives by which the actions of mankind are regulated.

There is one other point in Sir Astley Cooper's character which it occurs to me to notice before I quit the subject, and I do so merely because it gives me the opportunity of contradicting some most false and injurious statements which have been lately put forth respecting him. Although he derived from his practice a larger income than was ever obtained by any other person, either in the medical profession or in any other, he never exhibited in his profession any thing approaching to the vice of avarice. He was in the greatest degree liberal, and apparently careless as to the remunerations which he received. I say this with the utmost confidence, having never known nor heard of a single instance to the contrary during my long acquaintance with him.

CLINICAL LECTURE,

Delivered at University College Hospital,
February 23, 1841,

By SAMUEL COOPER,
Senior Surgeon to the Hospital, &c.

GENTLEMEN,—Having within the last few days lectured in the College upon Injuries of the Head, I consider it advantageous to you, that any cases in the Hospital, illustrative of this difficult, but most interesting subject, should now be noticed, and commented upon. The doctrines taught over the way are thus put, as it were, to the test of experience; and the instruction given in the College, is here in the Hospital illustrated, corrected, or extended. In the hope, then, of rendering your views of certain points relative to injuries of the skull and brain, more accurate, I invite your attention to the following cases and observations.

CASE I.—*Fracture of the base of the skull, and of the clavicle and ribs, followed by extravasation and death.*

Clay Weymer, æt. 45, admitted under Mr. Quain, Dec. 4th, about 5 in the afternoon, for an accidental fall from a van on his right shoulder, and the right side of his head. He was stunned, but soon recovered his senses. Directly after his entrance to the hospital he was capable of walking across the room with

a little assistance. When seated he inclined his head towards the right shoulder, and supported his arm on his knee, but was quite incapable of raising it to his head—circumstances usual in fractures of the clavicle. A small quantity of blood trickled from the external meatus auditorius. He complained of pain on the right side of the head extending to the forehead, and of pain about the right shoulder. He felt a slight giddiness, and some nausea, but his understanding was unimpaired; his sensation free; his surface moderately warm, though he complained of chilliness; his pulse quick and regular, but not full; pupils slightly contracted, but the iris very moveable under the influence of the light.

No fracture of the skull could be detected, nor was there any swelling or ecchymosis of the scalp; but a fracture of the clavicle, about an inch from the acromial end, was found to have happened; the inner fragment being thrust upwards and backwards beneath the trapezius.

The fracture of the clavicle having been adjusted in the usual manner, the patient was put to bed: bottles of warm water were applied to his feet, and some mild stimulant was to be given him, if symptoms of collapse came on.

Soon after he had been placed in bed, he vomited two or three times, and then seemed more comfortable; but about 8 o'clock, three hours afterwards, symptoms of compression were observed. His breathing became laborious; sensibility and voluntary motion were lost; pupils dilated; and pulse scarcely perceptible. Shortly afterwards he expired.

Examination seventeen hours after death.—A considerable quantity of blood had continued to flow from the right ear. The body presented no mark of violence, except a slight ecchymosis over the right shoulder, and the disfigurement of it from the fracture of the clavicle. A fissure, the sides of which were in close apposition, and perfectly immoveable, was found extending from an inch above the lower edge of the parietal bone, through the squamous portion of the temporal to the margin of the meatus auditorius.

On removing the calvarium, the skull was noticed to be everywhere thin, with scarcely any appearance of diploe; and over the right hemisphere the dura mater was extensively detached from the bones, and the interspace filled up by a large coagulum of bright-coloured blood, amounting to between six and seven ounces. This had come from one of the large posterior branches of the middle meningeal artery. The vessels of the pia mater were very turgid with fluid blood.

In the middle lobe of the brain, on the left side, and towards its inferior surface, over the petrous portion of the temporal bone,

were found two small ecchymoses or spots of extravasated blood.

The fracture being now further examined, was observed to extend through the roof of the tympanum and petrous portion of the temporal bone, to the carotid canal, and within the latter bone, and the mastoid cells, blood was also effused. The dura mater was not torn.

On the left side three ounces of blood were lodged between the dura mater and the petrous portion of the temporal bone, in which there was likewise extravasation. The fracture of the clavicle was comminuted, and the second and third ribs of the right side broken.

OBSERVATIONS.—A good example of the subsidence of the first effects of concussion; the return of the mental faculties afterwards for a short time, which amendment was soon permanently interrupted, and the patient destroyed by the continuance of the hæmorrhage from the torn branch of the middle meningeal artery on the right side, and also from other sources at the points specified, so as at length to cause a vast extravasation attended with a fatal degree of pressure. The situation of a good deal of the blood at the base of the skull would evidently have rendered trephining useless. The fracture at the base of the skull, and the spots of blood effused in the middle lobe of the left side, also imply that the violence had been very considerable. It has sometimes, indeed, been doubted whether a recovery ever follows a fracture of the basis of the skull. My friend Mr. Morton, however, has pointed out to me the particulars of such an occurrence, as recorded by Mr. Davies, of Hertford. A man was stunned by a fall on his head, but soon regained his senses, and no serious symptom having followed the return of sensibility, he was discharged on the eighth day after the accident.

During the perfect insensibility, which lasted about an hour, there was copious bleeding from the nose and ears, and the mouth was drawn towards the right side. Then deafness and hissing sensations were experienced in the left ear. The pupils were natural.

A few days after the man had left the infirmary, the mouth was greatly distorted, being pulled to the right side. There was no power of action in the muscles of the left side of the face; but the power of feeling remained equally on both sides of it. A noise in the head, and a discharge from the left ear, lasted for four months. The deafness, which had been at first in the left ear, subsided, and shifted to the right.

At the end of five months the man committed suicide. In the *post-mortem* exami-

nation, the brain and its membranes were found healthy. In the left temporal bone there were the remains of a fracture running obliquely backwards and outwards between the squamous and petrous portions, splitting the eustachian canal as far as the tympanum, and then extending further in the direction specified. There was also a fracture reaching from the tympanum to the groove of the lateral sinus, thus dividing the aqueduct of Fallopius, through which the portio dura passes, and injuring that nerve ; so as to ac- count for the total loss of the power of motion on the left side of the face. The fracture was so imperfectly united that the broken parts of the bone were separated from one another during the working of the saw.

Case II.—*Concussion, probably with other injury, of the brain, and fracture of the base of the skull, succeeded by fits.*

Michael Malony, aged 20, admitted under Mr. Quain, January 3d, at two o'clock, a.m.: fell from a height of eighteen feet, through a hole in a fire-escape, directly upon the crown of his head. On his admission blood was flowing from an irregular wound of the scalp, and from his right ear. He was insensible, but could be roused by phy- sical irritation ; his feet were cold ; the rest of the surface of his body was warm ; pulse very small and compressible ; the pupils were rather dilated, and the motion of the iris sluggish, though it acted under the in- fluence of light. The patient vomited just before he entered the hospital. The skull was exposed, but without any fracture of the part in view. His head was shaved, and cloths dipped in cold water applied to it and the wound. Bottles of warm water were put to the feet, and the patient was covered with blankets.

10 o'clock.—Has been quiet during the night, and taken drink occasionally. He is peevish and irritable when roused. About an hour ago he was able to get out of bed, and empty his bladder. Pulse 90, weak and compressible ; surface warm ; stomach not disturbed ; bowels confined.

Ordered ten grains of chloride of mercury, followed by a dose of house medicine.

4th.—Has spent a quiet night. Pulse 70, somewhat fuller, but compressible ; pupils dilated, yet iris moves under the influence of light : bowels constipated.

Venæsect. ad ℥xvj. ; Ol. Tiglii, m. j. Mucil. ʒj. 4tis. horis donec alv. re- spondeat.

5th.—Bowels opened freely. He is now more easily roused, and more sensible: face flushed; pulse 64, soft, and rather fuller.

Hydr. Chlorid. gr. ij. 4tis horis. Hirudines xx. ad tempora ; Empl. Canthar. ad nucham.

6th.—At 10 o'clock, p.m. attacked with convulsions followed by complete insensi- bility; stertorous breathing ; foaming at the mouth ; pulse 130, full and strong ; pupils dilated, but contractile ; feet cold. Bled to 18 oz. Pulse fell to 96. Patient remained stupid, and shortly afterwards had another fit, but less severe. Constipation.

Ol. Tiglii, m j. every hour till it acted ; Ant. Tart. ¼ at similar intervals, and Calom. to be continued. Blood not buffy, nor cupped.

7th.—Bowels opened. Another fit at 3 a.m.

8th.—At 5 a.m. several fits, followed by stupor as before. Pulse 96, and rather full and compressible; pupils dilated, but con- tractile. Patient feels cold. Warm bottles to the feet : croton oil to remove constipation.

10 o'clock, a.m.—Had fifteen fits, which generally returned every ten minutes. Vio- lent convulsive twitches of left arm ; head and mouth drawn to this side ; muscles of the face in violent action ; and a catching noise made in breathing.

12 o'clock.—Fits continue. Bowels con- fined. Turpentine enema, and sinapisms to the calves. In one of the fits the left eye opened and shut with convulsive rapidity. Distortion of mouth ; convulsive movement of the left arm and right leg.

Vespere.—Croton oil required for the con- stipation. The convulsions ceased about 6 o'clock. Bowels more open; urine passes freely. Patient nearly insensible, though he makes efforts when he has occasion to leave his bed. Feet cold ; surface of body warm ; pulse 86, and fuller ; gums sore. Calomel discontinued.

9th.—No return of convulsions, but much the same in other respects ; mutters " oh dear !" occasionally, and particularly when pressure is made on the epigastrium. Pulse small, 80 ; tongue not much coated. Ant. tart. discontinued. Abdomen to be fomented.

Intellects clearer, and patient more atten- tive to surrounding objects ; pulse 110 ; no more fits; epigastrium tender.

Hirud. xviij. ad epigastrium.

13th.—Has continued gradually to im- prove. Intellects clearer, and less pain in the head. Patient eats oranges in abundance, the first kind of food which he has taken subsequently to his admission, excepting diluents.

18th.—Some improper food given him by his friends yesterday has brought on pain in the right side of his head. His tongue coated, and bowels confined.

Calomel, gr. v. ; Mist. Salin. Aperiens 4tis horis.

19th.—Headache yet continuing, he was bled ad ʒxij., and the saline aperient mixture continued.

21st.—Twelve leeches applied to the temples; cold lotion to the head continued. Bowels open; wound healing, and bone covered by granulations.

23d.—Headache lessened, but now the patient has cough, with bronchitis. Mixture with Squills and Vin. Ipecac. prescribed, and a blister applied to the chest.

24th.—Bronchitis diminished. Has been getting deaf for the last two days in the right ear, from which there is a puriform discharge. Pupil of the right eye rather dilated.

> Hydr. c. Creta, gr. iv. ter die sumenda. Right side of head to be fomented, and meatus washed out with lint and warm water.

27th.—Deafness and discharge from the ear diminished; but little pain in the head now felt; tongue cleaner. Hydr. c. Creta continued.

February 3d.—Some return of pain in the right side of the head. Hirud. viij. ad tempora.

5th.—Feels quite well, and sits up a part of the day.

8th.—Sat up too long yesterday, and to-day has pain again on right side of head. Hirud. xij. ad temp.

Bowels open. Powders continued, as well as lot. plumbi acet. for ear.

18th.—Going on well. Pulse natural; tongue clean; no pain in the head.

OBS.—This case gives you a good illustration of certain effects sometimes arising from concussion of the brain, and probably other lesions with it, forming what may be termed a mixed case. The numerous fits of convulsions, somewhat resembling those of epilepsy, which attacked the patient, must have attracted your attention. Sir Benjamin Brodie has particularly adverted to them as an occasional consequence of injuries of the brain; and he regards them as more formidable in appearance than reality, as the patient, after they have subsided, frequently recovers without any unfavourable symptoms. Our patient was usually left in a state of stupor for some time after the fits, of which he had on one day not less than fifteen in rapid succession. The commencement of such attacks may take place directly after the accident, or, as in this instance, some days later; for the first fit was on the third day.

I believe, from what has occurred in several cases under my notice, that the statement of Sir Benjamin Brodie is correct, with regard to the cause of these fits of convulsions, viz. that they do not always depend upon simple concussion, but that a wound of

the basis of the brain, which causes extravasation of blood on the surface of that organ, will frequently produce such convulsions.

In our case, the dilated pupils, and some of the other symptoms, seemed to indicate the co-existence of a degree of pressure with concussion; and little doubt exists in my mind respecting some lesion of the basis of the brain.

You find also in this case an instructive example of the long tendency to inflammation and mischief in the head after concussion, and of the necessity of persisting, for a considerable time after the accident, in rigorous antiphlogistic treatment, comprising general and local bleeding, active purgatives, saline aperients, with tartrate of antimony, the exhibition of mercury even so as to affect the gums, cold lotions to the head, and a most careful reduction of the diet.

The bleeding from the right ear, and some other parts of the history of this patient, would justify the suspicion of a fracture of the base of the skull as one of the complications of the accident; but whether this has really happened or not, we have no means at present of ascertaining; and the convalescent state of the patient makes it likely that no instruction on this point from a post-mortem investigation will be afforded.

The following particulars of a case which was brought into La Charité, at Paris, and under the care of my distinguished correspondent M. Velpeau, I have been favoured with by my friend and pupil Mr. Morton. As they may throw useful light on the diagnosis of fractures of the base of the skull, I avail myself of that gentleman's permission to bring them under your consideration.

CASE III.—*Injury of the head—Fracture of the base of the skull.*

July 25, 1837.—Louis Jacques, æt. 50, was received into La Charité on account of injuries sustained by falling from a height of three stories. At the time he lost all consciousness; but after a time partially recovered his senses. There were two wounds of the scalp near the vertex, and one had laid the bone bare, which was fractured, though without much depression; and there was bleeding from the nose, mouth, and ears.

The next day the eyelids were swollen and blackened from ecchymosis. The right arm was found to be weaker than the left. The mind, though in some respects correct, was not quite perfect, nor collected. Pulse moderately strong. Tongue somewhat paralyzed. Leeches behind the ears, with low diet.

In lecturing upon this case, M. Velpeau expressed his belief that there must be a fracture of the base of the skull, which view he was led to adopt from the fact that, without direct violence, there had been produced

ecchymosis of the eyelids, and bleeding from the ears, nose, and mouth. The inference was also strengthened by the complaint repeatedly made by the patient of a deep-seated pain in the neck, close to the basis cranii. M. Velpeau was in doubt whether the partial paralysis of the tongue and arm depended upon the severe commotion of the brain, or upon a slight extravasation of blood upon the surface of that organ.

The prognosis was against the man's recovery, the only chances of which appeared to M. Velpeau to be in the strict employment of antiphlogistic measures.

26th.—The man is quite sensible, and able to sit up ; pulse quick, yet softish ; but the deep-seated pain in the neck is worse.

28th.—The patient, though quite sensible in the morning, died before night. A coagulum of blood was formed on the same side as the paralysis, and an extensive fracture of the base of the skull.

Obs.—This case, I have said, is instructive in relation to the diagnosis of fractures of the base of the skull. The remark made by M. Velpeau seems to me valuable, viz. that, when bleeding from the nose, mouth, or ear, follow an injury of the head, and has not been occasioned by a direct blow on those parts, or when an ecchymosis takes place in the eye-brow after such an accident, though the part itself has not been immediately struck, these circumstances are important considerations, corroborating the suspicion of there being a fracture of the base of the cranium, implicating the petrous portion of the temporal bone, or the roof of the orbit. The observation is valuable, because in plethoric and young persons bleeding from the nose and mouth will often come on from a trivial blow on the face, unattended with further mischief, and quite independent of mischief to the skull or sinuses of the brain ; but such hæmorrhage, and also ecchymosis of the eyebrow, without any direct violence to the parts which are the seats of these occurrences, surely are points in the history of the case highly deserving of attentive reflection.

SAINT MARYLEBONE INFIRMARY.

Contraction of the Biceps Muscle.

—— Hall, aged 55, an omnibus-driver, was admitted an in-patient under the care of Mr. Phillips. The account he gave of himself was, that more than two years ago, he fell, or was thrown, from his seat, and injured his arm, about the elbow ; that for some weeks he was unable to return to his work ; that when he did, his arm was not quite well, and that he could not make it quite straight.

He continued to follow his calling, but, from month to month, he found that the arm was more and more flexed. When he appeared at the Infirmary, the forearm formed with the arm an angle of about fifty-six degrees. Beyond this, extension could not be carried further than five or six degrees, and even the attempt to accomplish this was attended with much pain. It was very evident that the obstacle to further extension was the biceps muscle ; it was exceedingly tense and hard, and the indicator finger could readily be passed under the tendon and aponeurosis at the bend of the arm. The history of the case induced Mr. Phillips to conclude that the shortening of the biceps had been occasioned by low inflammatory action set up after the injury ; that before this action was dissipated he had re umed his former occupation ; and that the constant state of flexion required in driving through the streets had singularly favoured the disposition to contract ; that the affection was not functional or spasmodic, but depended upon change of structure. The mode of remedying the deformity which appeared to promise most success was by a division of the tendon and aponeurosis, which had undergone contraction. The patient was not a favourable subject for any operation ; though not a drunkard, he was accustomed to drink four or five-and-twenty glasses of beer daily. He was placed on full diet, and had two pints of ale daily. The operation was easily performed; a narrow tendon knife was passed on the flat, at first under the tendon, which was divided ; it was afterwards passed in the same manner under the aponeurosis, and that was also divided. As soon as this was accomplished, the arm could be placed in an almost straight position. A good deal of nervous excitement was occasioned by the operation, to relieve which he had, immediately, forty minims of Liquor Opii Sedat. in a pint of porter. No efforts at permanent extension were made for three days. After that, he carried a four-pound weight in the hand for half an hour three times a day. By this plan the arm was kept in almost complete extension, and the discomfort of permanent extension was avoided. The case proceeded very satisfactorily, as far as extension was concerned, but he complained of a good deal of superficial pain, which was, however, dissipated by the application of compression, and a belladonna plaster, around the forearm. Last week he was discharged cured. Before he was dismissed the arm was carefully examined ; the biceps muscle had lost all its former hardness, and the continuity of its tendon and aponeurosis appeared to be as complete as possible ; and flexion of the forearm could be accomplished with as much rapidity and force as before the occurrence of the accident.

Strangulated Femoral Hernia.

——— Clarke, aged 52, a helper in the Infirmary, consulted Dr. Harrison in consequence of constipation, which had resisted simple means. He prescribed a dose of calomel and opium, to be followed by a black draught. On the following day, at his visit, he found the constipation unrelieved, and she complained of some nausea and abdominal tenderness. In passing the hand over the abdomen, Dr. H. detected an irregularity and increased tenderness at the umbilicus, and he requested Mr. Phillips to look at it. It was examined, and found to be merely a projection consequent upon distended parietes from child-bearing. The pulse was 76. She was ordered a warm bath, and enemata of beef-tea and olive-oil, until the bowels were moved. On the following day there was no relief to the bowels; the pulse was 88, the tongue was more coated; there was some tympanitis, and there had been vomiting of fæcal matter. An hour before the visit, she had accidentally discovered a tumor in the femoral region, which she says she is confident was not present on the previous day, when she was put into the bath. The tumor was soon found to be a femoral hernia, and Mr. Phillips advised her to submit to the necessary operation, which was performed the same afternoon (January 1st.)

The following peculiarity occurred during the operation: the sac was so extremely ill defined, that it was impossible, with any certainty, to recognize it. It was very carefully opened, and, what appeared to be a gland, immediately projected through the opening which was made in it. Further examination showed that the gland-like mass was a small portion of omentum, and under it a knuckle of intestine was found: but not a single drop of fluid was there in the sac. With much difficulty a shallow director was insinuated through the stricture, and a blunt-pointed bistoury was passed along it; an incision was made, and was directly followed by a gush of at least five ounces of darkish serum; a good proof of the tightness of the stricture, which prevented the passage of a drop of this fluid into the hernial sac.

The operation completed, the patient was put to bed, and ordered to have turpentine fomentations to the abdomen, and to take nothing but a little thin gruel. In four hours after the operation she had a copious alvine evacuation, succeeded soon by a second which was more scanty.

2d, 8 a.m.—Tympanitis as well as tenderness increased; nausea very oppressive occasionally; pulse full, 88. Ordered to take

Hydr. Submur. gr. ij.; Opii, gr. ¼. 4tis. and to have Ung. Hydr. ʒi. rubbed in every six hours. The turpentine fomentation to be continued.

12 a.m.—Pulse harder, 90.

V. S. ad ʒx.

4 p.m. — Pulse has acquired its former force.

V. S. ad ʒxiv.

The blood on each occasion was cupped and buffed.

11. p.m.—No action on the bowels; tympanitis increased; pulse 90; complains of thirst.

3d, half-past 5 a.m.—Has vomited twice.

Enema Terebinth.

10 a.m.—Ex. Coloc. Comp. gr. iij.; Ex. Hyoscyam. gr. i. 2dis horis ad plenam alvi solut.

3 p.m.—Has vomited fæcal matter, largely, twice; tympanitis increased; pulse 96.

Enema c. Ol. Ricini, ʒij. statim, et rep. 2dis horis si opus fuerit.

12 p.m.—Two enemas were administered, and both have been retained.

Enema Tereb. statim.

4th, 8 a.m.—No sickness during night; one copious evacuation from the bowels; pulse 90.

3 p.m.—No further evacuation.

Sp. Tereb. ʒi.; Ol. Ricini, ʒij.; Liquor Potassæ, ʒij.: fiat Enema statim injec.

7 p.m.—Two copious stools followed the last injection; pulse 96; much thirst; gums becoming tender; tympanitis somewhat lessened.

Mist. Effervescens. To suspend the Calomel.

5th, 9 a.m.—Three stools during night; pulse 86; abdomen less tumid: tendency to diarrhœa: to have an opiate enema if necessary.

1 a.m.—Several very liquid stools since 9 o'clock.

Pulv. Kino Comp. gr. viij. 4tis.

10 p.m.—Three stools since last visit.

Tinct. Catechu, ʒiss.; Tinct. Opii, Min. xlv.; Jusculi, ʒiij.: fiat Enema statim injiciatur.

6th, 9 a.m.—Has had a good night; tongue improved; pulse 58; tympanitis stationary.

7th, 9 a.m.—Going on better; pulse 84.

2 p.m.— Two liquid stools.

Repr. Enema u. a.

9 p.m.—Two liquid stools.

Repr. Enema.

8th, 9 a.m.— Liquid stools persist.

Sumat. Ol. Ricini, ʒiv.; Liquor Opii Sedat. Min. vj. statim. This brought away three stools.

From this time the patient went on well, and rapidly became convalescent.

In this case there are two curious features : a perfectly dry sac, and a gush of serum from the abdominal cavity upon the incision of the stricture ; and a favourable termination, although there was abundant fæcal vomiting 44 hours after operation.

CASES OF PARTIAL AMAUROSIS*.

CASE I.—*Partial amaurosis — Inability to distinguish certain colours.*—Mary Bishop, æt. 20, unmarried, cigar-maker, admitted February 9, 1839. The early history of this case has already been given by my colleague, Dr. Fox ; it will be sufficient, therefore, to recapitulate here merely its prominent features. The patient stated that she had suffered, previous to admission into the hospital, two attacks of cerebral disease, one in the spring of 1837, and the other in the winter of 1837-38. After recovery from the first attack, objects for a time appeared to her double. The second attack left her entirely blind, in which condition she continued for four months. After this her sight began to return, and at the period of her admission into the hospital she could read large print ; as the heading of a newspaper. She was of a short, robust stature, full habit, very dark complexion, black hair and hazel irides, flushed face, colour of her face at times almost of a purplish hue ; catamenia suppressed. When she first came under my notice, which was in May, 1839, she had been largely depleted, and had taken remedies for the restoration of the menstrual discharge, under which treatment her sight had improved.

Whilst examining her at this time to ascertain the degree of vision she possessed, her reply to one of our questions led us to suspect that she was unable to distinguish colours. When asked whether she could see the figure in her dress, which was a calico one with red spots, she replied, " Yes, I see the *brown* spots." Our attention thus directed to the subject, we soon ascertained that while she could distinguish forms, even of small size, with accuracy, her perception of colours was exceedingly imperfect. Repeated and careful investigations during this and on several subsequent occasions, satisfied us that the only colours which she knew with certainty were *yellow* and *blue.* Nearly all other colours she termed brown, or hesitated to name, designating, however, their shades or intensity of colour accurately. Thus, a deep red she called a dark brown, a bright green light brown, and a very pale pink a very light shade of brown.

The patient was not at all sensible, when we commenced the investigation of her case, that she laboured under any particular de-

fect in distinguishing colours. She had noticed, she said, however, that grass and roses did not appear as they formerly did to her ; the latter especially did not seem of their natural colour ; but as her sight was imperfect, she considered this as a natural consequence. She remembered, when questioned, that as her sight began to return, *the first colour she perceived was yellow.* This fact is of much interest, and she stated it with a degree of confidence, and mentioned some particulars which lead us to believe it to have been the case. She asserted most positively also that she had formerly been as well able to distinguish colours as any other person.

With a view to a revulsive action on the brain, and also to re-establish the catamenial flow, the patient was ordered pills of blue mass, rhubarb and aloes, every alternate night, in a dose to purge actively ; mustard pediluvia at bed time, and a blister to the sacrum. Two days before her regular period I ordered, in addition, mustard cataplasms to be applied nightly to the inside of her thighs, and the same diluted with an equal part of flour to her mammæ.

On the 29th of May her catamenia appeared and flowed copiously, but continued only for a single day. It was followed, however, by very marked improvement in vision.

Nov. 30th.—Discharged this day, with her vision restored, and in good health ; the catamenia, however, still suppressed.

REMARKS.—The feature of most interest in this case is the inability to distinguish colours. This is, we believe, the first example hitherto recorded of this inability having resulted from disease, or been co-existent only with it. As a natural defect, the power of distinguishing forms being perfect, it is not rare. Several instances of this have come under our own observation, and not a few others have been mentioned by writers. Such of these last as have been recorded with sufficient details to furnish data for comparison, viewed in connection with the case we have recorded, lead to conclusions, which it may not be uninteresting to notice.

1. As a natural defect, inability to distinguish colours may exist in different degrees.

2. In the worst degree, the individual is able merely to distinguish shades,—the perception of colour is entirely absent. Examples of this are afforded in the two Harris's, who could distinguish a striped riband from a plain one, but could not perceive the difference between any one colour and another, except as darker or lighter, and in Dr. Elliotson's second case.

3. In the next degree the individual can distinguish only a single colour, and that

colour is always yellow. Thus Dr. Butter states that Robert Tucker knew to a certainty *yellow* only ; and it appears that the boy, whose case is recorded by Dr. Nicholl, was in the same condition. Now it may be called to mind that Mary Bishop states, when her sight improved, the first colour she recognised was yellow.

CASE II. – *Partial amaurosis from excessive use of the eye—cure.* David Lang, æt. 42, native of Scotland, weaver, unmarried, admitted October 2d, 1839. Habits very temperate ; for the last four years has abstained from animal food ; has worked hard during the day at his business, and devoted the evenings, until a late hour, to reading and writing. Sight commenced failing about eight weeks ago, since which it has been gradually growing worse. At present cannot see sufficiently well to weave, or read ordinary sized type. Can distinguish, however, large letters, as the heading of a newspaper. Sees better at night than during the day. Person spare, rather short ; face pale ; irides light blue, active ; no headache or sense of fulness of head ; pulse natural. Slight greyness of pupil, but three images of of a candle distinctly to be seen. Ordered the following :—

R Mass. Hydrarg. gr. vi.; Pulv. Rhei, gr. viij. ; G. Aloe, gr. i. M. ft. Pilul. No. iv. To be taken at bed-time.

Oct. 5th.—Pills have purged him actively. Ordered

Strychnia, gr. ij. ; Acid Acet. ʒj. ; Aq. Puræ. ʒj. M. ft. collyrium. A few drops on the eye daily.

When he appeared before the committee for the month, to be discharged, he read for them, with readiness, the smallest print of a newspaper, and stated that he saw as well as ever. He was so delighted with his cure, and grateful for it, that he insisted on presenting a small sum he possessed to aid the funds of the institution.

REMARKS.—The slight evidences of congestion which existed in this case induced us to trust to revulsive purgatives for its removal, and to commence too early with the use of strychnine. The mistake was, however, soon rectified. Cups to the nucha and back of head, cold water douche to the head, with mustard pediluvia, and purgatives, were then resorted to, and with immediate benefit. The strychnine was then recurred to, and doubtless aided in the cure.

ADVANTAGE OF APPRENTICESHIPS.

To the Editor of the Medical Gazette.

SIR,

I HOPE you will spare room, in your valuable periodical, for a few remarks elicited by

your able leader on the " apprenticeship system" in the last GAZETTE, and, ere the knell of that system is sounded, allow a feeble note to be raised in its praise. You are doubtless aware, Mr. Editor, that the effect of the late prescribed course of medical education has been to diminish very materially the number of pupils in the country, and the smaller towns; and if the apprenticeship system be entirely annulled, all the medical students will begin and complete their studies in the metropolis, or the larger provincial towns where the required lectures are given. But would not a serious injury be thus inflicted on the smaller hospitals and country practitioners ? The cases occurring in those institutions would not be rendered available for the purposes of medical education, and thus many valuable opportunities of acquiring knowledge would be lost; for it is not, perhaps, too much to say, that the few pupils who act as dressers in a provincial hospital, under the immediate eye of their masters, are as likely to acquire valuable information as those students who, in a crowd, attend the practice of the larger hospitals without an opportunity of exercising surgical manipulation ; and the " habit of observing, thinking, and acting for himself," which by the Quarterly is considered so essential to make a good practitioner, is as much encouraged in him who quietly dresses patients from day to day, in a smaller provincial infirmary, as in him who, during the bustle of surgical peregrinations in large hospitals, attends, even more than is customary, to the cases presented to his notice : and I would, moreover, add, the responsibility incurred by visiting and prescribing for the patients who partially come under the care of pupils in the country during their apprenticeship, excites more interest, and enforces habits of attention and reflection more effectually, than where such responsibility does not exist.

But the student who is designed to practise in the country (and many must) will be, in other respects, a loser by the entire abrogation of the apprenticeship system. He will lose all that salutary restraint, and that training of the mind to undergo privations, which are so necessary for youth. He will lose an insight into the management of private patients, the customary charges and book-keeping, and all the drudgery unavoidably connected with the practice of medicine in country districts. He will be unable to form an estimate of the situation which he must afterwards fill, or of the difference between the study of medicine as a branch of learning, and the practice of it as a profession by which he is to live ; so that, when commencing business in the country, after an attendance on lectures and at hospitals alone, where he has been enabled to

follow the full bent of his inclinations, he
will probably find that he cannot comfortably
submit to the necessary constraint on his
feelings and actions which would contribute
so much to his success ; that he cannot well
manage the whims and caprices of private
patients, and other little practical details ;
that, in short, he cannot endure, without
spending a miserable existence, the incon-
veniences and ills of a profession which he
was not prepared for; while, to his astonish-
ment, his more plodding, but, perhaps, less
scientific neighbour, inured to the hardships
of an apprentice, bears the midnight watch
and laborious journey with scarce a murmur,
and puts up with those toils and discomforts
which, in early life, he was accustomed to,
as a matter of course. There is, indeed,
Mr. Editor, something besides medical
knowledge necessary for ordinary provincial
practice, namely, a mind schooled and
trained to submit to that which must be
borne ; and if the apprenticeship system
must be given up, which, under your auspices,
I trust it will not, I much doubt whether the
country practitioners of the succeeding gene-
ration will be more happy themselves, better
suited for their situations, or for the service
of the public, than those of the present day.
But I am trespassing too much on your
kindness, and therefore, hoping that the
attention of provincial practitioners will be
awakened to the subject I have touched
upon, I leave the matter in abler hands.

I am, sir,
Your obedient servant,
A CONSTANT READER.
Gloucester, Feb. 2d, 1841.

NOTE FROM MR. HALL.

To the Editor of the Medical Gazette.
SIR,

IN the MEDICAL GAZETTE of yesterday, I
find the following note in a communication
from Dr. Hocken:—" Mr. Hall, in his
paper on Strabismus, in the MED. GAZETTE
for Jan. 22d, which contains many valuable
facts, has made perfectly free with the au-
thor's ideas on the etiology, pathology, and
form (?) ; and this without one word of
acknowledgment. In many cases, he quoted
nearly word for word : for instance, ' An
ulcer of the cornea may be the first origi-
nating cause of strabismus, &c. &c., the
diagnosis of double squint, &c.;' and yet
calmly palms them off as ' the result of his
own original experience.' "

Could I suppose that all who may read
the above would take the trouble to refer
to the several papers of Dr. Hocken and
myself, I should not hesitate to pass over
the accusation in silence. As the matter,
however, is too unimportant to interest any

but the parties immediately concerned, I may
observe that I was not aware of my being
indebted to Dr. Hocken for any ideas what-
ever, and therefore was not likely to offer
" one word of acknowledgment." My paper
consists of such cases as have come under my
own observation, with some of the inferences
to which they gave rise, and was written
without reference to any views of Dr.
Hocken.

By the use of inverted commas, one would
suppose the passages to be quotations.   I
never made use of the words in question, and
should have thought it ridiculous to speak of
" the result of my own original experience."

I am, sir,
Your obedient servant,
C. RADCLYFFE HALL.
Manchester Royal Infirmary,
Feb. 20, 1841.

"SUDDEN DEATH."

To the Editor of the Medical Gazette.
SIR,

ALLOW me through the medium of your
journal to ask the opinion of yourself, or any
correspondent that may be disposed to fa-
vour me with an answer, as to " what is to
be done in a case of sudden death ?"

Suppose a medical man, on being sum-
moned to a person who has " fallen down in
a fit," (to use a common expression) finds
his patient in a state of evidently fast ap-
proaching dissolution, with no pulsation of
the radial artery, and scarcely any of the
heart, with inspirations feeble and at long
intervals, and the face to all appearance
perfectly exsanguine, indicating a rupture of
the aorta or one of the contiguous large
vessels, by which the blood circulating in
the head has been suddenly diverted to the
chest, and thus distinguishing it from cere-
bral apoplexy, the prominent symptoms of
which are the congested and swollen coun-
tenance, stertorous respiration, and labouring
pulse.   In such a case is it not unscientific
and malpraxis to bleed ?   We all know that
the prevailing idea among the public is, that
bleeding should, in all cases of sudden death,
be immediately resorted to, to restore the
patient ; but in the case that I have endea-
voured to describe, will it not rather hasten
death (should life not be quite extinct on our
arrival) by causing another outlet of blood
from the system ? And is it not " infra digni-
tatem" that, to please the ignorant ideas of
the public, and more especially to avoid the
censure of the sapient juries that often sit in
judgment on our conduct, we should act in
direct opposition to science and our own
consciences ; though it is immaterial to the
patient in the present instance, as recovery
is quite impossible.   Nay, to go further, I

am confident that I am not the only one by many (for I must plead guilty to the fact) who have performed venesection, knowing at the same time that the subject of the operation was dead, to escape the censure that would otherwise be so liberally bestowed by persons quite ignorant of the matter.

Now in the latter case, as well as the former, where life is not quite extinct, should we not be quite justified in refusing to bleed, though urged by the by-standers so to do?

I am, sir,

Your obedient servant,

"INQUISITOR."

Feb. 23, 1841.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

I AM required by my vaccination contract with the Guardians of the East Ashford Union to specify what cases vaccinated by me have been successful or unsuccessful; and in the former case to sign a printed form of certificate furnished to every individual at the time of vaccination, to the effect that he or she has passed "*regularly* and *successfully*" through the disease.

Now, in the first case which was vaccinated with lymph sent by post from the National Vaccine Establishment, only one vesicle arose (four punctures were made), and this one, although otherwise regular in its course, was about forty-eight hours later than usual in the development of its stages (this I have continually observed when the virus has not been inserted in its recent liquid state). The second case was vaccinated from the above, and only one vesicle, similar in its history, was the result. The third and fourth had two vesicles, and the fifth three. In each case four punctures were made.

I am anxious to know how I should report the result of the first four cases; for although many surgeons maintain that whoever has had one mature vesicle has all the advantages which vaccination can confer, I know that others, of high authority, consider the safety of the vaccinated to depend very much upon the degree of intensity with which they may have been affected: such is my own private opinion; but as many other surgeons must have had similar cases, I should be glad to know from such of your readers as have paid most attention to the subject (Dr. Gregory, for example) whether surgeons vaccinating according to the provisions of the new act may best fulfil its intentions by putting such cases as I have described in the "successful" or "unsuccessful" column of their return.

I remain, sir,

Yours with much respect,

HENRY CRAWFORD.

Canterbury, Feb. 23d, 1841.

FEAR OF PHTHISIS IN SICILY.

So far as I am able to judge from what I have seen or been told of the climate of Sicily, I should consider it the best in Europe for a delicate patient; and yet, by reason of a strange prejudice on the part of the natives, that island is rendered almost entirely useless in this respect. They have, unfortunately, taken a notion into their head, I believe without any foundation, that consumption is not only occasionally infectious, but that it is always so, even worse than the plague or any other disease. Consequently they will not admit a person suspected of having a tendency to pulmonary complaints into their houses. If any one afflicted with this malady should die among them, a ban is put on the house, its furniture destroyed, and no one allowed to inhabit it for a period of many months. As this is ruinous to inn-keepers, and inconvenient to all, and as every native firmly believes in the truth of this persuasion, it becomes impossible for any consumptive patient to find house-room in Sicily. I have even heard of instances of such persons being allowed to perish in the streets, or in the country roads, to which they were driven by the excessive terror of the inhabitants.—*Patchwork*, by Captain Basil Hall, vol. iii. cap. 2.

SHOULD INVALIDS GO TO ITALY?

IN such hopeless cases it is often difficult to decide what is best to be done; but from what I have seen I should scarcely advise the friends of a delicate invalid to travel in Italy. Even a person in strong health is sure to encounter multifarious annoyances, which, though he manages to laugh at, and tries to make light of, must be almost intolerable to a worn-out frame, and more than proportionably depressed state of spirits. The naked floors of brick, or even of marble; the damp, and not always clean, beds; the sour bread; the oiley cookery; the sluttish attendance; the mosquitoes, fleas, &c. together with the total want of many small, and some great comforts, which, in England, have become necessaries of life, render Italy, or indeed almost any part of the continent, very little suitable for a poor, broken down, attenuated English invalid.—*Patchwork*, by Captain Basil Hall, vol. iii. cap. 9.

[In spite of this enumeration of hardships, we conceive that travelling is the best of all remedies for many an invalid. But let the patient take with him to Italy a pair of sheets, a mosquito net, and a spirit of tolerance.]

SIR ASTLEY COOPER.

To the Editor of the Medical Gazette.

Sir,

Many inquiries having been made as to the appearance of a Life of Sir Astley Cooper, I beg to inform you, for the information of the profession, that this distinguished surgeon has left ample materials for a most interesting biography, now in the hands of his nephew, Bransby Cooper, Esq., by whom the whole will be arranged and prepared for speedy publication.

A new edition of his beautifully illustrated work on the " Testis," which received the author's final additions, has passed through the press ; the plates are now in process of colouring, and the volume will be issued during the present month. His work on " Dislocations " I am now preparing to publish of an 8vo. size, with the plates redrawn, engraved on wood in the best style, and printed with the text ; carefully edited, with important additions, by B. Cooper, Esq. This practical work will be offered at a price to make it available to every student of surgery.—I am, sir,

Your obedient servant,
John Churchill.

Princes Street, Soho.
1st March, 1841.

LONDON HOSPITAL.

Dr. Cobb has been elected Physician to the London Hospital, in the room of Dr. Frampton, resigned ; and Dr. Pereira has been appointed Assistant-Physician, in the place of Dr. Cobb.

ROYAL COLLEGE OF SURGEONS.

At a Meeting of the Council, on Monday, the 22d inst., James Moncrieff Arnott, Esq. Surgeon to the Middlesex Hospital, was elected a member thereof, in the vacancy occasioned by the decease of John Ilowship, Esq.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, February 26, 1841.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXV.

*Hypertrophy of the brain: — Atrophy.
Acute Hydrocephalus: premonitory signs;
different modes of attack; stages of the
disease: anatomical characters; causes.*

Hypertrophy of the brain.—There is a
very curious morbid condition of the brain,
to which I shall advert before I take up the
consideration of certain cerebral diseases as
they occur in *children*. The condition of
which I am about to speak I was totally
ignorant of till I had been for some years in
practice. In the spring of 1833 I admitted
a young woman, 19 years old, into the Mid-
dlesex Hospital. Her countenance was sallow,
and her lips pale; and she complained of
pain in her chest and limbs, of great and
increasing debility, and wasting, and of
nightly perspiration. She had some cough,
and a frequent pulse; and although no mor-
bid sounds were audible in her lungs, I sus-
pected that they might contain small or
scattered tubercles. She had been in the
hospital scarcely a week, when she had a
violent fit of epilepsy; and when she was
somewhat recovered, she told us, for the first
time, that she was *subject* to such attacks.
The convulsions recurred on the same day,
and she became insensible, and remained so
during the whole of the next day, and till
the evening of the day after, when she died.
During this period of insensibility she had
many convulsive fits; the pupils were dilated,
the pulse 100, small and feeble. Leeches
were applied to the temples, a blister to the

neck, and afterwards to the shaven head, and
other measures were used; but in vain.

When the surface of the brain was exposed
by the removal of the skull-cap, and of the
dura mater, it was observed that the convo-
lutions were remarkably flattened, so that
the little furrows between them were nearly
effaced; and the surface of the arachnoid
membrane was perfectly dry. These are not
very unusual appearances: I had often seen
such before: and I ventured to say that we
should find some cause of strong pressure in
the central part of the brain; effusion of
serum into the ventricles, or a large extra-
vasation of blood. But to my great surprise,
and much to the discredit of my prophecy,
we found nothing of the kind; but the ven-
tricles were smaller than natural, and con-
tained scarcely any moisture. The skull-cap
was afterwards examined, and the bone was
found to be uncommonly thick, dense, and
heavy; and its inner surface, without being
rough, was very irregular. I regret that, in
this examination, the state of the blood-vessels
of the brain, and the consistence of the
cerebral matter itself, were not particularly
noticed. In the record made at the time by
my clinical assistant, it is merely stated that
the brain was otherwise healthy. There was
no disease in the lungs.

This dissection interested me much, for I
had never seen, nor heard of, any thing like
it before. But upon looking into some
modern authors, I discovered that the same
phænomena had been noticed by two or three
observers, who had very properly (as it seems
to me) considered them as the result of
hypertrophy of the brain. There is a very
good memoir upon the subject, by M. Dance,
published in the fifth volume of Breschet's
Repertoire d'Anatomie: and Andral gives
an account of the disease in his *Pathology.*
It appears that Morgagni had not overlooked
it, for he speaks of instances in which the
brain seemed too big for its bony enclosure.
When, in these cases, the skull is sawn

3 M

through, the upper loose portion of bone starts
up, as if moved by a spring, and the edges
of the bone remain widely apart. Laennec,
also, in *Corvisart's Journal*, states that upon
opening the bodies of persons whom he had
thought affected with hydrocephalus, he had
been surprised at finding a very small quan-
tity only of fluid in the ventricles, while the
convolutions on the surface of the brain were
strangely flattened ; proving that the cerebral
mass had undergone strong compression,
which could only have been occasioned by its
preternatural volume, and undue nutrition.

Besides the characters I have mentioned,
the hypertrophied and compressed brain is
firmer and tougher than natural ; it contains
but little red blood ; and sections of it are
seen to be unusually dry and pale.

In several of the cases of hypertrophy of
the brain recorded by authors, the patients
had suffered epileptic fits, or rather paroxysms
of convulsion ; and in some of them the
convulsions terminated in paralysis. Andral
states that the intellectual faculties have been
observed, in some instances, to become dull
and obtuse. Many of the patients were
subject to severe headaches. All these symp-
toms are common to various cerebral com-
plaints. The diagnosis of this rare disorder
can be no better than conjectural ; and its
treatment we have still to seek.

Andral remarks, what is very true, that
hypertrophy of the brain, *i. e.* an undue and
disproportionate development of that organ,
may, and does happen, without giving rise
to any morbid phænomena at all. But, in
such instances, the *brain-case* is equally en-
larged in capacity : so that no pressure upon
the cerebral mass arises from its own præter-
natural growth. It is only when the brain
increases faster than the bony sphere which
contains it, that the hypertrophy becomes a
disease. In my patient there was also, in
one sense, hypertrophy of the skull ; the
bone was considerably thicker, and more
compact and heavy, than is usual ; but the
capacity of the cavity had not undergone a
proportional augmentation : nay it might,
for any thing I know, be diminished in con-
sequence of the increased thickness of the
bone ; the case may have been one of con-
centric hypertrophy of the bone, without any
fault of the brain itself : but what makes
this the less probable is, that in other cases
the skull has been found of the natural thick-
ness and density ; but too small for its
contents.

It is of some importance that you should
be aware that the brain, and its case, may
be extravagantly developed without there
being any disease, or any symptoms of dis-
ease. M. Scoutetten gives an instance of
this which he observed in a child five years
old. Its head was as large as that of a well-
grown adult person. The skull was from a

line and half to two lines in thickness. The
dura mater adhered firmly to the bone, and
the cerebral mass exactly filled up the cranial
cavity. The superior and posterior part of
the brain was developed beyond measure,
so that to reach the ventricles it was neces-
sary to make an incision nearly three inches
in depth. There was nothing unusual to be
remarked in any of the cerebral functions of
this child ; it was just like other children of
the same age in respect of intellect. It died
of acute inflammation of the bowels.

The late Dr. Sweatman met with just
such another child a few years ago : and I
refer to his description of it the rather, be-
cause cases that occur near home are always
more interesting, and satisfactory, than those
which we merely read of in foreign authors.
Dr. Sweatman had never read of any thing
of the kind : but in August 1834, a little
boy, two years old, was brought to him on
account of the size of his head. It had been
gradually increasing from the age of six
months, till it had become so large as by its
weight to prevent the child from continuing
long in the upright posture. The boy was
active and lively, though thin. He never
had had any fit or convulsion ; but occasion-
ally seemed uneasy, and then would relieve
himself by laying his head upon a chair. He
had never squinted, nor was he subject to
drowsiness, or startings during sleep ; and
his pupils contracted naturally. His appetite
was good, and all the animal functions were
properly performed. Dr. Sweatman got Mr.
Mayo to see the child with him ; and they
both set it down as a case of hydrocephalus,
but agreed in thinking that in the absence of
symptoms it would be wrong to risk dis-
turbing his digestive organs by active medi-
cines. In the early part of 1835 the child
died of inflammation of the chest, and Dr.
Sweatman and Mr. Mayo examined the head.
I here shew you a cast of it. It measured,
from ear to ear, over the vertex, twelve
inches ; from the superciliary ridges to the
occipital, thirteen inches ; and in circum-
ference twenty-one inches. The anterior
fontanelle, which was quite flat, measured
across its opposite angles two inches and a
quarter by one and a half ; the posterior
fontanelle was completely closed, as was the
frontal suture. There was no absorption of
bone at any part ; on the contrary it was
becoming thicker. The dura mater adhered
with great firmness to the skull ; and a layer
of false membrane, as big as a crown-piece,
was found upon its upper and anterior
part. Beneath the arachnoid at that part
there was slight jelly-like effusion. In all
other respects the organ was sound. The
convolutions were perfectly distinct, and
retained their proper rounded shape. All
the ventricles were found empty, and not
dilated. The surfaces, however, of the me-

dullary matter, exposed by different sections, presented very unusual vascularity. The lesson we learn from cases of this kind is, that we are not to regard every child that has a very large head as a hydrocephalic child; and especially that we are not to inflict upon such a child a course of mercury, or other active remedies, unless some morbid symptoms appear. The *nimia cura medici* may in these, as in many other cases, destroy health; produce disease where none existed before.

Atrophy of the brain.—Having told you what I know of *hypertrophy* of the brain, it is proper that I should say a word or two respecting the opposite condition: of *atrophy* of the cerebral mass. There are two forms of this affection: one is congenital, and results from imperfect development, or an arrest of development of the brain in its fœtal state. In the other the change appears to take place in consequence of disease, either in the membranes of the brain, or perhaps in its arteries; though the effect of disease in the arteries is usually softening, which *is* a species of atrophy. But in the atrophy to which I am now alluding, the *volume* of the atrophied part is diminished, not its *consistence*. And the diminution of size may extend only to a few convolutions; or it may be most manifest in the interior of the organ; in the optic thalami and corpora striata for example. There is still another alteration to which some have applied the term atrophy, though improperly I think: I allude to those cases, which I shall speak of more particularly soon, in which the form and disposition of the cerebral substance is altered, the convolutions being unfolded, and the nervous matter spread out by a large collection of fluid in the interior cavities of the brain, constituting the disease called *chronic hydrocephalus.* I have not much to say upon what may be styled atrophy *proper* of the brain: that it will give rise to symptoms we cannot doubt, but that it shews itself by any peculiar or characteristic symptoms is what I have not discovered.

I shall content myself, on this subject, with showing you Cruveilhier's representation of a strongly pronounced example of atrophy of the entire cerebrum on one side. The drawing from which this engraving was made, was painted from the body of a patient who died in the Hôtel-Dieu, dropsical, in consequence of disease of the heart. He was forty-two years old. When you look at the engraving you will perceive that the left side of the cerebrum is diminutive compared with the right. It filled up, however, a larger space than it appears to do in the plate, for the lateral ventricle on that side was distended by a large quantity of serous fluid, which ran out when the ventricle was punctured; and then the surface of that side

of the brain sunk down, and collapsed. Still the convolutions on that side, and all the dimensions, are remarkably less than on the other. The anterior lobe projected half an inch farther on the right than on the left side. The frontal bone, you will observe, is much thicker; twice as thick on the atrophied as on the natural side; and the frontal sinus very wide and open. The internal parts of the brain are all diminished in proportion. There was a large quantity of serous fluid filling and distending the subarachnoid cellular tissue. The nervous matter was whiter and harder on the atrophied side. One very curious thing is, that the *left* lobe of the *cerebellum* was the bigger of the two; but there was no such marked differences between them as between the two sides of the cerebrum.

Now the patient in whom this singular disproportion between the two sides of the brain was met with, had been incompletely hemiplegic, as long as he could recollect, on the right side; and the imperfectly palsied limbs were shrunk and withered, and the fingers of the hand contracted. Yet he had managed to walk about with the help of a stick; and there was nothing remarkable, one way or the other, in the state of his intellectual faculties.

The same condition has been seen on both sides of the brain: the organ itself existing in miniature as it were, and lying at the lower part of the vaulted cavity of the cranium; the intermediate space being filled up with serous fluid. In long-standing cases of this description you must not suppose that the nervous matter has been compressed into a smaller compass by the effused fluid; but that the fluid has been poured out to fill that part of the skull which is empty of brain, and which must be filled with something. This condition of the cerebrum is accompanied by idiotcy.

Acute hydrocephalus.—I proceed in the next place to the consideration of that disease to which the name of *acute hydrocephalus* has been given. It is the *apoplexia hydrocephalica* of Cullen, in whose time it was not looked upon as being of an inflammatory character. It is, in fact, *inflammation of the brain*, as it occurs in *children*, and especially in *scrofulous* children. The inflammatory symptoms are not always well marked; and yet they do, of all the symptoms, call for the most attention. That the essence of the disease consists in inflammation we have abundant evidence, both in the juvantia, and in the appearances presented by the brain after death.

I made some observations, in the last lecture, respecting the nomenclature of diseases, and said something in defence of the name delirium tremens. Now it must be

confessed that the disease we are at present considering was unfortunately named, when it was called hydrocephalus. I repeat that it matters not at all what name we assign to a disease, provided that the denomination does not carry with it any erroneous notion in regard to the *nature* of the disease. I think hydrocephalus a bad name, because it reminds us of one circumstance only of the malady, viz. the serous effusion, which, so far from being the *cause*, is only a *frequent effect* of the disease. But hydrocephalus, or water in the head, is an appellation so established, both among ourselves and with the public, that I cannot venture to propose any change.

After what I have already stated in respect to inflammation of the brain in adults, you will be prepared to hear that acute hydrocephalus (for I shall take the liberty of restricting that term to the disease as it occurs in *children*)—I say you will not be surprised to learn that acute hydrocephalus furnishes a great variety of symptoms ; and many variations in the mode of their coming on, and in their combination, and succession.

It is of the greatest importance to recognize acute hydrocephalus in its *earliest* stages; and even to look out for indications of its approach. I shall, therefore, describe those changes in the state of the young patient, which have been found to be, in many cases, premonitory that the disease was impending. But such symptoms are by no means always followed by acute hydrocephalus ; nor is acute hydrocephalus always preceded by such symptoms. Still, when they do occur, they should put us upon our guard.

Precursory symptoms.—The *precursory symptoms* to which I allude consist chiefly in a morbid state of the nutritive functions. The child loses his appetite ; or his appetite becomes capricious : he sometimes appears to dislike his food, and sometimes devours it voraciously : his tongue is foul, his breath offensive, his belly enlarges, and sometimes is tender ; his bowels are torpid, and the evacuations from them unnatural ; the stools are pale, and contain but little bile ; or they are dark, with vitiated bile, fœtid, sour-smelling, slimy, or scybalous ; and the child loses his former healthy aspect, becomes paler, and thinner. Even already there are some indications of derangement of the cerebral functions ; the child is heavy, languid, and dejected ; his customary spirit and activity are gone ; he gets fretful and irritable, and is manifestly uneasy ; and sometimes he shows a little unsteadiness and tottering in his gait.

In very young children, when the disorder is at hand or incipient, an unnatural wakefulness is often observable ; a frequent sudden cry or scream, a clenching of the little

fists, and a turning in of the thumb towards the palm of the hand, give warning also of the approaching malady.

Now when this sort of alteration is observed in a child who has any hereditary title to scrofula, or who bears the marks of the scrofulous *diathesis*, or is even a precocious and particularly clever child, and still more if he present any other indication of scrofulous *disease*, there will be much ground for apprehending that mischief is brewing within his head. I advert to these tokens of scrofula, because the inflammation, in a majority of cases, if not in all, is of a scrofulous character. But there is this peculiarity in it, which distinguishes it from scrofulous inflammation in most other parts, viz. that as it occurs in an organ of delicate structure, and one which is essential to life, its progress is more rapid, and it is more necessary to treat the disease vigorously.

It has been made a question whether the derangement of the digestive organs that has just been described is or is not the *cause* of the affection of the brain ; or whether both the abdominal and cerebral disorder be not common and concurrent effects of the same cause. It is said that the stomach and bowels are more in the way of being acted upon by injurious influences than the brain, and that, therefore, the complaint may be supposed often to originate in their derangement ; and great good, it is alleged, is done, the disease of the brain is often *prevented*, by remedying the disordered state of the stomach and bowels. On the other hand, it may be stated that a similar derangement of the digestive organs often comes on and lasts long in children, without leading to hydrocephalus ; and hydrocephalus often attacks a child in whom no such symptoms of abdominal disease have appeared. We can never be certain, therefore, that hydrocephalus has been prevented, in any given case, by remedies addressed to the digestive organs. I cannot think the question is one of much practical importance : whether the disturbances of the nutritive functions *cause* the brain disease, or merely *indicate* it, they are equally valuable in directing our attention to the head.

In these little patients any source of irritation seems to act as an *exciting* cause ; surgical operations, which are sometimes necessary at that tender age—falls or injuries of any kind—painful dentition.

Modes of attack.—There are, at least, three several ways in which this disease may make its attacks ; and with these it is proper that you should be acquainted.

In the first place, it may come on *gradually ;* after those symptoms which have already been spoken of as being premonitory. Probably this is the way in which it most frequently commences. After a period,

uncertain duration, in which the child has complained of occasional pains in the belly and head, and signs of derangement of the stomach and bowels have been present, the pain in the head begins to be more severe and to recur more frequently ; it is not mere headache, but generally a sharp shooting pain, recurring at intervals ; sometimes it affects one side of the head more than the other : the little patients wake and shriek out with the pain, and this in children is a very characteristic symptom ; and as coma comes on this shrieking gives place to an habitual moaning, which is scarcely less characteristic. Very often in the beginning of the disease there is pain and stiffness at the back of the neck : sometimes there is much pain of the limbs in the early periods, and in some children extreme tenderness of the scalp, so that they cannot endure to have the head shaved. The pain of the head becomes complicated with vomiting, and both these symptoms are aggravated by motion. Very often nausea is excited by the erect posture, and the patient begs to lie down. The child sighs frequently, and looks grave or sad ; his eyes are pained by a strong light, so that he knits his brows. The pulse becomes rapid, and the disturbance and irregularity in the abdominal functions increase. This stage of the complaint may last ten days or a fortnight, the child becoming daily more weak, and more peevish, and looking more and more ill.

In the second form of attack there are no premonitory symptoms ; or they occur for a very short while only before the disease sets in suddenly and violently, with acute pain in the head and high fever ; or with convulsion : the face is flushed, the eyes are brilliant ; there is intolerance of light and of sound, and there are pain and tenderness of the abdomen. In short, the disease, when it commences in this manner, is very like an attack of continued fever. You may find these varieties described in Dr. Cheyne's excellent treatise on this disease. " We are led to suspect," he says, " some deeply-seated evil from the frantic screams and complaints of the head and belly, alternating with stupor, or rather lowness, and unwillingness to be roused ; and we are struck with the great irritability of the stomach, which exists in a degree beyond what we generally find it in the fevers of this country ; retching and vomiting being brought on by a change of posture, and certainly by every attempt to sit up in bed ; and the disordered state of the bowels, which attends this irritability of the stomach, is also remarkable ; and when at any time the child has a little respite from the violence of these symptoms, we find our suspicions confirmed by his looks ; for when the features do not express pain or terror, there is not unfrequently a vacancy of look, the eyes being *set*, with an expression of dejection which is peculiar to certain diseases of the brain." The mode of attack which has now been described, although the most regular in its progress, is not so common as the first, nor as the third, which I have yet to mention. The *third* way in which the disease makes its advances is very insidious : the head symptoms supervene upon the subsidence of some other disorder : scarlet fever, small-pox, hooping-cough, or any inflammatory or febrile complaint, or even after painful dentition. In these cases the early symptoms are often but slightly marked, or do not take place at all ; the occurrence of convulsions or paralysis affording the first evidence that the brain is implicated. This is the most dangerous form of hydrocephalus. It has received the appropriate title of *waterstroke*.

Stages of the disease.—In whatever way the disease makes its invasion, it is apt to be attended with many and variable symptoms ; and different observers, with the view of facilitating the description of the disease, and of making it more intelligible and more easily remembered, have divided the symptoms into groups, and considered each group as characteristic of a particular *stage* of the malady. But they have not all done this in the same way. It may be of use, however, to inform you of the different classifications which have thus been proposed. Dr. Whytt, who was almost the first person in this country who wrote upon this disease (I believe Dr. Paisley, of Glasgow, was *the* first : you may see his paper in the third vol. of the Edin. Med. Essays), Dr. Whytt I say, whose description is an extremely good one, took the *pulse*—which undergoes very remarkable variations in the course of the disease—as the ground of his division. He makes three stages of it therefore ; the first, in which the pulse is frequent ; the second, in which it is slow and irregular ; and, the third, in which it again becomes frequent and feeble. These successive fluctuations in the pulse are to be noticed in very many cases. Dr. Gölis, again, an eminent German writer on hydrocephalus, whose little work has been translated by the late Dr. Gooch, as being the best book on the subject that he was acquainted with, makes four stages, according to what he believes to be the condition of the *brain* in each. First, he has the period of *turgescence*, which corresponds with that period in which the premonitory symptoms occur ; secondly, the period of *inflammation ;* thirdly, the period of *effusion ;* fourthly, the period of *palsy.* The two last would appear to be almost identically the same. Dr. Cheyne makes three stages ; which he finds marked, not like Dr. Whytt, by the state of the circulation, but by the state of the nervous system. Thus

he calls the first the period of *increased sensibility*, when every stimulus produces an impression more than proportioned to its common effects. In the second stage, that of *diminished* sensibility, the child is not easily roused, his pupil is dilated, and his pulse slow; he is lethargic, with obstinately costive bowels. The third stage with him is that of palsy and convulsions, in which there is squinting, rolling of the head, stupor, convulsions, with a rapid thready pulse.

Cases often occur, however, that baffle all these attempts at classification. Convulsions, instead of being among the *last*, are not seldom among the very *first* symptoms. The pulse is sometimes remarkably *slow* at the *outset;* sometimes *frequent through the whole disease;* and sometimes *perfectly natural*.

I do not make these statements to magnify the difficulty of distinguishing the disease; for the diagnosis is really not so difficult as it has sometimes been represented; but to shew you that you cannot trust to any succession of symptoms, still less to any one symptom, as being pathognomonic of the disease.

The symptoms that occur during the first stage are very variable, as you may suppose from what I have said of the different modes in which the disease is apt to set in. Those that are most constant are, pain of the head, severe shooting pain I say it seems to be, for the child puts its hand there, and cries out frequently " Oh! my head;" restlessness; inability to sit up; very disturbed sleep, with grinding of the teeth, and from this sleep the child often starts apparently in terror, and with a scream. The head is hot externally; the little patient is annoyed by light, or noise: the pupils are contracted most commonly during this stage; the child is unwilling to be disturbed, and, therefore, does not reply readily to questions; but the replies, when made, are correct and rational. This stage is marked also by vomiting, a total loss of appetite, a white tongue, offensive breath, costive bowels, unnatural stools, green often, or black, like tar, scanty and high-coloured urine. Dr. Gölis says that the abdomen, which has been tumid and tender perhaps, sinks down and becomes flat, without any increased excretion by stool; and that this is a very characteristic symptom. The pulse in this stage is frequent and sharp. In short, the symptoms are such (in general) as indicate very plainly that inflammatory action is going on within the head. Now the symptoms that characterize this first stage of the complaint sometimes rapidly pass into those which belong to the second. They may not be present for more than a few hours; or they may last a day or two,

or several days; it is very seldom, I believe, that they continue longer than a week. The period answers, in the general character of the symptoms, to the period of *excitement* in encephalitis, which, in truth, is very much the same disease, modified by its occurrence in the adult subject.

So also the *second stage* of acute hydrocephalus corresponds, in its general features, with the period of *collapse* in encephalitis. The pulse becomes irregular, extremely variable and fluctuating, and often *slow*; it is easily accelerated, however, by the smallest exertion—by taking the child out of bed, or even raising him into a sitting posture. With this slowness of the pulse comes on a diminution of sensibility, and general heaviness and stupor; the pupils dilate, the light is no longer troublesome, the vision is imperfect, often it is doubtful whether the child sees at all. If the eye be closely examined and watched, the degree of light remaining the same, the size of the pupil will frequently be seen to fluctuate, or oscillate, till at last it is wide open and immoveable; while this goes on, squinting takes place, and double vision when the child can yet see any thing. One or both eyes are turned in, or more rarely outwards. Noises do not now disturb or irritate the child—who lies on his back, with the eyes half closed, in a state of drowsiness or stupor, which is occasionally interrupted by some cry or exclamation expressive of pain. Convulsions frequently occur, but not uniformly; slight and partial spasmodic twitchings; or general and long-continued convulsions; paralysis; sometimes hemiplegia. The urine and stools are passed unconsciously. Sometimes the child, with feeble and tremulous hands, is incessantly picking his lips, or boring his fingers into his ears or nostrils.

This stage may last a week or two. And what is remarkable, it is often attended with remissions, sometimes sudden and sometimes gradual — deceitful appearances of amendment, and even of convalescence. The child regains the use of its senses; recognizes those about him again; appears to its anxious parents to be recovering;—but in a day or two it relapses into a state of deeper coma than before. And these fallacious symptoms of improvement may occur more than once.

The third stage does not differ materially in the character of the symptoms that accompany it, from the second, except that the pulse again becomes frequent, nay, uncommonly rapid; beating sometimes 200 strokes in the minute, so that you can scarcely count it. Dr. Whytt, in one instance, counted more than 210 pulsations. The child rolls its head perpetually from side to side; moans continually; waves its hand

in the air, or one hand, the other frequently being palsied; sometimes there is paralysis of one side, and convulsive twitchings of the other. The circulation is very unequal; one part of the body will be found hot and dry, and another covered with a cold sweat; the cheeks are alternately pale and flushed; the child is raving, or insensible; the rapid pulse gets more and more weak; and at length the patient expires. In many instances death takes place in the midst of a strong convulsion. This last period is of very uncertain duration; it may be over in a few hours, or it may last a fortnight.

For my own part, I conceive that for all practical purposes it would be quite enough to make two stages only of this disease. In the first, the symptoms are those of active inflammation of the parts within the cranium, or of some of those parts; in the second, we have the symptoms that result from the consequences and products of the inflammation, from softening, and from the effusion of serum. And frequently these sets of symptoms are, in some respects, common to both these causes, and more frequently still they are mixed up together; effusion taking place, yet the inflammation going on. And we may understand how the whole collection of symptoms may vary and fluctuate, and assume an uncertain character, according as the inflammatory process has ceased, or is still in progress, according as it exists alone, or is mingled with the further source of cerebral disturbance that is furnished by its own events; and according as the inflammation may have come to an end, while its events remain behind, and declare their presence by appropriate signs in proportion to their place, and extent, and their various kinds and combinations.

Anatomical characters.—What are these events? In other words, what are the morbid appearances presented after death in acute hydrocephalus?

In some cases we find traces of inflammation of the membranes of the brain; a firm adhesion of the skull-cap to the dura mater; occasionally some adhesion of the opposite surfaces of the arachnoid membrane to each other. Very commonly there is an effusion of serous fluid beneath the arachnoid, in the meshes of the pia mater, and especially in the depressions between the convolutions. You would suppose, upon looking at this collected fluid through the arachnoid, that it had the consistence of jelly, but it is not so; if you divide the arachnoid, by means of a sharp scalpel, a perfectly limpid fluid makes its escape. Not unfrequently there are layers of coagulable lymph interposed between the arachnoid and pia mater: this is a most unequivocal evidence of foregone inflammation; and it is

more frequently met with in the strongly marked cases. When portions of the cerebral mass are removed by slicing it, a great number of red points are often observed, speckling its cut surface: I mention this appearance just to say, that, to the best of my belief, it does not warrant any conclusion in respect to the state of the brain before death. We find these red spots numerous in many cases, when there had been no cerebral affection manifested during life; and they are not always to be seen when we are certain that there has been inflammation. With respect to the nervous matter itself, it is said to be sometimes softer than natural, and occasionally it has been found infiltrated, as it were, with serous fluid, *wet*, and *so* rendered soft. Gölis describes an instance of this kind, in which, he says, the fluid could be expressed from the cerebral substance as from a sponge.

But the most common and characteristic change is *softening of the central parts of the brain, with an effusion of serous fluid into the ventricles.* Generally the effused fluid is thin and watery; serosity rather than serum. It contains less animal matter, perhaps, than any other animal production. Dr. Bostock found that of 100 parts, 98·6 consisted of water, 1 part of salt, and ·4 only of animal matter. It is not, therefore, in common, coagulable by heat. The quantity effused is uncertain; speaking generally, it varies from two to six ounces.

But the effused fluid is not always clear and limpid; sometimes it is turbid, like whey, or even puriform, with flocculent shreds floating in it. These have been considered as flakes of coagulable lymph; but I question whether, in many cases, they are not merely fragments of the softened and broken down materials in the neighbourhood; for the septum lucidum, the fornix, and other parts forming the walls of the ventricles, are very commonly found softened, and pulpy, or entirely disorganized. The septum lucidum is perforated perhaps by a ragged irregular opening, the softened portion having fallen out: the fornix has lost its consistence, and often its figure, or falls asunder when the most gentle attempt is made to raise it. Dr. Abercrombie holds not only that this softness is the result of inflammation, which I think cannot reasonably be doubted, but that the inflammation of these central white parts constitutes the essence of the disease, in very many cases of acute hydrocephalus; and what bears him out in this opinion is the interesting fact, that this softened condition of the septum lucidum, fornix, and corpus callosum, may be fatal without any effusion of serum, and without any other morbid appearance, although with all the symptoms which are

usually considered to indicate acute hydro-
cephalus. He relates two striking examples
of this kind ; one of them was as follows :—
A woman became affected with violent pain
in her head, shooting from temple to temple.
She was extremely restless, tossing from one
side of the bed to the other ; her eyes were
slightly suffused, and impatient of the light ;
pupils contracted ; the pulse 60, soft and
rather weak. She was repeatedly bled, both
generally and topically, and used purgatives,
cold applications to the head, blistering, &c.
For three days she was much relieved by
these measures; the violent pain was re-
moved, and she complained of pain only
when she moved her head. She was quite
sensible, but oppressed, and inclined to lie
without being disturbed. At the end of
four days her speech became affected, of
which she was aware, for she said she felt a
difficulty in getting out her words. Then
came stupor, and at times incoherence, and
double vision, and at last coma, and dilated
pupil. She died on the eighth or ninth day
of the disease.

The fornix and septum lucidum were
found broken down into a soft white pulpy
mass : there was no effusion in the ventri-
cles, and no other disease in any part of the
brain.

Not unfrequently scrofulous tubercles are
discovered in the substance of the brain ;
and it is probable that these would have
been *more* frequently met with, if they had
always been carefully looked for. They
consist almost universally of a cheesy kind
of matter, like that of tubercles in the lungs.

You will find a good deal said by writers
on this disease, of morbid appearances
found in other parts besides the brain, and
especially in the abdominal organs,—en-
largement of the liver, inflammation of its
peritoneal covering, a preternatural develop-
ment of Peyer's glands, tuberculous matter
in the glands of the mesentery. One re-
markable change is very often seen, viz.
intussusception of the small intestines.
This probably takes place a short time only
before death, and appears to be the result
of spasmodic or irregular motions of the
bowels, analogous to those which are observed
in the voluntary muscles. The intussus-
cepted portions are easily pulled out, and
shew no marks of inflammation.

Pathology and causes of the disease.—
There have been endless discussions respect-
ing the true pathology of acute hydrocepha-
lus, and it may be proper that I should
offer you a few remarks upon this point,
before I proceed to the treatment of the
disease.

I need not, I conceive, take any farther
pains to convince you that the disease is
essentially inflammatory. We are inevitably

led to that conclusion by the *symptoms,*
which nearly resemble those that occur
when undoubted inflammation has arisen
from injuries of the head : by the *appear-
ances on dissection,* which are *always* such
as inflammation may have produced, as
softening and effusion of serum ; and *fre-
quently* such as nothing but inflammation
could have produced, as suppuration, and
the formation of adventitious membranes ;
and lastly, by the unequivocal relief given
(as we shall see) by blood-letting, and other
evacuations, the blood drawn being some-
times also sizy.

Now many persons, as I have already
hinted, lay great stress, when discussing the
pathology of acute hydrocephalus, upon the
previous unhealthy state of the nutritive
apparatus. They hold that the primary
disease—the *fons et origo mali*—lies in the
stomach, or bowels, or liver ; and that the
brain affection is secondary, and caused by
sympathy with these distant parts : and this
opinion they fortify by referring to the
frequency of organic disease, met with after
death, in the abdominal viscera. In accord-
ance with these views of its origin, they pro-
pose to cure, or to prevent, hydrocephalus,
by redressing the faulty condition of the
digestive organs.

Now this, in my judgment, is not only
an erroneous, but an unsafe doctrine : for it
tends to divert our attention from the head,
and to suggest a feeble and inadequate plan
of treatment. The grand predisposing cause
of acute hydrocephalus is certainly the scro-
fulous diathesis, and this is why we see the
complaint run so often in families ; so that
one child having died of that disorder affords
much ground for apprehending that others,
belonging to the same family, will become
victims to it. The constitutional tendency
is hereditary, and children born with it are
liable and likely to have strumous disease
set up in various organs at once, or perhaps
in succession ; not, however, a succession
of cause and effect, but of common relation
to one pervading disposition. We need not
be surprised that scrofulous inflammation
should affect the brain and abdomen at the
same time. When we find obvious organic
disease of the brain, scrofulous tubercles for
instance, which must have been antecedent
to the hydrocephalus, it would be just as
absurd to look to the abdomen for the cause
of the hydrocephalus, as it would be to seek
in the brain for an explanation of the cause
of diarrhœa or dysentery, when the liver or
colon were known to be diseased.

I do not mean to assert that the morbid
conditions of the brain and of the abdomen
are perfectly independent each of the other.
The vomiting that is so constant a feature
of acute hydrocephalus, the constipation that

is so common a consequence of head affections, afford familiar evidence of the influence which cerebral disorders may exercise upon the abdominal functions. Conversely, any disease in other parts of the body may react injuriously upon the brain, and may sometimes be regarded as an exciting cause of disease in that organ.

The period of life is also a strong predisposing circumstance; acute hydrocephalus being very much more frequent during infancy and childhood than at any subsequent time. It is said that fifty children are attacked by it in the first five months of life, for one child that has it afterwards. But it may occur at any age up to the twelfth or fourteenth year. After that period it is comparatively rare.

Whatever tends to deepen and aggravate the scrofulous *diathesis* — improper or insufficient nutriment, exposure to cold, inadequate clothing, impure air — may be regarded as a *predisposing* cause of acute hydrocephalus. And whatever tends to call scrofulous *disease* into action, may be reckoned among the possible *exciting* causes of acute hydrocephalus. Any general irritation may bring it on. It sometimes supervenes upon the drying up or repression of eruptions, as tinea capitis, or sores behind the ears. Such eruptions, therefore, occurring in strumous children, we must not attempt to cure suddenly; and free purging should be employed when they begin to disappear. The irritation produced by difficult and painful dentition is a very frequent exciting cause; and this is a source of danger which, in many cases, may be obviated by timely and judicious management. Violent heating exercise has sometimes, apparently, kindled the cerebral inflammation. Among the exciting causes we may place all physical injuries which jar and stun the brain; blows on the head, falls from a height, although the head may not be the part struck; and all moral agencies which shock or strongly disturb the nervous system; severe bodily pain, violent fits of anger, sudden fright. Göüs goes even so far as to say that great terror and distress of mind *in the mother* during the latter months of pregnancy may lead to the occurrence of acute hydrocephalus in the child, and he brings forward this curious fact in support of his opinion:—A large proportion of the children that were born in Vienna soon after the bombardment of that place by the French, in 1809, were seized with convulsions within a month after their birth, and died of inflammation within the cranium; effusion of coagulable lymph between the membranes, and of serum in the ventricles, being discovered on dissection.

CLINICAL LECTURES,

By Dr. Corrigan,

Delivered at the Hardwicke Fever and Whitworth Hospital, Dublin,

At the Commencement of Session, 1840-41.

Lecture II.

Manner of using the stethoscope.—Division of sounds into two classes.— 1st. Class, Simple sounds or murmurs; 1. Healthy vesicular murmur; 2. Puerile vesicular murmur; 3. Sonorous and sibilous murmur; 4. Tracheal (bronchial and cavernous) murmur. — 2d. Class, Compound sounds or rattles: 1. Crepitating rattle; 2. Mucous rattle. — Pectoriloquy and Bronchophony. — Ægophony, how produced.—Metallic resonance, &c.

I believe a knowledge of auscultation can be rendered much more simple and easy of acquirement than it is generally supposed to be. I cannot, perhaps, better expend the time of a lecture in this early part of a session, than in devoting it to laying down such rules as will, I hope, render the study of auscultation simple, and the attainment of a knowledge of it comparatively easy. By bringing the subject before you at this early part of the session, you will have ample time for testing, by practice, the rules which I would lay down for guidance in acquiring a knowledge of auscultation, and the correctness of the classification I propose to adopt.

Auscultation is called mediate when a stethoscope is employed, and an erroneous opinion is, perhaps, even rather generally entertained, that a stethoscope is employed to magnify sound. A stethoscope has no such power; it conducts sound, but does nothing more. It is, as a solid substance, a better conductor of sound than the air which intervenes between the ear of the physician and the parietes of a patient's chest, and it is, therefore, used as a better medium for conveyance of sound to his ear. The naked ear, where it can be used, or immediate auscultation, as its employment thus is called, will give the sound often better and more distinct; but the side of the head cannot, in many instances, and for obvious reasons, be directly or immediately applied to the chest; and, in some instances, it is necessary to define exactly the extent of some particular sound, which the small size of the cup of the stethoscope enables us to do, and which we could not do, where we have the side of the head, as in immediate auscultation, applied over a large extent of surface of the parietes of the chest. For those reasons it is frequently desirable to use

the stethoscope, or mediate auscultation, in preference to the naked ear, or immediate auscultation. Previously to proceeding with our subject, there is one caution I wish to impress on you in using the stethoscope : it is, to be careful to keep the extremity of the stethoscope in close apposition with the surface on which it is applied. I have seen this so commonly neglected, that I know the caution is called for. Nothing is more usual than to see a person who is most anxiously endeavouring to learn ausculta- tion, foiled in all his endeavours by want of attention to this apparently trivial circum- stance. He applies the stethoscope accu- rately at first, but the moment his eye is off it, in bending his head to it, he uncon- sciously inclines the stethoscope to meet his ear, instead of keeping it fixed in its position ; and the result is, that more or less of the trumpet end of the stethoscope is raised from contact with the surface—the stethoscope touches with only a portion of its rim, and it then ceases to convey any sound. To avoid this, apply the stethos- cope accurately, so that every portion of its rim shall be in contact with the surface ; and then, preserving it so, bring the ear to the cap of the stethoscope, taking care that it is not altered in the least from its original position.

There is, in the outset of a beginner's at- tempts to learn auscultation, a difficulty in his way, arising from a slight carelessness of expression in the work of Laennec, and which has been copied in most of the com- pilations formed out of it. Laennec says, speaking of healthy respiratory murmur, " On entend, pendant l'inspiration et l'ex- piration, un murmure léger," &c. In this there is an error. The healthy respiratory vesicular respiration is *only* heard during *inspiration*, or the sound during expiration is so very feeble that it may be considered as absent. Whenever a sound is heard, during expiration, of even very moderate degree of loudness, unless at the root of the lung, or very close to the trachea, there is always disease. Had Beau paid attention to this fact, he would not, I think, have origi- nated his theory, that the respiratory murmur heard through the chest is the sound, not of the current of air passing into the air-vesi- cles, but is merely the propagation of the sound generated by the passage of the air along the nasal passage and pharynx and trachea. Were his opinion correct, the respiratory murmur should, throughout the chest, present the same character which be- longs to it in those passages, of being heard equally loud in inspiration and expiration ; but as it differs in the remarkable character of being audible only during inspiration,

this difference of character is, I think, a conclusive objection against Beau's theory.

Our facility of becoming acquainted with the sounds of respiration will be greatly in- creased, if we keep always in mind a classi- fication that almost of itself suggests itself ; a division of the sounds heard on ausculta- tion into two classes—

1. Simple sounds, or murmurs.

2. Compound sounds, or rattles.

There is no ear, however unformed, that is not able to distinguish between these two classes ; there is no one who cannot, even when he hears a sound for the first time, no matter how strange it may be to his ear, at once say whether the sound is one produced by the simple blowing of air, " a simple sound or murmur," or whether it is one generated by the admixture of air and liquid together, " a compound sound or rattle." All the sounds heard in the chest belong to one or other of those two kinds ; and if, when you hear a sound of the exact nature of which you may be in doubt, you will first refer it to its class, your labour in determining what it is will be very much diminished. A want of attention to this simple classification, in mixing up together confusedly all sounds under the one head of râles, and a mistranslation of the French word " râle," has added very unnecessarily to the auscultator's difficulties.

We shall commence with our first class ;

Simple sounds or murmurs.—These are the sounds to the production of which a current of air alone is necessary. Their character is easily recognised even by the most untaught ear. The first of this class is the healthy vesicular murmur. There is no need of describing it. It possesses the character of being synchronous with the act of inspiration and it ceases to be audible during the act of expiration. If the act of inspiration be performed with greater rapi- dity than natural, so that the velocity of the air traversing the smaller tubes is conside- rably increased, the sound becomes in pro- portion louder ; and, when this loudness is remarkable, the sound heard is " puerile respiration," or puerile vesicular murmur. The respiration is naturally quicker in chil- dren than in adults, and hence the sound is louder. This loud respiration is the natural respiration of the child or infant, and hence its name. When a considerable portion of a lung in an adult is prevented by effusion into the pleura, by deposition of tubercle, by the obstruction of aneurism, pressure upwards of a large liver, &c. from perform- ing its share of duty, there is extra work thrown upon the remaining lung.

To enable it to do the extra duty, the respirations are increased in frequency from

15 to perhaps 40 in the minute ; and, in proportion to the frequency, is the loudness of the sound, or, in other words, the degree or intensity of puerile respiration. This explains to us why puerile respiration is an indication not to be overlooked. It tells us that the respirations are more rapid, and the vesicles in more energetic action, than natural ; and we immediately, therefore, on hearing it, turn our attention to discover the cause. It tells us, you will remember, nothing of the nature of the cause which has given rise to it. Respiration may be puerile, even though the absolute number of respirations in the minute is not increased, provided each act of inspiration occupies a very short space, or is a rapid act. When a chest is narrow, or deficient in development, in proportion, compared with the rest of the body, the respirations make up in rapidity and frequency what the lungs want in capacity. The respiration in such individuals is naturally puerile. Individuals with such chests are more disposed to phthisis than others. Our third species is " sonorous and sibilous (or wheezing) murmur." This sound is identical with the " râle sonore," and " râle sibilant," of Laennec. The sonorous and sibilous murmur only differ from one another in tone. When the sound is produced in the larger bronchial tubes, it is the deep-toned or sonorous sound ; when it is produced in the smaller tubes it is the high-toned wheezing, or sibilous murmur. The stages of a case of croup give us the progress of this sound, from its deep low tone up to the high whistling or sibilous note. In the commencement of croup, before the narrowing of the larynx is very considerable, the sound of the air passing in and out gives a low-toned rough sonorous note ; as the orifice of the larynx, by the progress of the disease, becomes narrower and narrower, the sound becomes sharper and sharper, until at last it becomes a heightened, acute, whistling, or sibilous sound. If similar changes occur in the bronchial tubes within the thorax, similar results follow. When the larger bronchial tubes are narrowed either by deposition of viscid mucus within them, or by a tumor pressing from without, the sonorous or low-toned murmur is heard ; when the smaller tubes are similarly affected, the sibilous or high note is heard. When those sounds are generated in the larynx, we hear them with the naked ear, because there is nothing intervening between the larynx and the ear to mask or intercept the sound, but, when generated within the chest, the tissue of the lung is so bad a conductor of the sound that it conveys it but feebly to the parietes of the chest ; and then, in order to hear it, it becomes necessary to interpose the stethos-

cope as a connecting medium between the parietes of the chest and the ear. The mode of production of sonorous murmur was very satisfactorily shewn in a case of aneurism some time since under my observation. The tumor rising from the arch of the aorta pressed on the lower part of the trachea. Over the first bone of the sternum, and extending from this a little on each side, there was very loud sonorous murmur, but, as the stethoscope was moved away from this point to any other part of the chest, the sound became less and less loud. There is one form of disease, emphysema, in which sibilous murmur presents a character so remarkable that it may be considered diagnostic of the disease. The character is this—that the sound, the sibilous murmur, continues after all external respiratory effort or motion has ceased. In other diseases, a sound, whatever it may be, is coincident with either the act of inspiration or expiration, or both, but there is no sound when the chest is at rest.

Emphysema presents this remarkable character particularly, when at all aggravated by the supervention of even trifling bronchitis—that, when the chest is quite at rest, there is still heard a clear, and occasionally even a very loud, sibilous murmur ; indicating that there is air still in motion within. I believe the mode in which this singular phenomenon is produced is this : that a number of the air-cells, which are greatly dilated, are distended with air in the act of inspiration ; that, from their narrow necks, they cannot be emptied so rapidly in the act of expiration as the natural-sized cells in their neighbourhood, and that hence, after the naturalized cells are quite emptied, the distended and enlarged air bullæ continue to pour out through their narrow orifices the compressed air into the surrounding cells, and the air, in its passage into neighbouring tubes or air-cells, produces that clear sibilous murmur, or musical wheezing, which is so frequently heard within an emphysematous chest after the termination of each act of expiration. In some of these instances the sounds are as varied and as musical as those of a harmonicon.

Tracheal, bronchial, and cavernous murmur.—I include all these under the one head ; I have a good authority for doing so. Laennec says (vol. i. p. 55), " under the name of bronchial respiratory murmur, I designate the sound of inspiration and expiration in the larynx, trachea, and larger bronchial tubes ;" and a little farther on (p. 558), speaking of the most marked form of cavernous respiration, he describes it as " only a more palpable tracheal or cavernous respiration, heard in cavities and in large bronchial tubes, when the pulmonary tissue

around them is indurated." I know you will be told by some that it is easy to distinguish bronchial from cavernous murmur. I do not think it is, when there is considerable induration round a large bronchial tube; and we have evidence to the same effect in those passages I have just quoted from Laennec. You can always make your ear familiar with this sound; it exists always naturally in the trachea, and hence you can at all times study it. Its remarkable feature is, that it is equally loud in the act of expiration as of inspiration.

A large bronchial tube may be considered as a continuation of the trachea, and hence it is not to be wondered at that we should often in disease hear the same sound from it; but it will naturally be asked here,—since form, and shape, and construction of the larger bronchial tube, are so identical with the trachea,—why we do not hear a similar sound at all times from a large bronchial tube. It is because, intervening between the bronchial tubes and the ear of the auscultator, there is in health the tissue of the lung, the worst conductor of sound that it is possible to conceive; as badly calculated to conduct weak sound as a mass of loose wool. The sound is heard with facility from the trachea, because the stethoscope can be applied directly on the trachea itself; but it cannot be heard from a bronchial tube, because the tissue of the lung intervenes to mask or smother the sound; but let a portion of lung around a bronchial tube become solidified, it then becomes a good conductor of sound; the sound of the air passing to and fro along the bronchial tube is then conveyed to the ear as distinctly as the sound heard in the trachea. Thus it is that when bronchial murmur is heard, it tells us that instead of the healthy loose vesicular texture of the lung, there is now interposed some solid structure which conveys the murmur of bronchial respiration to the ear, and thus bronchial respiration becomes a sign of solidification of the lung, from tubercle, from pneumonia, or of the existence of an intrathoracic tumor. The sound of cavernous respiration is very like that of bronchial respiration: it is the same character of sound, more intense, but so like it that it requires a very practised ear to distinguish between the strongest degree of bronchial or tracheal respiration, and cavernous respirations. Indeed, the tracheal respiratory murmur has all the most marked distinguishing characters of cavernous respiration. The mass of air acting on the sides of a cavity acts as the mass of air acts on the sides of the trachea, or of a large bronchus, and as the acting cause of the sounds is similar, it is only reasonable to expect the sounds themselves to be similar. We have

other means, however, of distinguishing between bronchial and cavernous respiration. The latter will most often be accompanied with gargouillement on coughing, or with signs drawn from percussion, or even from the history of the case, that will enable us to distinguish between a cavity and a solidified lung surrounding a bronchial tube. Laennec has said it would be of great consequence to be able always to distinguish bronchial from vesicular respiration (vide vol. i. p. 87); but he gives no precise mode of distinguishing them. The following simple rule, which I have for some years been in the habit of laying down, will be always sufficient for this purpose:—vesicular murmur, even when puerile, is only audible during *the act of inspiration*; bronchial respiration is audible both during *inspiration and expiration*, and equally loud during each of those acts. This terminates our class of simple sounds or murmurs; and let us now sum up:—

1. Healthy vesicular murmur.
2. Puerile vesicular murmur.
3. Sonorous and sibilous murmur.
4. Tracheal (cavernous and bronchial) murmur.

Compound sounds or rattles.—We shall now pass on to our second class, or rattles properly so called. This class is most easily distinguished from the preceding. All the sounds belonging to this class are produced by the admixture of air and liquid, of some kind, in the air tubes or vesicles; and the character of a sound thus produced is easily detected by any ear, even though the hearer may not at first be able to say what the precise sound is. If a sound be heard within the chest which gives to the ear the impression of air and liquid mingling together, it must belong to this class; and there are only two sounds in this class, the " crepitating rattle" and the " mucous rattle."

1st. *Crepitating rattle.*—Various similes have been made to enable the young auscultator to recognise this sound. It has been compared to salt crackling on the fire, to the noise made by rubbing a lock of the hair of the head between the finger and thumb, &c. These are bad similes, for this reason—that they lead you away from the manner of production of the sound. The sound is exactly that of small bubbles breaking through fluid, and it is thus produced in the diseases in which the sound is heard—in pneumonia, and in œdema of the lung. In those diseases the vesicles of the lung are occupied by a serous exudation, and the air, broken by the minute branches of the bronchia into very small bubbles, makes, by breaking through this serous fluid, the crepitating rattle. You can very easily generate

it; half fill a common phial with water, and add to the water a few drops of mucilage, so as to give it very slight viscidity, then shake the bottle, and while the bubbles are still breaking in numbers on the surface, hold the mouth of the phial to the ear, and there is a very distinct crepitating rattle heard, which continues as long as the bubbles continue breaking through the fluid. If too much mucilage be added, the passage of the bubbles is so slow, or they are so large, that the sound is not generated in perfection. [The experiment was shewn.] I am indebted to Spittal's work on Auscultation for the hint as to this mode of generating the sound. You can thus at pleasure make and study the sound, to render your ear familiar with it. There is a sub-genus of this sound made by Laennec, and of course adopted by all his compilers, called subcrepitating rattle, and described as characteristic of, and produced by, œdema. I do not believe there is any such subdivision available in practice, or recognisable by the ear. Laennec himself says (vol. i. p. 341), "We must confess that it is sometimes difficult to distinguish those two affections, œdema and pneumonia, from one another, by the stethoscope." If we recollect that in œdema equally as in pneumonia there is a serous exudation into the air-cells, and that the sound in both diseases is produced by the mingling of minute air-bubbles and fluid, we must, I think, admit that the sounds must be the same. Subcrepitating rattle may, then, be excluded altogether.

I have a similar observation to make of *dry crepitating rattle.* I do not believe this sound exists at all. I have sought for it over and over again, and never yet have been able to meet with it. Laennec has stated that it belongs to emphysema. Now of all diseases that are common in this country, emphysema of the lungs is one of the commonest. I do not think in the winter season you can go into a ward in any hospital in Dublin without seeing one or more cases of it; and if dry crepitating rattle belonged to it, I think we could hardly fail of recognizing it sometime or other. Laennec has compared it to the sound produced by the crackling of a dry bladder, leaving it to be inferred that the sound is produced by a similar crackling of the emphysematous lung; but a lung, no matter how emphysematous, can never be dry in the cavity of the chest, and when we feel a lung that is very emphysematous, one of its most remarkable characters is that it feels like soft wool, much more destitute of any crackling feel than a healthy lung. Laennec gives no satisfactory proof of having heard it; of emphysema he gives four cases.

No. 1. Not examined at all by the stethoscope.

No 2. Case was followed up to death, and signs noticed; viz. absence of respiratory murmur, clearness on percussion, and râle sibilant. There is no observation of dry crepitating rattle among the signs. The post-mortem shewed extensive pulmonary emphysema.

No. 3. The signs are also given in detail, but again no dry crepitating rattle noted; yet post-mortem, as before, revealed very extensive pulmonary emphysema.

No. 4 gave the same result.

Laennec has stated that dry crepitating rattle is more characteristic of interlobular emphysema than of the pulmonary form. He however admits (page 33) that he never had an opportunity of seeing any one die with this affection. I have had several opportunities of examining the chest for this sign, in persons who got interlobular emphysema from fractured rib, and I have never been able to detect the sound. October 14th, a man died in Jervis-Street Hospital, with subcutaneous emphysema of the whole body, the result of fractured ribs. I examined his chest very often and very carefully for dry crepitating rattle, but could never discern it; yet, on post-mortem examination, there was both pulmonary and interlobular emphysema to such an extent that the lung did not collapse; and it looked, on the chest being laid open, as if composed of flocculi of white wool. The patient had been for years asthmatic. There was very sharp crepitating rattle in the subcutaneous tissue when it was pressed upon, but none in the chest.

There are only two cases given by Laennec in which he says he heard the sound; but as there was also acute catarrh in those cases, and there was no post-mortem in either, no stress can be laid on them. I believe that the sound heard in emphysema of the lung, when of a crackling character, is merely a variety of mucous rattle produced by the catarrh which so often aggravates emphysema; and that, in the multiplicity of his observations, Laennec, led away by a theoretical notion of the crackling of an emphysematous lung, described it as a dry rattle. I think this opinion is greatly strengthened by the observation of a case of emphysema. If examined just when an exacerbation or asthmatic attack is coming on, there are heard all varieties of wheezing or sibilous murmurs through the tubes, arising from their narrowing, caused by congestion of the mucous lining of those tubes at this early stage, but no crepitating rattle. But as the attack terminates in expectoration, the sibilous and wheezing murmurs become

mingled with rattles, which are, however, not dry, but moist or mucous rattles. I think the conclusion we may safely arrive at is, that there is really no such sound within the chest as dry crepitating rattle.

2d. *Mucous rattle.*—This sound is always most easily recognised. We have all heard what is popularly called the death-rattle in a dying person. When a quantity of mucus, pus, or blood, in the trachea, is churned up in the act of respiration with the air passing through the trachea, the mucous rattle in this situation, and thus generated, is easily heard by the ear, without approaching it even closely to the trachea. If the same rattling of any one of those fluids and air is taking place lower down, in the first, second, third, or fourth-rate bronchial tubes, there is the same sound produced; but it is necessary to bring the ear either directly, or through the medium of the stethoscope, to the parietes of the chest, to hear it. The sound is easily recognised as produced by the admixture of air in large bubbles with some liquid; and as the bubbles can only be large in either good-sized bronchial tubes or in a cavity, when heard it always indicates either effusion into the larger tubes, or, when the bubbles are remarkably large, and the rattling confined to a particular locality, it indicates that there is a mass of liquid collected into one spot, and then the sound is called gargouillement. Gargouillement is only an extreme degree of mucous rattle, circumscribed in its extent.

We have now gone through the two classes of sounds, and divided into two classes they will now stand thus :—

1st Class.—Simple sounds or murmurs will contain—

1. Healthy vesicular murmur.
2. Puerile vesicular murmur.
3. Sonorous and sibilous murmur.
4. Tracheal (cavernous and bronchial) murmur.

2d Class.—Compound sounds or rattles :—

1. Crepitating.
2. Mucous.

These are all the divisions that are necessary for any purpose. It is easy, when a sound is heard, to at once say, from its nature, to which of these classes it belongs, and this being ascertained, it is not difficult to determine which of the sounds it may be. The voice, heard through the medium of the stethoscope, presents some alterations of consequence to be acquainted with. If the stethoscope be applied over the larynx or trachea in any individual, and that individual speak, the voice will come so sharply through the stethoscope, that the hearer would fancy the person was speaking

to him through the tube of the stethoscope. The same resonance extends along the bronchial tubes into the chest, but is lost, in ordinary circumstances, by the loose tissue of the lung intervening between each moderately-sized bronchial tube, and the walls of the chest; but if the tissue of the lung be rendered solid by pneumonia or tubercular deposition, then the sound is readily conveyed from the bronchial tube, and the voice is heard from within the chest nearly as distinctly as when the stethoscope had been placed over the larynx or trachea. To the voice thus heard from within the chest, the name of bronchophony or pectoriloquy is given. They are but different degrees of the same sound. If there be a cavity, the multiplication of the sound within it gives a sound exactly analogous to that heard from the trachea ; or if there be a good conducting medium between any large bronchial tube and the surface, the voice is heard from it with the same clearness. In a case of aneurism, pressing on the right side of the trachea, related by Drs. Graves and Stokes, in the Dublin Journal, 1834, it is noted that " well-marked pectoriloquy may be heard on applying the stethoscope to the anterior portion of the tumor." And, in Laennec, vol. i. p. 65, it is observed that " in thin subjects, particularly children, there is, at the superior internal angle of the scapula, a bronchophony in intensity equal to pectoriloquy."

These observations all prove that there is no difference in kind between bronchophony and pectoriloquy. The difference is only in degree. The sound is only deserving of the name of pectoriloquy when it comes so sharp into the ear as to obliterate altogether the natural voice of the patient ; but there are all shades of this, from very slight resonance up to this intensity.

There is a singular form of bronchophony heard in some cases of pleuritic effusion, to which the name of ægophony is given from, the singular bleating resonance, resembling that of a goat, which accompanies it. This preparation will help us to explain the mode of its production. [A preparation of the trachea and bronchial tubes, the tissue of the lung having been removed, was exhibited.] This preparation shows us a large branch of bronchial tubes going to the large lower lobes of the lung on each side. When effusion takes place into the cavity of the pleura, the lower lobes are pressed upwards ; this brush of bronchial tubes is also pressed upwards ; the tubes are also pressed close together, and then there is a bundle of bronchial tubes lying close together in the angle of the ribs, and a little below the scapula. If over this place the stethos-

cope be applied and the patient speak, the whole bundle of tubes vibrates together, and there is a corresponding increase of resonance given to the voice, from which it derives its name of ægophony. If the effusion be very great in amount, the sound is lost, for then the sides of the tubes are pressed together, and the lung is forced away from the angle of the ribs. If the effusion be not sufficient in amount, the sound is not heard, for then the bronchial tubes are not pressed together so as to give the necessary resonance. The sound of ægophony is only present at a particular stage of the amount of effusion. It is a sign of very little practical value. We have it only when we do not stand in need of it; and, except as a matter of curiosity, it is hardly worth taking notice of. In pneumo-thorax there is such an extent of reverberating surface, that when the patient speaks a ringing accompanies the voice as if the patient spoke into a bell, and if a bubble of air break on the surface of the fluid in the cavity of the pleura, or a drop of liquid fall on the surface of the larger mass below, a similar ringing accompanies it. The former is metallic resonance ; the latter metallic tinkling. There is no mistaking them for any other sound. If you will now remember the two grand classes, and first ascertain, on hearing a sound, to which class it belong, there will be almost no difficulty in determining what the particular sound is, while knowing the mode of production of each will much facilitate its recognition. I have found the divisions I have made in this classification sufficient for all purposes, whether of scientific or practical investigation, and I think you will, on trial and experience, agree with me.

ON HIP DISEASE AND LUMBAR ABSCESS.

By Wm. Oliver Chalk, Esq.

Resident Surgeon to the Royal Sea-Bathing Infirmary, Margate.

(For the Medical Gazette.)

The earlier indications of hip disease, such as flattening of the nates, slight limping, pain on pressure in the groin, enlarged inguinal glands, canting of the pelvis, with apparent lengthening of the limb, &c. &c. have been described by various authors ; but above all, pain in the knee has been esteemed one of the chief and premonitory symptoms of its approach ; this circumstance alone being considered sufficient to indicate

disease of the articulation itself. Too much importance, however, has been attached to this as a diagnostic mark, and it has proved, in my estimation, a constant source of error ; for I shall be enabled hereafter to show that this symptom almost always accompanies incipient lumbar disease, and that it is generally absent in the earlier, and not always present in the latter stages of morbus coxæ. When we take into consideration the relative situations of the psoas muscle and lumbar nerves which are destined to supply the lower extremity, it must be at once apparent that abscess forming in that situation (whether as a consequence of carious vertebræ, or, as often happens, of a deposition of tuberculous matter in the cellular tissue abounding in the neighbourhood of that muscle) must transmit pain along the course of the nerves, as they are naturally involved in the disease ; and hence the hip, the thigh, and knee-joint, become alternately or simultaneously affected. The flattening of the nates, and wasting of the muscles of the thigh, are equally common to the early stages of hip and lumbar abscess, the cause being the same in both instances. The patient throws the weight of the body on the sound limb, maintaining the opposite one in a state of quietude by every possible means in his power ; and in this way the canting of the pelvis, and the muscular atrophy consequent on inactivity of the extremity, arise.

The various modes of examination recommended by authors to ascertain if disease be situated in the hip-joint are open to objection. We are told by some to use flexion and extension alternately, and to rotate the limb outwards and inwards; and that by these means we shall not fail to discover a crepitus, &c. If the affection be so far advanced as to give rise to this sensation, it will rarely happen that a necessity can exist for a proceeding fraught with so much suffering to the patient*, as in that case there will be other pathological phenomena sufficiently demonstrative of the condition of the joint, without resorting to such means. Pain, imparted by extension and rotation of the limb outwards, cannot be

---

* I have more than once seen severe symptoms ensue not only in this, but in other, diseases of joints, after an examination so conducted.

considered indicative of morbus coxæ alone, for it is quite certain that in both instances the psoas muscle is brought into forcible action, and, therefore, if disease be situated in that part, pain must be transmitted along the course of the nerves: hence the patient refers it to the hip and knee. Pressure behind the trochanter affords us no better means of diagnosis; for if an accumulation of pus exists in the lumbar region, the ischiatic nerve will always be found more or less sensitive on pressure: thus an examination so conducted, and in this particular situation, is inconclusive. Not less so is that where pressure is made in front of the joint in the groin. The psoas and iliacus internus muscles, as they quit the pelvis, pass immediately over the articulation; consequently any inflammatory excitement from the formation of abscess in the first mentioned of these must naturally tend to render it highly sensitive to pressure. (That such is really the case, I have had frequent opportunities of proving). Again, the very common coincidence of sympathetic enlargement of the inguinal glands in both disorders, is another source of pain, and, therefore, not to be depended on as pathognomonic of morbus coxæ only.

It is quite certain that whenever flexion, extension, rotation outwards and inwards, are resorted to in disease of the joint, pain must be the consequence, as by all these means the head of the femur is moved in the inflamed socket. But extension and rotation, as I have before mentioned, are equally productive of it in the earlier stages of lumbar abscess.

Another method of examination is adopted by some surgeons. The patient is placed in a supine position, the thigh is bent on the pelvis, and then the knee is struck by the hand; and if pain is given to the articulation, they consider it a sufficient evidence of disease. But this also is liable to objection, as the sensation so produced may be equally conveyed to the psoas muscle. To obviate some of these difficulties, I usually adopt the following method:— The patient being placed in bed or on a couch, lying on his sound side, I use percussion immediately over the great trochanter, by which means the shock is more surely and immediately communicated to the joint: and if pain is

produced by it as well as by flexion, rotation, &c. &c. it may be considered in most instances characteristic of coxalgia.

The pain is often very acute even on very slight percussion. The following case is a good illustration of the fact.

Henry Lancaster, æt. 11, admitted as an out-door patient, June 6th, 1836, suffering under disease of the hip, on the right side. States that about eighteen months since he received a violent kick in the groin, and that at the same time he fell down a flight of stairs. He complained of slight pain the following day, which, however, soon ceased, and he experienced no return of it until three weeks afterwards, when the hip-joint became painful, and has continued more or less so up to the present period. The toe is turned inwards, and since the recurrence of the symptoms he has been in the habit of resting the heel of the affected limb on the instep of the sound one; and such at this time is the common position of it: he says distinctly that he has never had any pain in the knee, and that, when lying down, the hip-joint is comparatively easy. He limps in his walk, and uses a stick. On slightly percussing the trochanter, he experiences acute pain. Rotation, flexion, and extension, also produce considerable suffering. His general health is much impaired; the tongue is furred, pulse feeble and quick, bowels costive, motions of a light yellow colour, pain on pressure in the region of the liver. Leeches were applied to the epigastrium, followed by a blister. Alterative doses of mercury, together with tonics of sarsaparilla and bark, were exhibited. He was ordered the warm salt water-bath three times a week, followed by the warm douche, applied immediately over the joint. This treatment was persevered in for six weeks, at the end of which time he left the Infirmary, having recovered the use of his limb, the articulation being entirely free from pain, and his general health reinstated. I have already observed, that pain in the knee is not always present in the latter stages of hip disease, although it is obvious that such must generally be the case, especially when suppuration has taken place in the cavity of the joint, for under such circumstances the soft parts become implicated in the disease, and

pain as a necessary consequence is transmitted along the nerves of the limb.

The two following cases, which terminated fatally, are instances of the absence of pain in the knee-joint, from the beginning to the termination of the disorder.

Ann Mervin, æt. 7, admitted on the 4th May, 1836. The local symptoms were as follows : great flattening of the nates on the left side ; limb lengthened to about two inches ; the trochanter, knee, and ankle joints, lower than those of the sound extremity ; the foot turned outwards, and the leg extended. There was no perceptible alteration in the osseous structure. Flexion, extension, &c. &c. caused great suffering. Slight percussion over the trochanter communicated acute pain to the articulation. She complained of pain in the upper and fore part of the thigh, and stated distinctly she had never suffered in the knee*. She was in a state of extreme debility and emaciation, and labouring under contant febrile accessions. The pulse was extremely quick and feeble, the tongue furred and very red at the tip, constant diarrhœa, evacuations of a clay-coloured and yeasty appearance. She was also suffering from a short hacking cough, acompanied by occasional dyspnœa. The abdomen was generally tender, especially in the hepatic region. The treatment was chiefly palliative ; and every endeavour was made to remove the more urgent and distressing symptoms, but with little success. She died on the 21st of June following.

A post-mortem examination was instituted a few hours after death. On reflecting the integuments of the hip, I was struck with the atrophous appearance of the gluteal and subjacent muscles. They were so thin and flaccid, and so pale in colour, that they could hardly be said to exhibit the characteristics of muscular fibre. The capsular ligament was entire : on dividing it, the head of the femur, which was in a state of incipient caries, was readily disengaged from the cotyloid cavity. The ligamentum teres was entirely destroyed and removed by absorption, not the slightest vestige of that structure remaining. At the point corresponding with the attachment of the ligament

* As the patient was so young, I made particular inquiries of her parents, who corroborated her statement in this respect.

and the synovial glands or apparatus, the bone was exposed to about the size and appearance of a sixpence. The synovial surfaces had lost their usual shining appearance, from the absence of the natural secretion. Small portions of tubercular matter were observed on the head of the femur and in the cavity of the joint. The viscera of the chest were in a healthy state ; the liver was atrophous and of a pale yellow colour ; the gall-bladder contained scarcely any bile, and what little there was, could scarcely be said, as far as appearances went, to vary from its natural state, except that it was unusually inspissated. The spleen was very small, but not much altered in structure or appearance. Some of the mesenteric glands were enlarged ; the greatest size not exceeding that of a large pea.

Esther Bond, æt. 8, admitted May 19th, 1836, suffering under disease of the left hip-joint, in its suppurative stage. There is considerable fulness of the nates, more especially in the vicinity of the articulation, forming a hard and circumscribed tumor ; the prominence of the great trochanter cannot be traced ; the parts are highly sensitive and painful ; percussion over the joint causes severe suffering ; the limb is wasted, lengthened, and turned inwards. She lies with the knee bent, and rests the limb on the sound one ; but the thigh is not flexed on the pelvis. Any attempt at flexion, extension, or rotation, produces excruciating pain. There is a sinous opening on the middle and exterior of the thigh, from which about 4 oz. of tolerably healthy pus is discharged daily. She states distinctly that she has never experienced any pain in the knee. Her general health is much deranged ; pulse quick and small, bowels inactive, evacuations unhealthy, urine thick and scanty, depositing a copious red sediment ; hectic fever, profuse night sweats. The patient remained under treatment for a period of five months, during which time a variety of means were adopted, but without success. She died of cerebral disease, October 15th.

The body was examined a few hours after death. On reflecting back the integuments and the gluteus maximus a large cavity was disclosed, communicating with the opening on the thigh, from which the pus flowed freely. The subjacent muscles were entirely de-

3 N

stroyed, with the exception of some of their tendinous insertions about the neck of the femur. The capsular ligament was for the most part destroyed by the ulcerative process, although it was just sufficiently entire to retain the head of the femur *in situ*, which, to-

gether with the cotyloid cavity, was in a carious state. The latter was so extensively affected, that a large perforation existed at the bottom of it, through which about 2 oz. of pus had escaped and lodged at the side of the rectum. The woodcut, No. 1, (copied

Fig. 1.—*Case of E. Bond.*

A. Perforation at the bottom of the cotyloid cavity.

from a copperplate engraving which was executed from the preparation in my possession), is a representation of the state of the parts. The thoracic and abdominal viscera were next examined: the former were healthy. The liver was engorged, and presented on its convex surface two or three patches of yellowish induration, which afforded considerable resistance to the scalpel on incision. The gall-bladder contained about a drachm and a half of inspissated bile, not varying much from its natural colour. A few of the mesenteric glands were tubercular, and enlarged to the size of a pea. The whole substance of the brain was in a marked state of ramollissement* : the lateral ventricles contained about 12 oz. of serum. The arachnoid membrane was thickened in places, and its vessels highly congested.

The foregoing cases appear to me illustrative of another fact, namely, that whenever the ligamentum teres, and the synovial apparatus or glands, are destroyed by inflammation, caries

of the socket may commence at that point. If, in the first case, (that of Ann Mervin), the patient had lived long enough, it is obvious that destruction of the bone would have proceeded from that spot where it had been denuded of its natural covering. In the second, (that of Esther Bond), it has been seen that almost the whole of the bottom part of the cavity was destroyed, and it is probable that it originated in this circumstance. In both instances, it will be remembered, the limb was lengthened: in each the disease originated from violence to the hip-joint—a circumstance which I ought to have mentioned in detailing their respective cases. I have also another preparation in my possession, wherein the bottom part of the cotyloid cavity is destroyed by caries forming a small opening into the pelvis. This was the case of Daniel Macarty (to be hereafter mentioned), who suffered from lumbar abscess, and consecutive disease of the joint. The part in which affections of the articulation first arise has been the frequent subject of discussion ; but it is plain that if they are produced by violence,

* The ramollissement could not be attributed to decomposition, as the post-mortem inspection took place in less than four hours after death.

either the synovial surface, cartilage, round ligament, or bone, may be injured, according to the nature of the accident; and, what is most likely, more than one of these structures may suffer at the time. It is therefore extremely difficult to decide upon this point; nor does it appear to me of any great practical importance: let the disease commence where it will, parts so intimately connected and mutually dependent on each other as the complex apparatus of the hip-joint, must soon be involved. Accordingly, whenever we are called upon to examine those who have died of this affection, the destruction that has taken place is generally great. The extent to which this may proceed is shown by the woodcut, No. 2. It is the case of George Abel, æt. 6, admitted

Fig. 2.—*Case of George Abel.*
May 14, 1835, suffering under disease of the right hip. The local symptoms were most severe, especially during the latter period of his existence. There was a sinus on the middle and outer part of the thigh, discharging a fœtid and unhealthy pus. The patient endured excruciating pain in the hip, knee, and leg, on the slightest movement. He rested the limb affected on the sound one, and lay with his hand grasping the thigh just above the knee. The pain was constant, his rest broken, and when he slept, which was for short intervals only, he generally awoke screaming with intense agony. The general symptoms were not less severe. He was constantly suffering from febrile accessions, followed by profuse sweats, ardent thirst, pulse feeble, and so accelerated that it could scarcely be counted. The abdomen was generally tender to the touch, more especially in epigastrio. He died about six weeks after his admission.

On examining the joint, I found that the bones entering into its formation were entirely separated, the head of the femur, pubis, and ischium, lying detached, and these, together with the ilium, were in a state of caries. Pus had been extravasated beneath the periosteum on the dorsum of the latter bone, forming a small cup-shaped depression on its surface. This will be seen by referring to the woodcut. The destruction of the soft parts was so complete, that the head of the femur fell through the opening made by the first incision in the integuments. The thoracic viscera were generally healthy. The liver was small and atrophous, of a uniform dull yellow colour, and so light, that when a portion was thrown into water it floated on its surface. The spleen was indurated, and the mesenteric glands slightly enlarged. One of the symptoms peculiarly characteristic of hip affections in their earlier stages, is the manner in which a patient stoops to pick up any thing from the ground. He bends the knee, but does not flex the thigh on the pelvis, and endeavours, by stooping the body forward, to obtain the desired object. The reason of this proceeding is obvious: if he attempted it in the usual manner, he would be obliged to rotate the head of the femur in its socket, and thus produce pain. It has been stated by some authors, that the limb is thrown behind the patient in performing this action, but in doing so the head of the femur is brought into movement; and I shall be able to show that the last-mentioned manner of using the limb is peculiar to persons affected with psoas abscess.

[To be continued.]

COMPOUND CATHETER FOR THE TREATMENT OF STRICTURES IN THE URETHRA.

To the Editor of the Medical Gazette.

Sir,

In the number of the Medical Gazette published on the 22d ult., Mr Foulkes. of Liverpool, has published an account of an instrument, for the treatment of strictures of the urethra, which is, in all essential respects, identical with a "compound catheter" which I have, for ten years past, been in the habit of using. Both instruments consist of three catheters, incased one within another; the only difference being, that while his smallest catheter is of the ordinary construction, mine has an open orifice, like the other two, so as to admit the passage of a probe-pointed silver wire. This instrument was constructed for me in the year 1831, by Mr. Peter Aitkin, of this city. I showed it soon after at a very full meeting of the Medical Society of Glasgow, which then counted among its members most of the eminent medical men in the city. My friend, Dr. Lawrie, Andersonian Professor of Surgery, has been in the habit of showing it to his class when lecturing upon stricture. I have myself employed it in practice, not only in private, but at the public hospital, and have pointed out to the students there its peculiar construction and advantages, both in the wards, and in my clinical lectures. The instrument, therefore, has been long very well known in the medical circles of Glasgow.

The instrument made by Mr. Aitkin is of silver, but I had long intended to have a similar instrument formed of elastic gum; but was prevented from doing so by our having no catheter-maker in Glasgow to whom I could apply. In the month of September, last year, a catheter-maker from England called upon me, at my house, for the purpose of disposing of his instruments. I mentioned the subject to him; and as my silver instrument was then at the hospital, he called there next day, by my direction, when I showed it to him. He proposed to give silver tips to the catheters, just as has been done in Mr. Foulkes' instrument; but on my objecting to these, as likely to irritate the urethra, he said it was quite practicable to make the instrument without them,

and received his order accordingly. I neglected to take this gentleman's address, and I have never since had any tidings of him, or of the instrument which he promised to make.

I beg, most especially, that I may not be understood to say, or in the most remote manner to insinuate, that Mr. Foulkes received, through any of the channels I have mentioned, or in any other way, any hint or suggestion which might have assisted him in the invention of his new instrument. It is quite possible that the same principle may occur to the minds of two different individuals, without any communication; and it is also possible, although it is a more remarkable coincidence, that they should carry the principle into the details of its practical application in the very same way. My objects in now addressing you are, in the first place, to express my concurrence in Mr. Foulkes' recommendation of the instrument as a highly useful one; and, in the second place, to do what Mr. Foulkes, and every other man who has ever taken the trouble to invent an instrument and get it constructed, will acknowledge to be just and natural— viz. to establish that I did invent the said instrument about the year 1822, had it constructed in the year 1831, and have since been in the habit of using it in practice.

May I, therefore, request the favour of your inserting the following abridged extracts from my note-book for 1831, under the title "Stricture Apparatus."

During the last ten years I have been intending to have an instrument constructed for the treatment of strictures of the urethra. The idea first occurred to me, when I had a number of such cases under my care in the infirmary here (1821-2). I have since thought of it every time a case of the kind presented itself, but it was only lately that I put the design into execution, in consequence of the occurrence of a case of great difficulty, which baffled all the usual modes of treatment. [Here follow the details of this case, to which I was called by my late pupil, Mr. Alexander, and which ultimately required the operation of puncturing the bladder through the rectum.]

It is only with an instrument of small size that we can hope to pass a narrow stricture of the urethra. Difficulty is often experienced in passing such an

instrument, even in the healthy state of the passage, from the point getting entangled in the lacunæ, or folds of the mucous membrane, when the pressure of the instrument is no longer exerted in the direct line of the axis of the urethra, but obliquely upon one side, so as to endanger the formation of a false passage. When, therefore, in a case of stricture, difficulty is experienced in passing a small instrument, we are never sure whether we are pressing directly against the obstruction, or laterally against the sides of the urethra. The instrument here described is chiefly intended to obviate this difficulty, by introducing all small instruments in the inside of others of larger size. It consists of three bent silver tubes, incased one within another, and open at both ends; so that each of the two smaller passes easily along the one immediately larger, and out at either end. The tubes are all segments of the same circle, 23 inches in diameter. The largest (A, fig. 1) is 10 inches long, and one-fourth of an inch in thickness; the second (B) is an inch longer, and one-sixth of an inch in thickness; the third (C) is twelve inches long, the sixth part of the whole circumference of the circle, and one-eighth of an inch in thickness. A probe-pointed wire (D) passes along the inside of the smallest tube, and exceeds it in length by about an inch.

FIG. 1.

a. Outer or largest tube.
b. Middle tube.
c. Smallest or inmost tube.
d. Probe-pointed wire.
e. Slips connected by chain.
The point of each of the tubes is rounded, so as to pass along the urethra without irritating it; and the upper orifice is cut obliquely, and exactly parallel to the direction of the point, or to the tangent touching the circle there: in this way, by merely inspecting the outer orifice, we know at once the direction of the point. The upper part of each of the two smaller tubes and of the probe-pointed wire is graduated, so as to indicate, in decimal parts of an inch, the exact distance it may have passed be-

yond the extremity of the tube immediately larger.

When the instrument is to be used, we convert it into a single piece, (as shewn by fig. 2,) by placing the smaller

FIG. 2.

The instrument put together, and the different tubes fixed by the slips.

canulæ within those immediately larger, and the probe-pointed wire within the least. The points of the smaller canulæ are made to project, so as to give the instrument a rounded conical point; and in this form the whole is secured firmly by introducing two slips of silver (E, fig. 1,) at the top, between the canulæ. The circular form of the instrument requires a slight difference in the mode of introduction from the usual method of introducing the common catheter. The instrument is carried on till it meets with an obstruction; we then withdraw the silver slips, and endeavour to overcome the resistance of the stricture by manipulating with the smaller canulæ and probe; or, if found necessary, with bougies or elastic catheters introduced through either of the two larger canulæ.

The account, given at length in my note-book, of the advantages of the instrument, may be thus abridged:—
1st. The instrument acts on the principle of a wedge, the dilatation by the larger canulæ exterior to the stricture assisting the action which the smaller canulæ and probe exert upon the stricture itself. 2d. We can employ forcible dilatation by means of the probe or smaller canulæ, or elastic instruments substituted for them, with much more safety than with any single instrument, because we are more certain that the force which we employ is directed in the line of axis of the urethra. 3d. In cases of false passage, the compound instrument is much less liable than a single one to enter the false passage, because the smaller pieces cannot so readily take a lateral direction from the line of axis.—I remain, sir,

Your obedient servant,
ANDREW BUCHANAN, M.D.

Glasgow, 110, St. Vincent Street,
    Feb. 15, 1841.

VACCINATION.

To the Editor of the Medical Gazette.

SIR,

YOUR last number contained a letter from Mr. Henry Crawford, vaccinator to the East Ashford Union, requesting information, on a point of vaccine practice, from the correspondents of your journal generally. I cannot be insensible to the compliment paid me, by selecting my name from among the many who are fully competent to reply to the question, and willingly offer to him and your readers the results of my reflection on the case submitted to us.

Mr. Crawford inquires whether a person can conscientiously be registered as having been " regularly and successfully vaccinated," in whom, out of four incisions made, one only takes effect ; and that one is retarded in its normal course, by 48 hours.

The question is an important one. I firmly believe that if a person so vaccinated were in after-life to be attacked by small-pox, there are medical men who would seize on these two facts, and adduce them as evidences of imperfect or untrustworthy vaccination. On the other hand, if a child so vaccinated were to pass unscathed through a variolous epidemic, such exemption would by others, or perhaps by the very same parties, be brought forward as proof of the correctness and sufficiency of the original vaccination. So prone are we to judge by the result. The question, however, ought to be decided independent of all such ex post facto reasoning. Mr. Crawford judiciously inquires, whether under such circumstances the child is to be at once registered as a case of successful vaccination. In my opinion, sir, he is ; and for the following reasons.

If an attempt be made to revaccinate a child, in whom only one (retarding) vesicle appears, after the lapse of one, two, or three years, such an attempt will fail. I have tried it frequently, and always with the same result. This satisfactorily proves that the system has received from the one vesicle a certain influence which it did not previously possess ; and this insensibility to renewed insertions of the vaccine virus I hold to be the only legitimate criter on of perfect vaccination. Fur-

ther, it will be found that a vast number of persons who trust for their safety to vaccination, bear upon their arms only one cicatrix, while many who take small-pox subsequently have three or four.

With regard to the retardation of the vaccine vesicle, I feel still more confident in the soundness of this opinion. A too rapid course of the vesicle—a premature areola, and an abbreviation of the ordinary course of the disease —undoubtedly indicates imperfection ; but it is otherwise with delay, for full time is then given for the development of constitutional influence. We see all this well exemplified in the phenomena usually called *Bryce's test* (reinsertion of the lymph on the 4th or 5th day after the vaccination), and in the common results of *revaccination*. Rapidity of progress every where indicates imperfection, but I know of no facts which tend to impugn the sufficiency of retarded development. It often arises from that same inactivity of the vessels which determines the number of effective incisions. That is to say, it will often be found, as in Mr. Crawford's case, that, where one only out of four or five insertions takes effect, that one is *retarded* in its course.

These several considerations incline me to say that Mr. Crawford is fully justified in returning his four cases as " successful vaccinations," and in claiming the payment made and provided in the Act for the same.––I am, sir,

> Your obedient servant,
> GEORGE GREGORY, M.D.

31, Weymouth Street,

NEURALGIA.

To the Editor of the Medical Gazette.

SIR,

CONCEIVING the result contained in this letter to be both interesting and important, I take the liberty of forwarding it to your journal, and by that means adding it to the stock of public facts.

E. L., a female, aged sixty-three, residing in Osborne Street, had for several years been affected with a most painful condition of the nerves of one side of the face, coming on in paroxysms of the utmost severity, mostly towards night. At various times she had tried

most of the usual remedies, without experiencing any thing but temporary alleviation. On the 8th of November, during the night, I was sent for, and found the patient in a state of the severest pain. I administered a powerful opiate, which did not produce any material relief; and sleep was not procured until the system was completely exhausted and worn out by suffering. We had the same painful scene repeated on the following night. Under these circumstances, as the branches of the facial nerve seemed to be principally affected, the pain shooting across the cheek down towards the lower jaw, and occasionally upwards towards the temple, I proposed the division of the facial nerve in the parotid gland, after its exit from the foramen. To this the poor woman gladly consented, and I proceeded to perform the operation by making an incision betwixt the mastoid process and the lobe of the ear. My next incision brought me in contact with a nerve, which I supposed, from its situation, to be the auriculus magnus nerve, one of the ascending branches of the cervical plexus. On raising this nerve with my forceps, a state of tension seemed to be produced upon all the nerves of the face which were affected with the pain, and the patient exclaimed that was the place from whence all her pain proceeded. Under these circumstances, as the operation for the division of this nerve is trivial compared with the division of the facial, and as it was just at hand, I determined to try the effects of its division; and the result was most satisfactory: the woman passed a delightful night, and enjoyed some good sleep. The next day she had a little pain, and from that time to the present she has been perfectly well, except having, on one occasion, a very trifling degree of pain. Four months have now elapsed since the performance of this operation, and during this interval the patient has been exposed to the intense inclemency of the recent winter. I am not one of those who would pay too much attention to a solitary case; yet, as a single fact, this seems to me to be important, inasmuch as the means employed have effectually cured, for four months at least, and I hope permanently, a very severe case of neuralgic pain. If I may be permitted to draw any pathological inferences from the fact, I think they would be

the following. First, that some of the most severe forms of neuralgic pain are dependent not upon any diseased condition, but simply upon their possessing too great a quantity of their proper nervous energy; and secondly, that this can be reduced by cutting off a collateral, as well as a direct, channel of supply.—I am, sir,

Your obedient servant,
T. T. LAMBERT,
Member of the College of Surgeons.
Hull, March 2, 1841.

STAMMERING.

To the Editor of the Medical Gazette.

SIR,

I BEG to submit to your notice a brief statement of my recent proceedings relative to the cure of stammering, premising that I am at the present time actively engaged in collecting materials for a more lengthened explanation of my views upon the subject.

In the practice of my department of the profession, it has been usual with me to explore the condition of the mouth and pharynx in every case of deafness committed to my care. I have thus discovered that a large number of patients suffering from deafness are affected with enlargement of the tonsils and uvula, and an irritable condition of their investing membrane and the pharynx generally. It has been my constant practice, when I have considered these states at all contributing to the imperfection in hearing, to remove either the tonsils or the uvula, or portions of both, according to the nature of the case, with the most marked and immediate benefit, as far as the hearing may have been concerned. In December last it occurred to me to operate in this manner on two patients. They were, at the time of treatment, so deaf, that I did not then address my questions particularly to them, but to their parents, so that I was unaware of any impediment to speech in these instances. Some time after, as the cure of deafness advanced, I learned from the parents that both children had been stammerers from infancy, and, as much to my surprise as gratification, that the cure of stammering had ensued immediately on the excision of the tonsils. At the time at

which I write, the subjects of both these cases remain free from any impediment, though their stammering previously to the operation is represented to me as having been very decided. I had before this remarked that persons with enlarged tonsils were affected with thick and imperfect speech, for which I had often, during the last year, practised excision with the happiest effect, in restoring the voice to its original clearness. Since the cases above mentioned, I have operated on upwards of forty persons, all of whom have immediately felt themselves relieved of their impediment. Many have seemed wild with joy, or have shed tears of pleasure, at the instantaneous restoration they have enjoyed. After the operation, the difficulty of speech which remains is referred by the patient to the lips; they express themselves entirely free from the original difficulty. Something must be allowed for the long misuse of the organ of voice, and the existence of habit, in rendering the voice less perfect than in the natural state. In fact, after their relief, patients have yet to learn the proper use of the vocal apparatus.

I have performed the operation by means of a scalpel, tenaculum, and scissors, without any serious hæmorrhage, and with a small amount of pain, which has appeared somewhat greater in the case of the uvula than the tonsils.

In reflecting upon the subject, the explanation I have at present to offer is, that to produce stammering, the dorsum linguæ, the palatine arches, velum palati, and uvula, approximate together so completely, and perhaps irregularly, as to leave no room for the expulsion of air from the larynx. In a person who stammers, no air issues from the mouth during the abortive effort to speak; but it does so as soon as the patient is relieved from this state, so as to produce sound. The most violent contractions of the abdominal muscles can be seen attempting to force up the diaphragm and expel the air; sometimes all the respiratory muscles, and even those of the body generally, are thrown into violent spasmodic action, as the individual grasps some near object to assist the expulsive effort. In some cases, when there is nothing abnormal about the tonsils or uvula, I find a great congenital narrowing of

the entrance from the mouth to the pharynx.

I submit that the operation, which I believe I am the first ever to have proposed or performed specially for the cure of stammering, relieves this malady by making, as I excise the tonsils or uvula, an opening in the valvular obstruction I have described as being formed by the joint agency of the tongue, palatine arches, and soft palate. You will perceive that the principle of my operation is quite different from that ascribed to M. Dieffenbach, and since practised. it is said, with success, in France, by MM. Amussat and Phillips, and in this country by Mr. Bennett Lucas. This operation appears to me to rest upon the principle that the tongue is chiefly concerned in the production of the voice; whereas, I would inquire, does not this organ rather serve to modulate the voice after it has issued from the pharynx, &c., while in stammerers it is the fresh production of sound which creates the difficulty, rather than its subsequent modulation?—I am, sir,

<div align="center">Your obedient servant,

James Yearsley.</div>

29, Sackville Street,

<div align="center">

AN ACCOUNT

OF

DIEFFENBACH'S NEW OPERATION FOR THE CURE OF STUTTERING.

WITH CASE.

</div>

To the Editor of the Medical Gazette.

Sir,

We have lately read, in the daily papers, several paragraphs from correspondents, concerning a new operation for the cure of stammering. The French papers have likewise furnished us with accounts of it. But it seems that the English journalists merely copied the French, who obtained their information from the German daily papers, which, indeed, stated the effect of the operation correctly, but described the manner of performing it very imperfectly, and without entering into the particulars at all, as I found on reading them three or four weeks since. The same remark has been made by M. Velpeau, in a discussion which took place at the Academy of Medicine on

the 16th of February. It is, therefore, not surprising that the English and French journals should describe incorrectly the nature of the operation, and the manner of performing it, as practised and originally proposed by its discoverer. It is to that bold and distinguished surgeon, Dieffenbach, who lately enriched surgery with that beautiful operation for strabismus (which I first performed in Great Britain, as is decisively evident from my publications, and the testimony of several periodicals), that we are again indebted for the discovery of a cure for stuttering. On the 22d of last month I received from my friend, Professor Dieffenbach his memoir on this subject, as addressed to the Institute of France, and dated the 31st of January, 1841. From the information obtained from this source I was enabled to perform this new operation according to the rules laid down by him, an account of which operation, as well as the leading points of the professor's letter to the Institute," are laid before the profession in the following paper ; and if you can find room for it in the next number of your valuable journal, you will greatly oblige. sir,

<div style="text-align:center">Your obedient servant,
Aug. Franz, M.D.</div>

19, Golden Square, March 9, 1841.

Professor Dieffenbach says, in the above mentioned memoir, that " the infirmity of stuttering had long engaged his attention, but its probable cure suddenly occurred to him while a patient who had come to him to be operated on for strabismus addressed him with stammering accents. He was led to the idea of removing this impediment by an operation, from observing that the nervous twitchings of the eyelids, and spasms of the muscles of the face, which frequently accompany squinting, immediately disappear after the division of the muscles of the eye. He had frequently seen that by dividing the frænum linguæ, in cases where it was too much tied down, as also by other operations on the tongue or on the soft parts situated at the back of the mouth, some improvement was obtained in those cases where there was a slight hesitation in speech, but never in actual stuttering. He therefore reasoned that in this infirmity the disturbance in the mechanism of speech

must originate from a dynamic cause ; viz. from a spasmodic state commencing in the trachea, but more especially in the rima glottidis, from whence it extends to the tongue and the muscles of the face and neck : consequently he came to the conclusion that an interruption of innervation in one of the parts affected might be followed by an alteration of the nervous influence, and therefore by a suspension of the disturbance in the mechanism of speech. He thought that this alteration would be most certainly obtained in the nervous action of the vocal organs, by dividing the root of the tongue right across, and through its whole thickness : for doing which he has proposed three different methods :—

1st. The horizontal transverse section of the root of the tongue ;

2d. The subcutaneous transverse section of the root of the tongue, with preservation of the mucous membrane ;

3d. The horizontal transverse section of the root of the tongue, with excision of a portion in the form of a wedge.

The Professor has operated in two cases according to the two first and more easy methods, but finding that although the patient was able to pronounce a few words without stammering immediately after the operation, yet on its recovery the impediment was not entirely removed, he does not speak in such high terms of these as of the third method. According to the latter he has performed fourteen operations : the earlier cases, he states, are perfectly cured not only of the stammering but also of the spasmodic contractions of the muscles of the face, neck, and thorax, and the latter cases promise an equally favourable result. He therefore pronounces this method of performing the operation, notwithstanding its severity, as far superior to the two former, " since by cutting out a transverse portion of the tongue the alteration of the nervous action on the vocal organs must be more decided; the tongue likewise becomes shortened, and its tip turned upwards, which latter circumstance has always been considered as contributing materially to the removal of stammering."

The Professor further hints, that "in selecting a case for this operation, the

greatest circumspection is required; that in the execution of it, great dexterity and quickness are necessary, on account of the situation of the tongue, and the enormous hæmorrhage which of course takes place; and that in the after-treatment peculiar care is to be observed. If a strict attention is not paid to these circumstances, this operation, which inflicts so great a lesion on an important organ, may either be followed by destruction of the tongue, or even by loss of life." The first operation for the cure of stuttering was performed by the Professor on the 7th of January, 1841, on a young gentleman 13 years of age, and was followed by a perfect cure. In this case, he excised a piece, of the shape of a wedge, from the root of the tongue, being three-quarters of an inch at its superior part, and extending through its entire thickness. I shall not enter here into the details of the operation, as they will be seen from the following case, operated upon by myself, according to Dieffenbach's third method.

Case.—George Read, 17 years of age, of a strumous habit, but otherwise strong and healthy, except an herpetic eruption upon the lips, with which he has been afflicted some time. His parents, brothers, and sisters, were not afflicted with any impediment in their speech, neither was the patient so up to his father's death, which took place eight years ago, and made such an impression on his mind, that immediately after its occurrence he began to stutter. This infirmity, according to his mother's account, has gradually increased up to the present time; so that now he is scarcely able to speak, even to his own family, without great hesitation, though composed and free from excitement in mind and body. He, however, succeeds best in expressing himself by singing in a high pitch what he has to say. When he is in the slightest degree agitated, he can with difficulty stammer out one or two words only, and then his speech becomes convulsively interrupted, and, ultimately, entirely stopped; but when in the least excited, if he attempts to address a stranger, speech entirely fails him. When he first called on me, with his mother, his countenance exhibited the utmost degree of melancholy, the result of this trying calamity. His palate is highly arched, and rather narrow; his

tongue could be well raised, and freely moved in the mouth. He aspirated all the vowels, and pronounced them thus —h-h-h-a, whe, whi-hi, who-h-o-o, whu-h-u-h-u; consonants whose pronunciation commences with a vowel, he pronounced thus — hhell, hheff, hhess, &c.; the other consonants he pronounced with more or less difficulty; but d, t, b, and p, he could not pronounce at all. When he attempted to speak, he thrust his head forwards, moving it from side to side; his lips were drawn together, and protruded; and the muscles of the mouth, at the same time acting convulsively, drew them in every direction. The alæ nasi moved as in a paroxysm of dyspnœa. The eyes started forward, and began to water. The muscles of the face were in convulsive motion, as also those of the neck, although in a less degree. The larynx was drawn upwards. His mother informed me that, when in this state, he experienced a sensation of rigidity of the tongue, and as if it were too large for his mouth; as also of constriction of the muscles of the neck, but more especially of those of the larynx. I wished to make him speak a few words; but while attempting to do so, his eyes protruded, tears ran down his checks, and the convulsive movements of the muscles of his face and neck, but especially of those of the mouth, became so violent, that he was obliged to desist. During the whole time he was with me, the only word he could in any way pronounce was the word no, which he did as if written thus—h-h-n-nho-o. As he was utterly unable to answer any question, I was obliged to have recourse to his mother as interpreter, who knew from the motions of his lips what he wished to say.

On my explaining to them that a new operation for the cure of stuttering had been tried, and had succeeded in many instances, they readily consented to have it performed, as his stuttering to this dreadful degree, almost equivalent to dumbness, rendered him exceedingly wretched in mind, incapacitated him for business, and cut him off from all intercourse with any but his relatives.

On the 1st of March I performed the operation at the mother's house, in the presence and with the kind assistance of Dr. Ure, Messrs. T. Fowke and W.

Hering, who before the operation satisfied themselves of the patient's utter inability to pronounce the simplest word. The patient was seated in a high chair opposite the window; his head being held in a perpendicular position by one assistant, who, at the same time, drew the angle of the mouth backwards by means of retractors. His tongue being thrust forwards was seized by a pair of strong forceps, (furnished with teeth to prevent them from slipping), which I gave to another assistant to hold; by these means the tongue was steadied and compressed transversely. Having seized the tongue, posteriorly to the forceps, with the thumb and forefinger of my left hand, I compressed it transversely, and at the same time elevated it; then passing a long, curved, pointed bistoury, from the left side beneath the tongue, and at the posterior half, until I felt the point at the right side with my forefinger, I cut directly upwards, dividing the tongue right through. I now grasped the tongue in front of the wound with a pair of long forceps, armed at the point with teeth, pressed it firmly together, and with a small straight scalpel made a section from above downwards, commencing on the dorsum linguæ about half an inch anteriorly to the division already made, and meeting it inferiorly; by these two sections a piece of the shape of a wedge was cut out of the tongue at its posterior half. The wound was now united by six ligatures of thick silk, which were passed in such a manner as to encircle in depth and breadth a considerable portion beyond the margin of the wound, and were forcibly drawn together in order to restrain the hæmorrhage; this was so far successful that only a slight oozing continued for a short time. That the loss of blood during the operation was very considerable is not to be wondered at, when we consider the size and number of the blood-vessels divided. The patient bore this severe operation well, but became rather faint towards the termination, and afterwards vomited large quantities of blood which he had swallowed. As soon as he had washed his mouth with a little water, I was exceedingly pleased to hear him pronounce words which, previously to the operation, he was utterly unable to articulate; such as time, powder, &c., without the slightest hesitation or stammering, and without any twitchings of the lips, or even convulsive movements of the muscles of the face or neck, and immediately afterwards I was surprised by his saying with facility and distinctness, "there is some blood running down my shirt." He was now put to bed, and desired to be kept quiet, and directed not to be allowed to speak, and to have his mouth kept cool by means of cold water. On my calling in two or three hours time I found the case proceeding favourably; no re-action had as yet taken place.

March 2nd.—The patient had slept well during the night. Some febrile action towards night; pulse 120, but skin moist. On examining the mouth I found the tongue somewhat swollen and discoloured; he complained of no pain, but only a feeling of heat in his mouth: there was a great secretion of saliva and mucus, and some difficulty in swallowing. He took, during the day, a good deal of beef-tea, and towards evening a dose of castor oil. Was ordered to continue the application of cold water to the mouth.

3d.—He passed a very good night; was almost free from fever. The pulse had fallen to 95. Tongue rather more swollen; not painful, but thickly covered with a brown substance. To take a saline mixture every three or four hours.

4th.—Still going on well. Pulse 80. I now removed two ligatures, and found that union had taken place.

5th.—Swelling of the tongue greatly abated; but the copious secretion of saliva and mucus still continuing as before. He was now able to swallow liquids with but little difficulty, and was so far recovered as to sit up for a short time. He spoke a sentence or two without the slightest hesitation or stammering, and without any convulsive motions of his lips or face. The remaining four sutures were removed, after which, by cleaning the mouth with some water, a great deal of the brown substance before mentioned came off, leaving the mucous membrane perfectly clean and healthy; in the neighbourhood of the wound, however, it remained adhering to the tongue.

7th.—The tongue still continues clean; can be moved freely, but not without some degree of pain; speaks without stammering.

9th.—Has for the first time taken a

walk in the open air. The movements of the tongue less painful. The mother gives a favourable account of the progress of his speech.

Perhaps it may be as well to state that the muscles divided in this operation are the lingualis, the genio-hyo-glossi, the hyo-glossi, and the stylo-glossi.

I think, previously to undertaking this operation, we ought to consider well whether the nervous system of the patient is sufficiently strong to stand so severe a shock—whether he will, from age or constitution, be able to bear so considerable a haemorrhage as that which is here inevitable ; and it would be advisable likewise to ascertain that the heart and large blood-vessels are in a healthy state. The further remarks I had purposed to make on this important operation will be appended to another paper, in which I shall, on a future occasion, communicate to the profession the final result of the above case, as al-o the first and second methods of performing Dieffenbach's operation for stuttering, which I have not yet described. But I cannot conclude this account without returning my thanks to my friends, who took great interest in this case, and kindly assisted me through it.

MEDICAL GAZETTE.

Friday, March 12, 1841.

THE TOUCHSTONE OF MEDICAL REFORM.*

THE three letters which Mr. Green has addressed to Sir Robert Inglis and the public, contain, expressed in a more popular form, the sum and substance of what he has hitherto written on the same subject exclusively for the profession. In these, however, he has entered more closely than hitherto into the details of the question ; and this is

the more important, inasmuch as many of the suggestions he offers are drawn from opinions which prevail, we believe, extensively in the council of the College of Surgeons, and are likely to guide that body in many of the changes which they contemplate making, or seeking to have made, in their constitution.

The first of the letters is " On the Character of a Medical Man in connection with the nature and objects of a profession." In sketching an imaginary picture of what the medical man should be—in showing how he should be *skilful* in manipulation, and in applying all the resources of his art—a *philosopher,* possessing the knowledge of those laws, or rational grounds, which form at once the principles and ultimate aims of all professional knowledge—a *gentleman,* whose conduct is to be the pledge that he pursues his profession as a liberal science, and is in all things guided by strict honour—and a *christian ;*—in sketching this, the author has unconsciously drawn his own portrait. A noble thing it would be if one possessing all these qualities in a high degree could be an adequate representative of the profession generally ; but it is at present past all possibility. Medical men must be, in a measure, adapted to the state of society around them. The public, it is in these days too manifest, either cannot or will not, afford to maintain practitioners of the rank and elevation in society which Mr. Green and all good men would wish them to hold ; and so they who should be philosophers become many of them, against their will, tradesmen. Who, that united in himself all the high and ennobling qualities that are in the *beau ideal* of the surgeon, would consent to have his services tendered for ? who, of such a class, would be paid unwilling eighteen-pences, or be, for shillings, at the nod and beck of overseers, relieving officers,

* In Three Letters, addressed to Sir Robert Harry Inglis, Bart., M.P., by Joseph Henry Green, F.R.S.

and parish beadles ? Why, none : the true philosopher will rather starve : the more ordinary sort will rather follow the usual practice, drop his philosophy, and earn money by an honest but even degrading practice.

Nor are contracts, the tender system, and the screwing down of remuneration for medical aid, confined to those who dispense the public money ; they alone, indeed, may publicly advertise that they follow such systems ; but there is hardly a master of a household who does not privately pursue the same course ; who does not make the expense enter as one of the most important *items* in the question of what medical practitioner he shall employ ; and who, when the question comes within a suspicion of the *cætera* being *paria*, does not decide at once for the cheapest. And so it comes to pass, that, what should be a science, is, in many cases, only an art ; and that what should be a profession is a trade ; and that the index of the medical character is, in reality, not what the dignity of the science and the profession requires, but the money which the public are willing to pay for medical services.

This state of things, it is manifest, will continue just so long as the access to the rights of medical practice are so easy that the public can be supplied with practitioners at their own price ; so long as any can practise unexamined and unlicensed ; and so long as examiners are obliged to admit to the diploma all who are possessed of only a *minimum* of knowledge. The only remedy lies in preventing the public from setting the standard of professional acquirement by the rule of their own willingness of expenditure ; and this, as we have always held, can be done only by raising the standard of medical education, and making its attainment compulsory upon all. By this only can those to whom trade is natural

and pleasing, be prevented from bringing those who hate it down towards their own level. Just as, in ordinary society, the fashion, to which the wisest are forced to succumb, is the invention of fools ; so, in these more important things, the standard of respectability is set too nearly at the level of the lowest, because the majority cannot afford to hold themselves far above it. For although medicine may be such a science that it can be followed for its own sake, without any reference to its being a lucrative business, yet we apprehend that there is not more than one in a hundred of those who pursue it, who does not look to it, in the first place, as the source from which he will derive his necessary maintenance ; and who will not, therefore, confess that science has very generally to bow before necessity, whenever they come in contact.

To this most important, because most influential part of the question, Mr. Green barely alludes ; the consideration of the effect which medical remuneration has upon the medical character seems never to have been entertained by him. And this has probably resulted from his never having felt personally the necessity of considering it ; for our author has the double good fortune of being by nature and by education fitted to personate the model character he has drawn, and of being by patrimony set far beyond the temptation of descending from his elevation. However, though by different routes, we have arrived at nearly the same results: he, by a contemplation on the dignity of the science and art of medicine, and on the benefits its liberal exercise would confer upon society—we, by a simple view of the condition of medical practice, and the causes which have mainly contributed to its present state of degradation. The result of either consideration must be, that medical education should be made

more general and more liberal—that the amount of knowledge required for the diploma should be raised from its present *minimum*, and that more power should be given to governing bodies, to enable them to prevent the infraction of the privileges of their members, and the necessarily consequent damage of the public welfare. And this brings us to Mr. Green's other letters.

The second of these is, "On the institutions calculated to educe and foster the professional character." These are, in a word, universities and colleges. In them

"A medical education may be best grounded on those universal elements of science which are the essential constituents of every liberal profession; and a medical education cannot be complete except in such institutions where alone, discipline both moral and intellectual, systematic instruction, and a pledged direction and supervision of the studies, can give the requisite security for the progress and completion of the student's labours; and where the *alumni* are induced habitually to regard themselves as members of one body, brothers in the same household," &c.

All which may be very true, and may perhaps be realized some centuries hence; and we quite regret to descend from the vision which the author has drawn in such pure English, and with such enthusiastic eloquence, to the actual facts of the case. But unless the relation in which the public at present regard the profession be utterly altered, the members of the latter *cannot afford* to be educated in universities; at least the majority of them cannot. In the present state of things, and for some years to come, there must be apprenticeships, and dispensing of medicines, and many other things which one educated in such a university as the author pictures would hold in utter contempt. We say in *such* a university; for to imply, as he does, that the Colleges of the London University are

examples of institutions in which the advantages of collegiate education are obtained, is absurd. To them, students come as to any other medical school— not for the cultivation of the pure and most austere sciences—nor for the research of ancient learning—nor for the study of the physical sciences for their own sake—nor to form in themselves any sentiment of honour and gentlemanly feeling—but simply because they have heard of the reputation of the medical teachers, and are anxious to obtain, on the easiest and most secure terms, the knowledge that will enable them to pass their examinations. We know not, in short, any important respect in which the medical schools of the University and King's Colleges differ *in kind* from those of any of the large hospitals: to increase the number of colleges of this kind would not, as far as we know, be of any greater benefit than an equal addition to the number of ordinary medical schools; for to medical students they afford none of the advantages of a university education, however excellent may be their systems of medical instruction.

Indeed, the fact that these two colleges have failed to induce any proportion of medical students to accept the advantages, which their other classes afford, of obtaining a mere liberal education, is to us a sufficient proof that the time is not yet ripe for requiring education in a university as a part of the title to a diploma. We believe rather that this will not come except as the consummation of such improvements as are suggested in the third letter, "On the Regulation and Economy of the Medical Profession."

It cannot be doubted, the author holds, that the legislature is bound, for the security of the public, to provide for the maintenance of a medical profession, and to establish such criteria of

the competency of the members as the public shall be qualified to estimate in guiding their selection; and, therefore, it is a consideration of the practical difficulties, rather than any doubt of the principle of interference, that would prevent his urging the legislature to withdraw its countenance from the quack, and to protect, by penal law, his patients.   Certainly, for public offices, none but the tested and legally approved should be selected.

One of the main evils of the present state of medical practice, the result of the existence of so many separate governing bodies, forming what the author well likens to " a many-headed monster, which, in its heterogeneous authorities, feebly regulates its ill-combined functions," is the absence of any uniform standard of qualification ; so that it is impossible for the public to judge of the competency of any one possessed of any diploma. There should therefore, he holds, be an efficient *head* for the government of the whole profession ; and this should be a *State Council for Medical Affairs*, emanating from and responsible to the Government.   It should consist of various members, but of as few as the nature of its constitution would permit ; they should be members from each of the medical corporations of the United Kingdom, nominated and recommended by their brethren, but appointed by the Crown ; and to these should be added a small proportion of Lay Assessors, also appointed by the Crown, who would be for judicial authorities and legal advisers, and one of the members of the Government.

The functions of such a State Council should be, briefly—the power of approval or denial of all bye-laws and ordinances emanating from the several medical corporations, so that, without altering or impairing the functions of any, the characters of all may be as-

similated ; the taking cognizance of the practices of unqualified persons, and of dishonourable practices among those who are licensed; the superintendence of all matters appertaining to the public health; state medicine and medical police (including the provision for the defect of the present Poor Law in its relation to medical men) ; and the regulation and supervision of the institutions for instruction, with an especial view to the obtaining of an " harmonious adjustment of a multiplicity of means to a common aim and end."

Such is the general system of alteration proposed. The remainder of the Letter contains remarks on changes that might be beneficially introduced into the existing medical corporations, and especially into the constitution of the College of Surgeons.   Presuming that the public and the profession would derive advantage from making the diploma of the College compulsory on all who act as surgeons, the College, if this were granted to it, should undoubtedly be amenable to the country, which it is not now, nor can reasonably be expected to be, so long as it is legally a matter almost of indifference whether a surgeon have its diploma or not. This responsibility would be provided for by its being under the control of the State Council for Medical Affairs; but, besides this, it would probably be necessary to provide some means by which more of the members of the College should have a share in its management. For obvious reasons an open election would be disadvantageous; but for the election of members of the Council, an elective privilege should be conceded to certain members of the general body. Bearing in mind that the College is unalterably and eminently an institution for the promotion of the *science of surgery*, it follows undeniably that the first condition for enjoying the elective franchise should

be that of practising surgery exclusively; the electors must be those who are surgeons by profession, and not those who make surgery a subsidiary qualification to medicine, midwifery, or pharmacy. Between these two classes a distinction should be made, by the titles respectively of *Fellows* and *Licentiates ;* and the former should be fitted by a high standard of surgical education, not only to be electors, but to be eligible to all offices of honour and trust in the College. For this purpose the candidate for the Fellowship of the College should be, at least, twenty-four years old; should have graduated in arts in a British university, or be competent to pass an equivalent examination; should have testimonials of high moral character; should pass an examination in the ancient medical authors, anatomy and physiology, pathology and surgical therapeutics; should have been engaged six years in professional study; and should be required to furnish a series of clinical reports. Although others than pure surgeons might undergo this examination, and become Honorary Fellows of the College, none others should have the elective franchise, unless they were surgeons of county hospitals.

But here we must cease—at least for the present. We shall probably recur to this latter part of the subject; but, whether we do or not, our readers will do well to peruse the pamphlet before us. Both for the high talent and liberal feeling which it displays, and for the authority under which it is published, it deserves the fairest and most serious attention.

ROYAL COLLEGE OF SURGEONS.

At a Meeting of the Council, on Wednesday, the 3rd inst., Benjamin Travers, Esq. was elected an Examiner, and John Flint South, Esq. (both of St. Thomas's Hospital) a Member of the Council, in the vacancies occasioned by the lamented decease of Sir Astley Paston Cooper, Bart.

LIST OF GENTLEMEN ADMITTED MEMBERS.

On the 3d, morning clear, otherwise cloudy ; rain in the evening. The 4th, evening overcast, with rain ; otherwise clear. The 5th generally cloudy ; raining all the afternoon and evening. The 6th and 7th clear. The 8th, morning overcast, with small rain ; otherwise clear, and remarkably mild. The 9th, morning foggy, otherwise clear.

Rain fallen, ·585 of an inch.

CHARLES HENRY ADAMS.

LECTURES

ON THE

PRINCIPLES AND PRACTICE OF PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

LECTURE XXVI.

Acute Hydrocephalus continued. Prognosis and Mortality of the disease. Treatment : blood-letting ; purgatives ; cold ; mercury ; blisters. Prophylaxis. Spurious Hydrocephalus. Chronic Hydrocephalus, or Dropsy of the Brain. Shape of the head and face. Anatomical conditions. Symptoms.

THE disease, of which I described the symptoms in the last lecture, acute hydrocephalus, is a very dangerous disease ; and, when once it is fairly established, many more die of it than recover. Our chance of saving the patient's life, by active treatment, is always greater in proportion as the complaint, or the tendency to the complaint, is detected *early ;* and for that reason the precursory symptoms possess so high an importance.

When our treatment commences while the symptoms are as yet rather those of the precursory state, than of the confirmed disease, it is impossible to say how many of those cases which, under such treatment, terminate favourably, would otherwise have ripened into well-marked hydrocephalus ; and we must be content to have it said, without its being possible for us to refute the assertion, that not all of the disorders which we treat as acute hydrocephalus are really instances of that disease. We must act upon the worst supposition, and not wait until the nature of the symptoms *demonstrate* that the malady is present, while they demonstrate also, at the same time, that it is

well nigh hopeless. These are cases which peculiarly demand decision on the part of the medical man ; and we are bound to act, in some instances, upon very slight indications ; as when, for example, we perceive what we think threatenings of acute hydrocephalus in a scrofulous child, or in a child belonging to a family in which others have already been cut off by that disorder.

It has been supposed, by some, that the case is hopeless after effusion has taken place, but we cannot be sure of that ; nay more, there are no symptoms by which we can ever tell *for certain* that effusion *has* taken place.

I remember to have heard it gravely maintained, in the debating societies which I sometimes attended when a student, that there are no such things as absorbents, and no absorption, in the brain ; and therefore that perfect recovery from serous effusion in that organ is impossible. But this notion is refuted by plain and well-known facts. We shall see hereafter, that blood poured forth within the nervous pulp is capable of being removed by absorption. How an opinion so palpably erroneous could ever have found credit, except with that class of men who can or will believe nothing which they cannot see, I am at a loss to guess.

The prognosis, always doubtful or bad, is a little better when the disease is violent, and occurs in tolerably healthy subjects, than when it creeps on slowly and insidiously, and in weakly, scrofulous patients. In the former case there is more room for the adoption of active measures ; and the disease is more likely to be amenable to remedies, and less likely to be obstinate ; it is also less likely to depend upon a permanent cause, such as the existence of a scrofulous tumor in the brain.

The probable issue of the disease is often judged of by the state of the pulse. The quick pulse belonging to the early stages of the disease will become slow ; but it may

become slow in two very different ways : it may diminish in frequency in a gradual and moderate manner, and then we may hope that the alteration proceeds from the progressive declension of the fever; or it may drop suddenly, which would be a reason for our fearing that the second stage of the disease was about to establish itself. We must take care, under the former circumstances, not prematurely to assert that the disorder is on the decline, and the patient safe. On the other hand, if the pulse has been morbidly slow, a gradual and slight increase in its frequency must be considered as a favourable omen ; while its rapid and great acceleration would shew that the disease was passing into its worst and final stage.

I have already cautioned you against being misled by that deceitful truce, and apparent improvement, which is apt to take place in the course of the disease. If the signs of amendment continue, or make progress, during two or three entire days, we may venture to admit a little more hope. But the patient can never be considered secure while any approach to what are thought symptoms of effusion remains; while the pupil continues dilated for example, or even so long as it does not contract briskly under a strong light.

The prognosis is especially bad when acute hydrocephalus supervenes upon other disease ; or when it is engrafted (as it sometimes is) upon the chronic form of the disorder. It is very seldom that the acute form subsides into the chronic.

To show you that we are warranted in the expectation of sometimes carrying our patient through this most perilous malady, I will mention a few statistical facts that have been recorded in respect to its mortality. Dr. Odier, of Geneva, states that, upon an average, eighteen cases of acute hydrocephalus occur every year in that place ; and of these six get well ; *i. e.* the recoveries are to the deaths as one to two. Dr. Gölis, to whose work I referred in the last lecture, and who had the charge of a large institution for children in Vienna, gives an account of thirty-seven cases, out of which five recovered. He had seen, upon the whole, forty-one instances of recovery from acute hydrocephalus. Dr. Mills, who has also written on the disease, has narrated twenty-eight cases, all of which died but seven ; and M. Bricheteau lost four out of eleven. Adding these together, and taking the average, we have seventy-six instances of the disease, and sixteen recoveries : rather more than one in five. The cases in which recovery took place were mostly those in which vigorous measures were adopted *early.*

Treatment.—The treatment resembles that which I have already recommended when adults are attacked with encephalitis. It consists, therefore, in blood-letting, purgatives, cold to the head, mercury, and perhaps blisters. Of course the differences of age will require some modification of these remedies.

The only event of the inflammation compatible with the safety of the patient is resolution ; and this we must endeavour to bring about (I cannot too often repeat it) by *early* as well as by free blood-letting : bleeding from the arm ; or by leeches ; or by cupping. You must bear in mind that in very young children, leeches produce the effect of general blood-letting. It is a matter of obvious importance to ascertain to what extent we may safely and beneficially carry the abstraction of blood in infants. Dr. John Clarke, a man of large experience (the elder brother of the present Sir Charles Clarke), says that very young children will very well bear the loss of blood, even to fainting, once or twice repeated : but that their powers are apt to sink if the bleeding, to that extent, be had recourse to oftener. For infants a year old, three ounces is reckoned a full bleeding. I do not like opening the jugular vein, for reasons with which you are sufficiently acquainted ; and if the requisite quantity of blood cannot be obtained from the vein in the arm, cupping from the nape of the neck may be substituted ; or leeches may be applied to the temples, or to the mastoid processes. It is necessary to recollect that leeches generally produce a freer discharge of blood in children than in adults, on account of the greater activity of *the* capillary circulation in the former. No general rule can be prescribed in respect to the number of leeches that should be applied ; three will take as much blood in one case as half a dozen in another ; but assuming that one leech will, on an average, cause the discharge of one ounce of blood, we may apply three of them to a strong infant of six months, when the symptoms are violent. Of course the bleeding is to be suspended if syncope occurs. In older children the quantity of blood necessary to be taken will be somewhat larger : six ounces of blood taken from a vein is a full bleeding, I should say, for a child five or six years old. I mention these quantities as mere approximations, as guides to what you may expect to find practically required : the true measure and test of salutary blood-letting in this, as well as in other inflammations, is to be found in the effect it has at the time. The first bleeding, in what manner soever the blood is taken, should be a sufficient one ; should produce a decided and manifest impression. By attending to this rule you will break the force of the disease more surely, and more safely too, than by drawing blood in frequent driblets ; a mode of using the remedy calculated to

subdue the patient rather than to overcome his malady. You must afterwards go on with the leeches to the head, or you must withhold them, according to the exigency of the particular case ; according to the condition of the pulse, the continuance or the cessation of the pain, the increase or diminution of the fever, and so forth. And you are not to forget that as you have to deal, in general, with scrofulous children, any *superfluous* removal of blood, the abstraction of more than is required for extinguishing the inflammation within the head, will be likely to prove injurious to the general system. After the full formation of the comatose state, a farther prosecution of the bleeding has sometimes been rapidly followed by death.

Next in rank and importance to bleeding come *purgatives.* They are to be exhibited with the threefold view of correcting depraved secretions, of clearing the alimentary canal of its irritating contents, and above all, of deriving, as the phrase is, from the head ; producing a discharge of the watery parts of the blood, and taking off the stress from the cerebral arteries. The best forms of purgative medicine to be used for these purposes with children consist of calomel and jalap, or calomel and scammony ; and if these do not act freely, senna and salts must be given in aid of them. I have already made you acquainted with Dr. Abercrombie's high opinion of the efficacy of purgative medicines in inflammation of the brain, whether in the child or in the adult. Dr. Whytt, again, states that he never saw even temporary relief of the symptoms produced by any other means than those which increased the evacuations. Purgatives are to be administered, therefore, at an early period. But sometimes the stomach is so irritable that it will reject them. A previous bleeding will often correct this ; and it is no small part of the benefit derived from the abstraction of blood, that it prepares the way for the more effectual operation of aperients and of mercury. A large clyster will often be of service, both in settling the stomach, and in procuring stools, when there is much vomiting, and a continual rejection of medicine given by the mouth. Dr. Cheyne mentions a form of medicine by which he sometimes succeeded in quieting the irritable stomach, and procuring evacuations ; he would give a drachm or two of magnesia, saturated with lemon juice, every two or three hours. You may sometimes get calomel and scammony, however, to remain on the stomach, when almost every other medicine is rejected. The purgative plan should be steadily persisted in for several days.

To show you how torpid the bowels are apt to be in this disease, and how difficult it

sometimes is to procure evacuations from them, I may mention the following circumstances which I heard Dr. Alison relate as having occurred in the practice of his uncle, the late Dr. Gregory, of Edinburgh. He had one patient who took 140 grains of calomel in the course of five days, yet his bowels were not relieved, till he had also taken two doses of jalap ; the first of 30, and the second of 35 grains. In another case, a child of twenty-eight months took in nine days 350 grains of calomel (nearly 40 grains a day) ; and in six of these days 136 grains of jalap (more than 20 grains a day) : the effects were a gentle purging from the jalap, none from the previous calomel, and but slight salivation. The child recovered after having been nearly in a comatose state. Of course large doses of this kind are never to be given, until the inefficacy of smaller ones has been ascertained.

Cold applied to the head :—I have before given you examples of its power. It is especially useful in the early periods of the disease, when there is much heat, and when evacuations have been obtained. I am doubtful about the propriety of keeping *ice* in contact with the surface of the head in very young children. It will in many cases be sufficient to lay a linen rag wet with cold water (or spirit and water, to promote evaporation), upon the child's head, taking care to renew it frequently, not merely as often as it gets *dry*, but as often as it gets *hot* ; or water may be poured from a pitcher upon the head, a basin being held under the chin. Dr. Darwall states that he has known cases, which seemed utterly hopeless, recover by letting water fall in a small succession of drops upon the scalp, and continuing it until the head no longer recovered its high temperature upon intermitting the dropping. I need scarcely say that under all circumstances it is expedient to keep the head somewhat elevated. The influence of this mode of applying cold to the head is increased, and, perhaps, rendered safer, by immersing the lower extremities of the patient at the same time in warm water*.

* Since this lecture was delivered, I have read Dr. D. Davis's recent publication on acute hydrocephalus. He adds the weight of his experience in attestation of the great efficacy of blood-letting, early performed, and carried to deliquium animi. He mentions, likewise, a mode of applying cold, which is new to me, and likely, I should think, to be extensively useful. It forms one of the many valuable purposes to which caoutchouc has of late years been turned. A bag, or hollow cushion, made of the water-proof material invented by Mr. Mackintosh, is first filled with very cold water ; then about half of its contents is suffered to escape, and the remainder secured by turning the stop-cock. Thus no air is included. Upon this cushion the patient's head is to be placed. The " water cushion" applied in this manner to

Different opinions have been held in respect to the value of mercury in this disease. Knowing how powerful an influence it has in controlling inflammatory action, and that the inflammation in acute hydrocephalus often leaves behind it traces shewing that it was of the adhesive kind, I should not omit giving mercury; but at the same time (as I stated when upon the subject of encephalitis) I should not give it with the direct object of affecting the gums, of producing ptyalism.   I believe the evidence respecting the efficacy of mercury carried to salivation in acute hydrocephalus is this :— that some few very desperate cases have got well, the improvement commencing at the time when the mercurial influence on the system was becoming apparent ; and that in other cases, the occurrence of salivation has been followed by *no* alleviation of the symptoms, but the disease has run on, unchecked, to its fatal termination.   But the truth is that it is a very difficult matter to salivate a child ; there is a great reluctance in the system, at the earlier periods of life, to take on the specific mercurial action ; and the disinclination seems peculiarly strong during the presence of this disease ; and the younger the child, the more difficult is it to affect the gums.   Perhaps this may be considered fortunate ; for when salivation does take place in these little patients, it sometimes proceeds to an alarming extent.   Dr. John Clarke, who employed calomel largely in a variety of diseases, never saw more than three instances in which salivation was produced in children under three years of age.

If you are desirous of taking the chance of the specific influence of mercury doing good, you had better give calomel as a part of the purgative plan, and rub in some of the mercurial ointment ; you had better do this than lock up the child's bowels by combining opium with the calomel; not to mention the injurious effects of opium in young children in general, and in the early period of head affections in particular.   The calomel should be given steadily, in full and equal doses, at equal intervals.   Green evacuations from the bowels, resembling wet tea-leaves or chopped spinach, usually follow its continued administration : and this appearance (like the rising of the gums in adults) is generally regarded as a proof that the influence of the mineral is felt by the constitution, and that it is doing all the good of which it is capable.

Of blisters I may repeat the substance of what I stated when we were considering encephalitis.   I should abstain from them

at the commencement of the disease.   Even when applied at a distance from the head, they are apt to prove a source of hurtful irritation in these young and susceptible subjects.   But in the second stage of the malady, I believe blisters are often of good service.   They may be applied to the nape of the neck, or to the head : and several may be applied in succession ; or the ulcerated surface may be kept open by the help of irritating ointment, such as the unguentum cantharidis, or the ceratum sabinæ.

These are the main remedies to which we trust in the treatment of acute hydrocephalus : bleeding, purgatives, cold, in the outset ; mercury and blisters, of more equivocal efficacy than the former, in the more advanced stages of the disease.   When there is much irritability towards the decline of the disorder, or in its latest period, opiates may cautiously be tried; they sometimes have appeared to be extremely beneficial : two or three grains of Dover's powder is a very eligible form of opiate in such cases.

I do not feel called upon to say any thing, in addition to what I stated in a former lecture, about other remedies that have been proposed in acute hydrocephalus ; digitalis, colchicum, squills, antimony.   I have told you the remedies which *I* believe to be the best ; and which will save the patient, when judiciously used, if the case be within the compass of our cure : and you will do well to learn how to manage these powerful means. I am confident you will find *that* more to your purpose then trying now this and now the other remedy because it is new, or because some persons tell you they have been wonderfully successful with it.

Let me say a word in reference to the *prevention* of this disease : concerning which your advice will be sure to be asked again and again.   In families, in which acute hydrocephalus has occurred, or that shew decided marks of the scrofulous diathesis, the earliest attention should be paid to any deviation from the healthy condition of any of the functions.   Children in such families should be kept upon a nourishing but light and unstimulating diet ; consisting of well-dressed vegetables, farinaceous substances, and a moderate proportion of animal food. Particular care should be taken to keep the bowels regular ; not that weakening purges should be given, but the bowels should be fairly relieved at least once every day.   Any disturbance of the digestive organs should be immediately corrected ; by antacids, laxatives, change of diet, and sometimes by mercurials, as the hydrargyrum cum cretâ. Such children should also, if possible, be brought up in the country, and freely exposed to mild and dry air ; and in winter great care should be taken to have them

the back of the head, does not preclude cold lotions to the forehead.   It will be necessary, so long as the application appears grateful to the patient, to replenish the cushion from time to time with cold water.—T. W.

ufficiently clothed. During the hazardous period of dentition, the state of the teeth and gums must be sedulously attended to. There s good reason for believing that a seton or an issue in the neck or arm has been very serviceable in warding off and preventing attacks of the disease. Dr. Cheyne mentions some striking instances of the good effect of establishing an artificial irritation at some distance from the brain, when there has been a disposition to disease in that organ.

There is another caution, too, which you will often find reason for suggesting : and that is, not to press or encourage the development of the mental faculties in children who are quick and intelligent beyond their years. Parents are apt to be proud of the early acquirements of their little ones : they are not aware that such precocity of the mind implies danger to the health of the body ; and they provide them with instructors, and to a certain extent abridge their hours of exercise and amusement, that they may do justice to their cleverness. But it is our duty to admonish them of the risks they are thus running : and to advise them to think only, for the present, of corroborating the corporeal strength of the child ; and to avoid over cultivation of his intellect until this langerous period of his existence is got over.

Spurious hydrocephalus.—There is still one point remaining, and one of great importance, in relation to the acute hydrocephalus of children. I told you in the last lecture, that the diagnosis was generally not difficult ; and I have told you in the present lecture, that it will be your duty to suspect sometimes upon a conjectural diagnosis, as if you *knew* the disease was present, or at hand, although, in truth, you only *suspected* it to be so. But there is a form of disorder very apt to be mistaken and treated for acute hydrocephalus, and one which may be rendered fatal, if the *remedies* of acute hydrocephalus be applied to it. Encephalitis, whether it occur in the child or in the adult, has its spurious double. As in morals, every virtue has its corresponding vice, which apes its actions and assumes its garb, so is it also with many opposite bodily disorders ; and it is of great moment that we should be capable of discerning the essential difference of character that lurks beneath external similarity of feature. It is a most curious, but unquestionable fact, that *anæmia* of the brain, a diminution of its natural supply of red blood, will produce symptoms very much resembling those which result from the diametrically opposite condition. If you pay no regard to the state of the general circulation, as indicated by the temperature and by the pulse, you will find the actual symptoms of syncope, and

of apoplectic fulness, to be identically the same. When a human being bleeds to death,—as many do from wounds, from uterine hæmorrhage, and so on,—what do we see ? Why the patients may have nervous delirium, become convulsed, and then insensible, with a wide and fixed pupil. The outward visible signs of concussion and of compression of the brain are very much alike. The vulgar always confound them, and are clamorous that a vein should be opened : a measure which would be proper and useful in the one case, but most mischievous in the other. It is the same with the functions of other parts : we have palpitation of the heart when that organ is insufficiently supplied with blood ; palpitation when it is over supplied : dyspnœa, or hurried breathing, when the lungs are congested ; hurried breathing when blood does not arrive in them plentifully enough. You must see that the importance of distinguishing between the causes of these analogous phenomena is immense. Several authors in modern times have noticed the condition of the brain to which I now wish you to attend : Dr. Abercrombie, Dr. Marshall Hall, and the late Dr. Gooch. Their observations were made and published each, I believe, independently of the other's. Dr. Gooch's paper is entitled, " Of some Symptoms in Children erroneously attributed to Congestion of the Brain." His description of the state in question is very graphic ; it is chiefly indicated by heaviness of the head, and drowsiness. The age of the little patients whom he had seen so affected was from a few months to two or three years ; they were generally small of their age, and of delicate health, or had been exposed to debilitating causes. Dr. M. Hall has found this condition to succeed the diarrhœa often produced by weaning ; or the ill-timed administration of purgative medicine ; or the application of leeches for some previous complaint. The physician finds the child lying on its nurse's lap, unable or unwilling to raise its head ; half asleep ; one moment opening its eyes, and the next closing them again, with a remarkable expression of languor. The tongue is slightly white, the skin is not hot, at times the nurse remarks that it is colder than natural ; in some instances there is at times a slight and transient flush. In all the cases that Dr. Gooch saw, the bowels had been already disturbed by purgatives ; the symptoms had invariably been attributed to congestion of the brain ; and the remedies employed had been leeches and cold lotions to the head, and purgatives—especially calomel. Under this treatment they had gradually got worse, the languor had increased, the pulse become quicker and weaker, and at the end of a certain number of days

the little patients had died : in two instances he had known, during the last few hours, coma to come on, stertorous breathing, and dilated and motionless pupils. Dr. M. Hall describes a precisely similar set of symptoms.

I will take one of Dr. Gooch's cases in illustration, and give it you in his own words. " I was going out of town (he says) one afternoon, when a gentleman drove up to my door in a coach, and entreated me to go and see his child, which he said had something the matter with its head, and that the medical attendant of the family was in the house, and just going to apply leeches. I went with him immediately, and when I entered the nursery I found a child ten months old, lying in its nurse's lap, exactly in the state which I have already described ; the same unwillingness to hold its head up, the same drowsiness, languor, absence of heat and all symptoms of fever. The child was not small of its age, and had not been weak ; but it had been *weaned* about two months, since which it had never thriven. The leeches had not been put on. I took the medical gentleman into another room, related the foregoing case (*i. e.* a case in which a child had been leeched out of its life), and several similar to it, which had been treated in the same way, and had *died* in the same way. Then I related to him a similar case which I had seen in the neighbouring square, which had been treated with ammonia and decoction of bark, and good diet, and which had recovered ; not slowly, so as to make it doubtful whether the treatment was the cause of the recovery, but so speedily that at the third visit I took my leave. He consented to postpone the leeches, and to pursue the plan which I recommended. We directed the gruel diet to be left off, and no other to be given than ass's milk, of which the child was to take at least a pint and a half, and at most a quart, in the twenty-four hours. Its medicine was ten minims of the aromatic spirit of ammonia in a small draught every four hours. When we met the next day the appearance of the child proved that our measures had been right ; the nurse was walking about the nursery with it upright in her arms. It looked happy and laughing. The same plan was continued another day ; the next day it was so well that I took my leave, merely directing the ammonia to be given at longer intervals, and thus gradually withdrawn ; the ass's milk to be continued, which kept the bowels sufficiently open without aperient medicine." This case contains both a picture of the morbid state, and a summary account of the treatment it requires. Instead of the sal volatile, you may occasionally substitute with advantage from five to ten drops of brandy mixed with arrowroot. You are to restrain diarrhœa if it exists ; give the child plain nourishing diet—there is none so good for it as that furnished from a mother's breast ; keep its extremities warm with flannel ; and if the season permit, let a current of mild fresh air blow freely over it.

When the symptoms are more ambiguous, you will derive great assistance in judging of the true nature of the case, by tracing the manner in which it came on, and the causes to which it seems to be attributable : and in very young children—in respect to whom the question is most likely to arise—you may often determine between congestion or exhaustion, between fulness or emptiness, by a very simple and easy test, which is not adverted to, as far as I remember, by any of the three writers whom I have mentioned. I mean, by taking notice of the state of the unclosed fontanelle. If the symptoms proceed from plethora, or inflammation, or an approach to inflammation, you will find the surface of the fontanelle convex and prominent, and you may safely employ, and expect benefit from, depletion. If, on the other hand, the symptoms originate in emptiness and want of support, the surface of the fontanelle will be concave and depressed ; and in that case leeches, or other evacuants, will do harm, and you must take to a better diet, ammonia, and so forth. It may be as well to remark, that in the unclosed state of the fontanelle, the observations formerly made respecting the peculiarity of the circulation in the brain, do not apply.

Chronic hydrocephalus. — All that has hitherto been said has relation to *acute* hydrocephalus, which is an *inflammation.* I have next to speak of *chronic* hydrocephalus, which is a *dropsy.* From some cause, not well understood, a watery fluid collects within the skull, most commonly in the ventricles of the brain ; and this occurring at the earlier periods of life. before the whole of the brain case has become solid, the containing parts yield to the increasing pressure, and the size of the head is augmented in various degrees ; at the same time the cerebral functions are more or less deranged. This dropsy of the cranial cavity often commences before the period of intra-uterine life is completed, and the head of the fœtus becomes so large, that it cannot pass with safety into the world. Accordingly, many of these infants perish at the moment when their separate existence commences :—*nascentes moriuntur.* The pressure of the maternal pelvis is fatal to them ; or the diseased head bursts ; or is crushed by the accoucheur, to preserve the life of the mother. The skull is emptied of its contents, and the shell, if I may so call it, collapsing, passes through the natural outlets.

In many cases, however, the dropsical skull is expelled entire and unhurt, and the infant lives for a shorter or longer period. Sometimes the fluid does not begin to accumulate till after birth : in a few days, however, or after some weeks, or some months even, the head is perceived to enlarge with a rapidity quite disproportioned to the growth of the other parts of the body ; and enlarging, it becomes misshapen also. The intervention of the membranous partitions called fontanelles and open sutures, between the ununited bones, allows the centrifugal pressure of the gradually accumulating water to modify the shape of the head. These membranous interspaces are unnaturally wide, and more numerous than in healthy children. Nevertheless the process of ossification goes on, but the bones are extremely thin. We see little islands of bone in seas (as it were) of membrane. By degrees, if the child survives, the proportion of membrane to bone becomes less and less, and at length the whole brain case is hard, and firmly closed up, its surface exhibiting an unusual number of joinings; there are many *ossa triquetra*.

Shape of the head.—In the meantime the direction and relations of the loose and yielding bones are altered. The os frontis is tilted forwards, so that the forehead, instead of slanting a little back, rises perpendicularly, or even juts out at its upper part, and overhangs the brow. The parietal bones bulge above towards the sides ; the occiput is pushed back ; and the head becomes long, broad, and deep, but flattened on the top. This, at least, is the most ordinary result. In some instances, however, the skull rises up in a conical form, like a sugar loaf. Not unfrequently the whole head is irregularly deformed, the two sides being unsymmetrical. Some of these rarer varieties of form are fixed and connate ; others are owing, probably, to the kind of external pressure to which the head has been subjected.

While the *skull* may be rapidly enlarging, the bones of the *face* grow no faster than usual, perhaps not even so fast ; and the disproportion that results gives an odd and peculiar physiognomy to the unhappy beings who are the subjects of this calamity. They have not the usual round or oval face of childhood. The forehead is broad, and the outline of the features tapers towards the chin. The visage is triangular. This great disproportion of size between the head and the face is diagnostic of the disease, and would serve to distinguish the skull of a hydrocephalic child from that of a giant. Heartless parents sometimes make a wretched profit of the deformity. A penny show of that kind existed very recently in the immediate vicinity of this College.

Anatomical characters. — When, after death, we explore the physical causes of these singular deviations from the natural figure and bulk of the cranium, we find that they proceed from the pressure of accumulated water : the complaint is manifestly a dropsy. But the situation of the water, and the condition of the brain itself, are subject to some curious varieties.

In a certain number of cases the brain is incompletely formed ; deficient in some of its parts, or even altogether wanting. That portion of the cranial cavity which should contain the nervous pulp is filled up by a thin pellucid fluid. From some unknown cause, operating during the period of intrauterine life, the progressive formation of the brain has been arrested. Marks of imperfect development are often visible in other parts of the same infants ; they have a hare-lip, a bifid spine, or a fissured palate. It is in cases of this kind generally that the skull, unnaturally small perhaps, is pinched up into a conical peak, and has considerable thickness. They are obviously hopeless cases. To the physiologist they are subjects of much interest ; for the practical physician they have none.

But in the majority of instances, when the infants survive their birth, the liquid is contained in the central cavities or ventricles of the brain, which are expanded into one. The convolutions are unfolded, and the cerebral matter is spread out into a hollow sphere ; the irregularities of the surface have disappeared ; the whole of the brain is smoothly extended in a thin layer, immediately beneath the bones and the membranes that connect them, and surrounds the inclosed liquid like a bag. Less frequently a different state of matters is seen. The liquid, instead of being included within the cerebral substance, lies in contact with the dura mater ; while the brain, perfect in all its essential parts, is at the bottom of the cavity. The difference, however, is more apparent than real : the two conditions are substantially the same, only that, in the one case, the solid parts that lie around the ventricles gradually expand as the fluid slowly collects, much as an air-balloon dilates in proportion as gas is introduced within it ; while in the other case the seams, or commissures (as they are technically called), that unite the hemispheres of the brain, give way, or are deficient, so that the ventricles and the general sac of the arachnoid form together one huge cavity ; the hemispheres are turned aside, or folded back ; the surfaces that naturally have a *central* aspect look *upwards*, and seem to constitute the summit of the cerebrum. This was the state of the parts within the immense skull from which the largest of the

casts before you was taken. It belonged to a man named Cardinal, who died in Guy's Hospital, in 1825, and of whom Dr. Bright has given a very interesting account.

Symptoms. — Now some of the consequences of this distension of the brain and skull with watery fluid are simply mechanical. The child is top-heavy. His large unwieldly head is too much for the muscles of his head to sustain without fatigue ; or even, when they are unassisted, to sustain at all. He walks gently and carefully, like a person balancing a heavy load upon his head ; or he holds and partly carries his head with his hands, as a milkmaid steadies and supports a pail ; or he reclines the weight of his burden upon the chair, or table, as he sits.

But far more important effects of the disease are those which relate to the three great functions of the brain. The child is soon found to be deaf, or blind ; or palsied in one or more of its limbs ; or idiotic ; or all these. In other words, the special senses, the power of voluntary motion, and the mental faculties, are apt to be defective or perverted. Instances, however, do occur, in which these functions are, for some time, but little deranged. The greater number of those who are afflicted with dropsy of the brain either recover or die during their infancy. Still, a few survive, bearing their complaint to the adult period, and even to old age ; and in some of these individuals who, with excessively large heads, have yet numbered many years of existence, the intellect and the senses, if not entire and perfect, have been sufficiently effective to answer the common wants and purposes of social life : the moral emotions strong, the feelings lively and correct, the memory tolerably retentive, the reasoning powers respectable. Dr. David Monro relates the case of a hydrocephalic girl, six years old, whose head measured two feet four inches in circumference. She is described by him as being " as lively and sensible as most of her age," and as " having a strong memory." Dr. Bright's patient, Cardinal, was nearly thirty years of age when he died. He was born in 1795. At the time of his birth, his head was only a little larger than natural : but it had a pulpy feel, as if it were almost destitute of bony matter. A fortnight afterwards, it began to increase rapidly ; and when he was five years old, it was but little less, according to his mother's account, than when he died. He could not walk alone till he was nearly six, and then only on level ground ; if he attempted to run, or to stoop, he fell down. He was sent to school when he was about six, and soon learned to read well and to write tolerably ; but writing he soon gave up, because, as he was near-sighted, it obliged him to stoop, which he could not

conveniently do. When a candle was held behind his head, or when his head happened to be between a spectator and the sun, the cranium appeared semi-transparent ; and this was more or less the case till he was 14 years old. About the age of 23, epileptic fits began to occur ; and after that, his health, which previously had been very good, failed somewhat. The ossification of the skull was not complete till two years before his death, the anterior fontanelle being the last part that closed. It has been mentioned that he was near-sighted ; but he was very quick of hearing, his taste was perfect, and his digestion good. Dr. Bright states that his mental faculties were very fair, and his memory tolerable ; but it was not retentive of dates. It was said that he was never known to dream. There was something childish and irritable in his manner, and he was easily provoked. He died, at last, of fever and diarrhœa. There were seven or eight pints of fluid within the cranium, in contact with the dura mater. On the base, or floor, of the skull lay the brain, with its hemispheres opened outwards, like the leaves of a book.

How comes it that the cerebral functions are thus sometimes fulfilled, or go on so well, when the machinery through which the mental powers are manifested—the instrument whereon and whereby the immaterial principle mysteriously operates—is so palpably and greatly deranged ? How comes it that life, and especially the life of the mind, subsists at all ? These questions open very interesting considerations. It would appear, from such cases as I have been referring to, that the curious arrangement and collocation of the several parts of the brain is rather a matter of convenient package than of necessary relation. The pulp which furnishes the medium of sense, and thought, and volition, is there, but it is disposed in an unusual shape. In neither of the two varieties of the malady that have been described as being compatible with prolonged existence, is there any necessary diminution of the cerebral mass. The brain itself, which forms a bag in the one case, and is split in halves in the other, has been found to weigh quite as much as a healthy brain at the same period of life. There has been no loss, therefore, of substance ; the pressure has been gradual, and it has not been made to act injuriously by counter-pressure ; no countervailing resistance has been afforded by the rigidity of the brain case : and thus the unopposed distending force neither causes absorption of the cerebral pulp on the one hand, nor, on the other, induces coma, or convulsions, or idiotcy, by its compression.

Most commonly, however, the mental

and voluntary functions are maimed or perverted ; and these serious calamities make parents look at a large head in a young child with anxious solicitude. But you are aware, after what I stated on this subject in the last lecture, that the head *may* be extravagantly large without dropsy of the brain and without disease.

We have just seen, that while the brain itself is gradually unfolded, or its hemispheres are parted and turned aside by the liquid accumulating within the cranium, the functions of the organ may suffer but little, so long as the yielding brain-case permits the expansion or separation of the nervous substance, without inordinate pressure. But as soon as undue pressure begins to be exercised, then morbid symptoms arise, or the defects that have previously shewn themselves are aggravated. Hence that period of life becomes a perilous period, at which the skull, by the closure of its fontanelles and sutures, loses its capability of farther expansion. In some rare cases the closed sutures reopen under the augmenting pressure, and a respite is thus obtained. Dr. Baillie has recorded an instance in which this happened in a boy seven years old. A similar case is mentioned in Dr. Yeats' work on hydrocephalus. The patient was a boy nine years of age. The sutures of his skull separated again after having been united ; and it was remarked that the teeth in the jagged edges, whereby the bones interlock with each other, were much fewer than is common. If this be always so when the sutures give way, it will serve to facilitate our understanding how such a phenomenon can take place. The skull may, however, go on expanding, although the sutures are permanently closed ; there still being left intervals between the several points of ossification, which intervals are covered by membrane only. The beautiful preparation on the table, shewing this remarkable state of the cranium, I have borrowed for your inspection from Dr. Sweatman's museum.

Indeed, although I have spoken of this complaint as being especially a disease of childhood, it does occasionally commence long after the skull has become a complete case of bone. Enlargement of the head, in these cases, is impossible ; but this circumstance, and the symptoms it is apt mechanically to produce, form the only differences between the disorder as it affects the child and the adult. In both cases disturbance of the cerebral functions arises, and at length convulsions and coma close the scene. In both a dropsical state of the ventricles of the brain constitutes, often, the only morbid change presented after death. A young and distinguished lawyer of my acquaintance had one or two attacks of rather sudden loss of consciousness, while

engaged in the Court of Chancery ; by degrees he became dull, stupid, forgetful, and, at length, insensible. In this condition he died. A large quantity of serous liquid was found distending the ventricles of his brain. No other alteration could be detected.

Dr. Baillie describes a case of chronic hydrocephalus that occurred in a man fifty years old. Six ounces of fluid were contained in the lateral ventricles. He had been paralytic on the right side of the body ; and for eleven months before his death had lost the recollection of his own language, with the exception of four or five words ; which he employed, with different intonations, to express his various wants.

The celebrated Dean of St. Patrick's afforded another instance of the same disease, attended with a similar interruption of the power of discoursing. The case, as related in Sir Walter Scott's *Life of Dr. Swift*, is curious, and contains an early suggestion of a piece of practice which in our own day has met with more favour. " A few days afterwards he sunk into a state of total insensibility, slept much, and could not without great difficulty be prevailed on to walk across the room. This was the effect of another bodily disease, his brain being loaded with water. Mr. Stevens, an ingenious clergyman of his chapter, pronounced this to be the case during his illness, and upon opening his head it appeared that he was not mistaken ; but though he often entreated the Dean's friends and physicians that his skull might be trepanned, and the water discharged, no regard was paid to his opinion or advice."

He remained from October 1742, to October 1745, in a state of silence, with few and slight exceptions ; and died in the 78th year of his age.

Gölis also mentions three instances in which this disease began in advanced life : two of the patients were above seventy years old ; the third, who was a physician at Vienna, likewise died in the decline of life, having suffered under the disorder for ten years.

Now, what can we do in these wretched cases ? Seldom much good, I am afraid. Yet something we must try, for parents will flatter themselves with hopes of a cure ; and to say the truth, there have been, under judicious management, a sufficient number of recoveries to forbid our despairing in any case, and to make it incumbent upon us to employ carefully all those measures which have occasionally brought the disease to a favourable termination. Gölis even affirms, that of the cases which began after birth, and which he saw and treated early, he was fortunate enough to save the majority.

LECTURES

ON THE

FUNCTIONS OF THE NERVOUS SYSTEM.

By W. B. CARPENTER, M.D.
Lecturer on Physiology in the Bristol Medical
School.

LECTURE III.

UPON reviewing all the anatomical facts
stated in the preceding lecture, it will be
perceived that ganglionic masses, characte-
rised by nuclei of grey matter, or of some-
thing equivalent to it, seem to be placed
wherever it is desirable that impressions
made upon the afferent nerves should excite
motions; and that, as we rise in the scale,
the number of centres possessing a diversity
of functions increases. We have seen that
sometimes these centres are, for the sake of
convenient disposition, united into one mass;
whilst, on the other hand, when the organs
are multiplied, they also are repeated to a
like extent, especially when it is desirable
that they should be able to act independently
of one another, as in the case of the suckers
of the cuttle-fish. It may further be re-
marked, that, wherever the presence of
special sensory organs, confined to one part
of the body, gives to that part a predominance
over the rest (the entrance to the alimentary
canal being always in this neighbourhood),
we find the ganglia with which they are con-
nected possessing a special relation with all
the rest, which these do not possess with
each other. It is obvious that, where visual
organs are developed, the impressions made
upon these will determine the movements of
the animal, more than those of any other
kind; and it would seem to be chiefly owing
to the information they communicate, that
the cephalic ganglion has such an evident
presiding influence over the rest, even when
smaller than any of them. This is, how-
ever, more the case in animals whose move-
ments are rapid, and in which, therefore,
the perception of distant objects is more
important—as in the insect tribes. Except
in the Cephalopoda, the subservience of the
nervous system to the nutritive functions of
the Mollusca is so great, that it might
almost be regarded as an appendage to the
digestive organs, destined for the selection
and prehension of aliment. But in the
more active members of that class, it derives
a more elevated character, from the develop-
ment of organs of special sensation and of
active locomotion.

A close relation may be traced between
the predominance of the cephalic ganglion,
and the evidence of the operations of sensa-
tion and volition, as manifested in the move-
ments of the animal. So long as food is

within its reach, we can scarcely regard the
prehension of it as an act of any higher
character than that of the infant when it
applies its lips to the nipple of the mother;
and this action is known (by observation of
acephalous monsters, and by experiments on
puppies, &c.) not to be dependent on the
presence of a brain, and may, therefore, be
regarded as not necessarily involving either
sensation or volition, although, in the perfect
state of the being, it is accompanied by the
former. But, when the animal has to exer-
cise its organs of special sensation, and to
put its general locomotive apparatus into
activity for the purpose of seeking its ali-
ment, its operations must be regarded as of
a higher order. Still, many of these may be
considered instinctive; that is to say, not
involving any reasoning powers, or any
notion of *purpose*, on the part of the animal
itself, but more analogous to those involun-
tary actions which result from the excite-
ment of the emotions in man. We may
take a well-known case in illustration—the
ejectment of the contents of the ink-bag
which takes place when the cuttle-fish is
pursued. This has been represented by
some as of a *voluntary* character, and as
indicating a *design* on the part of the animal
to conceal itself from its pursuers. But such
a supposition involves an amount of reason-
ing power on the part of the animal which
we can scarcely attribute to it; and, if the
action were not performed to as much ad-
vantage the *first* time as it might be on a
subsequent occasion, it would obviously be
of little use. It may rather be likened to
the expulsion of the contents of the rectum
and bladder under the emotion of fear, which
many of the human species (in their school-
boy days especially) know by experience to
result from an impulse uncontrollable by
the will. This view of its character is
strengthened by the fact that the secretion
of *ink* is really analogous to that of *urine.*

We shall now inquire how far these doc-
trines are applicable to the *Articulata.* The
animals composing this group all present, in
a more or less evident degree, a division into
segments, which have an obvious tendency
to resemble one another, as in the Radiata.
In the higher classes, however, this segmen-
tation is obscured by the modifications which
cause the different segments to assume dis-
similar forms and possess distinct functions;
whilst, in the lowest tribes, the soft texture
of the integument, as well as of the rest of
the body, prevents its manifestation. In
the intermediate groups, however, as in the
Myriapoda, it is very apparent; and here
we find a nearly perfect equality among all
the segments, with the exception of the one
which forms the head. In such, the nervous
system is merely a repetition of similar
parts, disposed, not in a circle as in the

Radiata, but in a continuous line. The most anterior of the ganglia, however, has an evident predominating influence over the rest, for the reason formerly specified; and this influence will be found, by comparison in other classes, to diminish with the loss, and to increase with the development of the faculties of special sensation which have their seat there. The locomotive powers are just as predominant in the Articulated series as are the nutritive functions among the Mollusca. Accordingly, we find the development of the nervous system to bear a special reference to them; and the sensori-motor divisions of it can be more distinctly separated from the portion which ministers to the organic functions.

Passing over the inferior groups, as affording no data of importance for physiological conclusions, we shall examine the nervous system as it exists in the *Myriapoda*. Here we observe a chain of ganglia running from one extremity of the body to the other, along the ventral surface, and in the median line. These ganglia are connected by trunks, which, on close examination, are seen to consist of two cords closely united. (In some of the Isopod Crustacea, in which the type of the nervous system is precisely the same, not only the longitudinal cords, but the ganglia upon them, are double through their whole length, being connected by a transverse cord in each segment.) The cephalic ganglion is bilobed; evidently consisting of two masses, which are united on the median line. These receive the nerves of the eyes and antennæ; but they are still of small size, in accordance with the low development of the sensory organs. The ganglia of the longitudinal cord are nearly equal, from one extremity of the body to the other. Each sends off nerves to its respective segment; and the branches proceeding from the different ganglia have little communication with each other. The highest of them, situated just beneath the œsophagus, is connected with the cephalic masses by two cords, between which that canal passes, encircled, as it were, in a ring. When we examine one of the ganglia of the ventral cord, and the nerves which seem to originate from it, we find that each nerve has three series of roots; one of which terminates, as in the other cases, in the grey matter of the ganglion itself; another interlaces with those of the opposite side; whilst the third is *continuous* with a *fibrous* portion of the cord, which may be traced uninterruptedly to the cephalic ganglia. When the structure of the cord itself is analysed, it is seen that the fibrous tract or column is throughout distinct from that which contains the ganglionic enlargements; and that it does not contribute towards the formation of

these, but passes over them (as was first observed by Mr. Newport,) like the analogous trunk in the arms of the cuttle-fish.

After what has been said of the offices which the ganglia perform in the Mollusca, and of the relation which they bear to the cephalic mass, we shall have little difficulty in understanding the character of the nervous apparatus in the Articulata, if our minds be unoccupied by any preconceived notion. When we examine into the actions of the ventral cord, we perceive that those of all its ganglia are similar to each other; being related only to the movements of their respective segments, and of the members which belong to them. In fact, these ganglia may be regarded as so many repetitions of the *pedal* or locomotive ganglion of the Mollusca. It is easily proved that the movements of each pair of feet may be produced by that ganglion alone with which it is connected; since a single segment, isolated from the rest, will continue to perform these movements for some time, under favourable circumstances. If an earthworm be cut in two, whilst crawling, each portion will continue to advance, though the anterior one only will permanently preserve its vitality. If a centipede be divided into several portions under the same circumstances, each will execute motions of progression for some time. But it is evident that these must be placed, in the living animal, under some general control, by which the consentaneousness of action that is essential to regular locomotion may be produced. This is easily proved by experiment. If in a Mantis, for example, the nervous cord be divided between the first and second thoracic ganglia, so as to isolate the ganglionic centres of the posterior legs, the limbs will continue to move energetically, but not with a combined object, and no progression will take place. We can scarcely account for the exercise of this general control, otherwise than by attributing it to the fibrous tract, which connects each of the nervous trunks immediately with the cephalic ganglia, as in the Mollusca; and this must, therefore, conduct to the sensorium (whose seat is probably in these) the impressions which there produce sensations, and convey downwards the locomotive impulse; whilst the ganglion of each segment, with the filaments proceeding from its nucleus, will form the circle necessary for the simply reflex actions of its members.

The independence of the segments, as far as their reflex actions are concerned, and their common subordination to one presiding centre of the will, are fully explained on this supposition. It is also quite conformable to the analogy both of the Mollusca and of Vertebrata. We have seen that, in the former, where the ganglia are more isolated

from one another and from the presiding centre, each appears to be the centre of simply reflex actions occurring in the organ with which it is connected; but that a part of the nervous fibres which seem to enter it really pass on to communicate with the cephalic mass, where alone, it may be surmised, *sensations* can be felt, and *voluntary* impulses excited. And on the other hand, in Vertebrata, we find the ganglionic or mixed portion of the spinal cord, and the simply fibrous tracts, performing functions respectively analogous; for, when any segment is isolated from the rest, reflex actions may be excited through it, in the production of which the white columns can scarcely participate, being structurally distinct from each other, and from the ganglionic portion of the cord, and continuous only with the fibrous portion of the brain; whilst pathology supplies us with numerous instances of the converse proposition, namely, the destruction of the ganglionic portion, without the functions of the parts below being impaired,— *their* ganglionic portion being segmentally independent, and their communication with the brain being maintained by a continuity of white or fibrous structure.

The number and variety of the reflex actions which take place in the Articulata after decapitation, is very remarkable; and they seem to have a consentaneousness proportioned to the closeness of the relation between the nervous centres in the respective species. Thus, in the Scolopendra, we find the ganglia of each segment distinct, but connected by a commissural trunk. Here an impression made *equally* upon the different nerves of *all* the ganglia, will produce a consentaneous action. Thus, if the respiratory orifices on one side of a decapitated Scolopendra be exposed to an irritating vapour, the body will be immediately flexed in the opposite direction; and if the stigmata of the other side be then similarly irritated, a contrary movement will occur. But different actions may be excited in different parts of the cord by the proper disposition of the irritating cause. In the higher classes, however, where the ganglia of the locomotive organs are much concentrated, the same irritation will produce consentaneous motions in several members, similar to those which the unmutilated animal performs. The *Mantis religiosa*, for example, ordinarily places itself in a very curious position, especially when threatened or attacked, resting upon its two posterior pair of legs, and elevating its thorax and the anterior pair, which are armed with powerful claws. If the anterior segment of the thorax, with its attached members, be removed, the posterior part of the body will still remain balanced upon the four legs

which belong to it, resisting any attempts to overthrow it; recovering its position when disturbed, and performing the same agitated movements of the wings and elytra, as when the unmutilated animal is irritated. On the other hand, the detached portion of the thorax, which contains a ganglion, will, when separated from the head, set in motion its long arms, and impress their hooks on the fingers which hold it. These facts prove unequivocally that the instinctive movements of these parts, which are performed in direct respondence to external impressions, require only for their stimulation the ganglionic centre with which the nerves that excite them are immediately connected. Another instance, related by Burmeister, is still more satisfactory in regard to the manner in which these movements are excited. A specimen of the *Dytiscus sulcatus*, from which the cephalic ganglia had been removed, and which remained in a motionless condition whilst lying with its abdomen on a dry hard surface, executed the usual swimming motions, when cast into water, with great energy and rapidity, striking all its comrades to one side by its violence, and persisting in this for half an hour.

Without describing in minute detail the forms which the nervous system presents in the higher classes of Articulata, or tracing that interesting series of changes which it undergoes during the metamorphosis of in-

Fig. 7.
Fig. 7.—Nervous system of Larva of Sphinx Ligustri; after Newport.

sects, a few particulars may be stated on these subjects, as having an immediate bearing on our present object. The nervous system of the Larva, like that of the Annelida, or Myriapoda, presents an obvious relation with the means and extent of locomotion possessed by the animal. Each segment (in general at least) possesses a pair of legs; and with each is associated a *pedal* ganglion. None of the movements of the animal (in those tribes which undergo a complete metamorphosis, to which this description more particularly applies,) are very energetic; simple and slow progression is all for which its structure is adapted; and the uniformity in the actions of its legs would render it easy to combine them at the will of the animal, even though their respective centres remain so much isolated from one another. But, in the perfect insect, the whole locomotive apparatus is concentrated in the thorax. The six legs (which are now all that remain), and the single or double pairs of wings, are all developed from its three segments; and a much greater variety of action is required, as well as more complete consentaneousness, on account of the increased number and velocity of the movements of the animal. We accordingly find

FIG. 8.

FIG. 8.—Nervous system of Imago of Sphinx Ligustri.

that the ganglionic matter of the ventral cord of perfect insects is more or less concentrated in the thoracic region; whilst the ganglia of the abdomen are usually few and small; the nerves to its segments, however, being given off as before at regular intervals. In some of the Coleoptera and Hemiptera, the concentration of the thoracic ganglia takes place to such an extent, that they seem to form but one mass; and this is the case also

among some of the Crustacea, the different forms of whose nervous system are exactly parallel to those of their congeners among the inhabitants of the air and land. The nerves which supply the wings of insects are found, in all stages of the development of these organs, to have a double origin. One root arises from the fibrous tract alone; whilst the other takes its origin from both tracts at the point of enlargement. When the ganglionic centres which supply the anterior and posterior pairs of wings remain distinct, there is a curious plexiform arrangement of their nerves, more or less intricate, according as the wings are destined to act with greater or less consentaneous energy, and absent when the anterior pair serve only as elytra, and do not assist in flight. This would remind us of the circular filament which was seen to connect the nerves of the arms in the naked Cephalopoda. Besides these nerves, the wings are supplied from the respiratory system next to be described, from which scarcely any branches go to the legs. This will be readily understood, when it is considered that the wings are developed, as it were, out of an extension of the respiratory apparatus*, and that its actions are closely connected with these movements.

Hitherto we have spoken only of that division of the nervous system of the Articulata which may be regarded as corresponding with the sensory and locomotive ganglia of the Mollusca; namely, the cephalic, the pedal, and (in some instances) the palleal. We have next to inquire what we find corresponding with the branchial ganglion. It is to be recollected that the respiratory apparatus of insects is diffused throughout the whole body, so that its presiding system of nerves must be proportionally extended; and we are, therefore, prepared to find the *branchial* ganglion of the Mollusca repeated, like the pedal, in each segment. Besides the nervous trunks given off from the ventral cord at its ganglionic enlargement, we find, in most of the Articulated classes, a series of smaller

FIG. 9.

FIG. 9.—Portion of nervous cord in the thorax of the Pupa Sphinx. A, B, ganglia of the cord; the connecting trunks between which, being separated widely, show, *a*, the respiratory ganglion; *b, b*, its nerves.

* See Principles of General and Comparative Physiology, p. 308.

nerves, given off at intermediate points, without any apparent swelling at the points of divergence. The connections of these are most distinctly observed in the perfect insect, whose respiratory system is developed more extensively than that of any other animal. It is seen, on a close examination of the ventral column, that a third tract exists on the superior or visceral aspect of the cord; and that these nerves are given off from minute ganglionic enlargements upon it. This tract seems to be quite unconnected along its whole course with the column upon which it lies. Its nerves, however, communicate with those of the sensori-motor system; but they have a separate distribution, being transmitted especially to the trachea, on the parietes of which they ramify minutely, and also to the muscles concerned in the respiratory movements. The latter, however, being a part of the general locomotive apparatus, are also supplied from the principal ganglionic column. These transverse or superadded nerves do *not* supply the muscles which open and close the stigmatic orifices of the trachea; and this might be thought inconsistent with the supposition that they are especially concerned in the respiratory function, if it were not recollected that the closure of the stigmata is an action more connected with the voluntary movements of the animal than with the mechanism of its aeration; it being in this manner that it prepares itself for flight, or for any other powerful exertion. These superadded nerves, then, which are evidently analogous to those of the gills and siphonic apparatus in the Mollusca, may be regarded as corresponding with the pneumonic portion of the par vagum in Vertebrata—which is in like manner distributed on the airpassages, and with its associated motor nerves. In comparing the nervous system of Insects with that of the higher Mollusca, it will be seen that they differ more in the relative proportions, and in the arrangement of their parts, than in their absolute character. In both there is a cephalic division of the ganglionic centres, in which sensibility and voluntary power appear to reside more particularly, if not entirely. In both there is a division specially appropriated to the locomotive apparatus, differing only in the multiplication of the centres in Insects, conformably with the arrangement of the members they supply; and sometimes, as we have seen, consolidated to nearly the same degree as in the Cephalopoda. In both, also, we find a division appropriated to the respiratory apparatus, in which there is a corresponding multiplicity of centres in the Articulata, in harmony with the universal distribution of their tracheal system. And in both, as we shall now see, there is a separate system of nerves, distributed to the alimentary appa-

ratus, and supplying the organs of mastication (with the salivary glands), deglutition, and digestion.

Of the *stomato-gastric* system, some traces may be found in nearly all the Articulated classes. Thus, in the leech, we find a minute ganglion existing at the base of each of the three teeth which form the mouth; these ganglia are connected together, and, to the cephalic, by slender filaments; and they seem also to be in connection with other filaments, which may be traced on the alimentary canal. As a specimen of its highly developed form, we shall take that which is described in the *Gryllotalpa vulgaris* (common mole-cricket). Here we find

Fig. 10.
Fig. 10.—Stomato-gastric system of *Gryllotalpa*. A, A, cephalic ganglia; *a*, anterior ganglion; *b, b*, and *c, c*, posterior lateral ganglia; *d, d*, cœliac ganglia.

it consisting of two divisions; one placed on the median line, which may hence be called the *median* system; the other running on each side at some little distance, and hence called the *lateral* system. The median system appears to originate in a small ganglion,

situated anteriorly and inferiorly to the cephalic mass, with which it communicates by a connecting branch on each side.   From this ganglion, nerves proceed to the walls of the buccal cavity, the mandibles, &c.   Its principal trunk, however, (the *recurrent* of authors) is sent backwards beneath the pharynx ; and on this a slight ganglionic enlargement is seen, where the connecting branches are given off, which unite it with the lateral system.   Its ramifications are distributed along the œsophageal tube and dorsal vessel; whilst the trunk passes down-wards to the stomach, where its branches inosculate with those supplied by the lateral system, and seem to assist in forming a pair of small ganglia, from which most of the

FIG. 11.
FIG. 11 —Stomato-gastric system in the Sphinx. A, A, cephalic ganglia; *a*, anterior median ganglion ; *b, b*, lateral ganglia.

visceral nerves radiate.   The ganglia of the lateral system are two on each side, lying behind and beneath the cephalic masses.   The anterior pair are the largest, and meet on the median line, just behind the cephalic ganglia, with which they communicate. Posteriorly to these lie the second pair, which are in connection with them.   Two cords pass backwards on each side, one derived from the anterior, the other from the pos-terior, of these ganglia.   They run along the sides of the œsophagus and dorsal vessel ; and, after inosculating with the branches of the central system, enter the two cœliac ganglia, from which branches radiate to the abdominal viscera.

This system of ganglia and nerves has an evident affinity with the *sympathetic* system of Vertebrata, as well as with some parts of the cerebro-spinal system, more especially with the par vagum.   It is to be remembered that the pneumogastric nerve of Vertebrata is distributed to three separate systems—the respiratory, the circulating, and the digestive.   As we know that the ultimate fibrils of nerves never anastomose, there can be no doubt that these branches might be separately traced backwards into their ganglionic centres ; and they may thus be regarded as *functionally* three distinct nerves.   There is no difficulty, then, in understanding that the respiratory system of insects and other Invertebrata may be analogous with the pneumonic portion of

the par vagum, although it bears no relation with the cardiac and gastric divisions of the nerve.   To these divisions the analogy of the recurrent nerve becomes sufficiently plain, when we look at its distribution upon the dorsal vessel, œsophagus, and stomach ; but its commencement in the anterior ganglion, which also supplies the mouth and pharynx, might seem to place it on a different footing, until we have determined the true analogy of this last centre.   It may be inferred from its situation, and from the distribution of its nerves, that this anterior is analogous both to the labial and pharyngeal ganglia of the higher Mollusca.   These appear to form a division of the nervous system, by which the actions *immediately* concerned in the pre-hension of food are performed, almost as independently of the cephalic ganglia as are those of respiration.   There would seem, however, a greater tendency towards the union of *these* centres with the œsophageal collar, than of those presiding over the re-spiratory function, which is more indepen-dent of the will ; and accordingly we find the *labial* ganglia apparently united with the cephalic in most of the Gasteropoda, whilst the *pharyngeal* forms part of the subœso-phageal mass in the Nautilus.   The division of the nervous system of Vertebrata with which this stomato-gastric system corre-sponds, is a question of more apparent diffi-culty ; but if we bring into comparison not only the highest but the lowest forms of the cerebro-spinal apparatus, the chief difficulties will be removed.   The analogies drawn from the distribution of the nervous branches would lead us to infer that the *third* division of the fifth pair (including its sensory and motor origins) the glosso-pharyngeal, and the gastric portion of the par vagum, would most nearly represent it.   Now, when the fifth pair is traced back to its true origin, it is found to be not a cerebral but a spinal nerve ; and it is then seen to arise from the medulla oblongata, in such close approxima-tion with the par vagum and glosso-pharyn-geai, as to show that, if this portion of the nervous centres were isolated from the rest, the nerves which proceed from it would form, anatomically as well as functionally, a natural group.   The fifth pair, like other spinal nerves, may act in a simply reflex character ; although, in man, it is usually under the dominion of the will.   In the lower animals we find these reflex actions bearing a much larger proportion to the voluntary, than in man ; and even in him we not unfrequently meet with cases in which the functions of the cerebral hemispheres seem suspended, whilst those of the spinal cord are unimpaired ; so that the prehension of food by the lips may take place without any effort of the will.   This has been ob-served in acephalous fœtuses, in puppies from

which the brain has been removed, and in profound apoplexy. Further, the connection between the fifth pair and par vagum is very intimate in Fishes, the class which approaches nearest in the character of its nervous system to the Vertebrata. We may reasonably infer, then, that the anterior ganglion is the principal centre of the reflex actions of the nerves which correspond to the third branch of the fifth pair, the glosso-pharyngeal, and the gastric portion of the par vagum in Vertebrata; whilst the branches which connect them with the cephalic ganglia bring these nerves more or less under the influence of the latter.

The *lateral* ganglia seem more analogous to the centres of the sympathetic system in Vertebrata; especially in the connection of their branches with all the other systems of nerves; and in the share which their branches have in the formation of the cœliac ganglia. This view of the relative functions of these two divisions of the stomato-gastric system, is strengthened by the fact, that the connection between the sympathetic system of Fishes and the par vagum is much more intimate than in the higher Vertebrata; although, even in the latter, as will be hereafter shown, it is by no means so slight as it appears.

There is an interesting variety in the conformation of the median division of the stomato-gastric system in some Crustacea, which shows its tendency to approximate with that which may be regarded as the analogue of the cerebro-spinal axis. In the *Astacus fluviatilis*, (cray-fish), for example, we find no separate anterior ganglion existing; but it seems replaced by two small ganglionic enlargements of the cords or peduncles which unite the cephalic ganglia with the first thoracic. From these proceed the branches which supply the mouth and muscles of the jaw, as well as others that unite with a median branch proceeding from the cephalic ganglion to form the recurrent trunk, which is distributed upon the œsophagus and stomach, where it presents one or two minute ganglionic enlargements. It is evident that the small ganglia upon the peduncles of the cephalic mass correspond exactly with the division of the medulla oblongata, from which the fifth pair and the par vagum are given off; so that the analogy, which has been previously drawn, would seem by this structure to be fully confirmed.

From the foregoing details, regarding the nervous system of the Articulata, it would, therefore, appear that the inferences which were drawn from the examination of its character in the Mollusca are fully applicable to the physiological explanation of its structure in this division of the animal kingdom, and thus derive important confirmation from

its phenomena. It has also been seen that the study of the arrangement of the parts of the nervous system in Mollusca may be most advantageously pursued before that of the Articulata is entered upon; since the great variety in the disposition of the different systems in that group, the isolation of their nervous centres, and the transposition and recombination of these in so great a variety of ways, affords us the key to their real character, which may be effectually applied to the elucidation of the more complex apparatus of Articulata*.

Upon taking a general review of the facts which have been stated, and the inferences which have been erected upon them, we perceive that between the strictly sensorial functions of the nervous system, and those operations in which its *internuncial* character only is employed, a tolerably distinct line of demarcation may generally be drawn. We have hitherto viewed this apparatus under two aspects :—1. As the instrument of the mind, by which it acquires a knowledge of the external world through the medium of sensation, and operates upon it by an exercise of volition. 2. As the means by which various movements are excited in the bodily structure, which are immediately necessary to the performance of the organic functions, and to its protection from injury. To these actions the general term *instinctive* may be given; that term being understood to imply the performance of a motion, or series of motions, *in direct respondence* to external impressions, *without the intervention of the will*, without any designed adaptation to purpose on the part of the animal, and often without its consciousness being necessarily affected. The first of these objects appears to be answered, chiefly if not entirely, by the cephalic ganglia, and the nerves proceeding from them. The second is carried into effect by the ganglia connected with each organ, or series of organs, whose movements are thus excited. We have seen, that, however small is the bulk of the cephalic ganglia compared with the sum of the other masses, these send nerves to every part of the body supplied by the latter; for the purpose, it would seem, of controlling, harmonizing, or antagonizing their actions. These nerves proceed as connecting trunks from the cephalic ganglia to the other cen-

* The view given above of the comparative structure and offices of the nervous system in the Invertebrated animals, is chiefly abridged from the author's Prize Thesis on this subject, in which additional details will be found, as well as many other illustrative figures and references to authorities. He has there, also, discussed the physiological explanation usually given of the double nervous cord of the Articulata; and having shown that it is neither consistent with itself, nor capable of being applied to the other Invertebrata, he has deemed it unnecessary to complicate the present sketch by introducing it.

tres ; and then divide into filaments, which unite with those proceeding from them to the several organs. Each organ, therefore, receives four sets of fibres ; an afferent and efferent set, which connect it with the cerebral ganglia, and are the channels of sensation, and of the influence of the will ; and an afferent and efferent set, which connect it with its own peculiar ganglion, and serve to convey the stimulus of impressions which produce motions by reflected influence. In proportion as the special sensory organs are developed, and the animal is less completely governed by *mere* instinct, we find the cerebral ganglia and system of nerves more predominant. We observe among the Articulata the greatest perfection of instinctive movements any where exhibited. In these movements there is a most remarkable adaptation of means to ends ; as in the construction of habitations by various insects, and especially the social Hymenoptera. But few persons will agree that this adaptation is performed by the mind of the animal ; since, on this supposition, every bee solves a problem which has afforded scope for the laborious inquiries of the acutest human mathematician. The adaptation is in the original construction of a nervous system, which should occasion particular movements to be performed under particular external conditions ; and the constancy with which these are performed by different individuals of the same species, when placed in the same conditions, leads at once to the belief that they must be independent of any operations so variable as those of judgment and voluntary performance. On the other hand, in the Vertebrata, we find the purely instinctive movement forming a smaller proportion of the whole actions, and brought under a more complete subjection to the sensori-volitional system. This is evident from the greater variety which the actions exhibit ; from the mode in which they are adapted to peculiar circumstances ; from the degree in which they may be modified by education ; and from various other indications of a superior kind of intelligence. At last, in man, those instinctive movements which are not immediately requisite (like those of respiration) for the maintenance of the organic functions, are placed under the control of the will. This is especially true of the locomotive organs, whose reflex actions are entirely guided by the will ; and they are only distinguishable when, from peculiar states of the system, the influence of the brain is suspended.

There is a *third* aspect, however, under which we are to consider the nervous system ; and this becomes more important in the highest division of the animal kingdom, on which we are now about to dwell. We have

hitherto spoken only of its influence on the contractile properties of the tissues to which it is distributed. It has, however, an important and direct connection with the purely organic functions of nutrition and secretion ; and we shall see reason to regard it as the means, not only of placing the *animal* in relation with the external world, but of harmonizing and controlling the organic changes taking place in its own structure, and of bringing these under the influence of particular mental conditions. It is the opinion of many, that all the organic functions are *dependent* upon the innervation supplied to them by the system of nerves which has been termed *sympathetic* or *visceral*. It is incumbent, however, on those who uphold the necessity of this nervous power, to prove it definitively, since all analogy leads to an opposite conclusion. We may regard the capability of separating from the blood a peculiar secretion, as a peculiar property inherent in the glandular membrane, just as contractility is the inherent property of muscular fibre. As the peculiar arrangement of the excitable and contractile tissues in animals requires a nervous system to act as a conductor between them, and to blend their actions, so do the complicated organic functions of animals require to be harmonized and kept in sympathy with each other, by some mode of communication more direct and certain than that afforded by the circulating system, which is their bond of union in plants. We have seen, in the foregoing sketch, that the visceral system does not exist in a distinct form in the lower classes of Invertebrated animals ; and also that the nervous system of these classes cannot, as a whole, be compared with it, although it may be regarded as containing some rudiments of it. As the divisions of this system become more evident, however, and the organic functions more complicated, some appearance of a separate sympathetic system presents itself, as in Insects and Cephalopoda ; but this is never so distinct as in Vertebrata. Hence it may fairly be inferred that, as the sympathetic system is *not* developed in proportion to the predominant activity of the functions of organic life (which is so remarkable in the Mollusca when contrasted with the Articulata), but in proportion to the development of the higher divisions of the nervous system, its office is not to contribute to these functions any thing essential to their performance, but rather to exercise that general control over them which becomes necessary according as they are more independent of one another, and to bring them into relation with the system of animal life.

ON HIP DISEASE AND LUMBAR ABSCESS.

By Wm. Oliver Chalk, Esq.

Resident Surgeon to the Royal Sea-Bathing Infirmary, Margate.

[Continued from p. 831.]

(For the Medical Gazette.)

The difficulty of effecting a satis- factory diagnosis amongst children is often very great, especially as their fears are usually excited by the ex- amination, which it is always necessary to conduct with the greatest attention, before we can determine whether the symptoms are those of lumbar or hip disease.

The case of Richard Bridge, æt. 6, is one in which I experienced this difficulty ; and as it is interesting I will relate it. He was admitted as an out- door patient, July 26, 1836. He had been treated according to Mr. Scott's plan. On removing the bandages, plaster, &c. the nates appeared slightly flattened. He did not complain of any pain on pressure. Percussion over the trochanter, rotation, flexion, and exten- sion, seemed to cause no inconvenience. He walked on crutches, but was able to do without them. His general health was delicate ; the upper lip rather thickened ; the tongue slightly furred ; pulse quick and feeble ; his appetite tolerably good. He complained of slight tenderness in the hepatic region. The symptoms commenced in the pre- ceding April, when he was first observed to limp ; but did not suffer much in- convenience in other respects.

As the case seemed to present no very urgent symptoms, I determined to try the effect of change of air and bathing. He began with the warm bath three times a week, and on July 30th commenced the use of the douche. He continued this plan up to Sept. 3rd, without any apparent change in his health or in the local affection. I then began an alterative treatment with mild doses of hyd. c. creta at bed-time, together with infusion of cinchona and iodide of potassa. This was preceded by the application of a few leeches, and a blister to the epigastrium. Under this plan his general health improved, his appetite increased, the tongue cleaned. These remedies were per- severed in until October 15th, when I

was suddenly called to see him. He was suffering great pain in the hip and knee, which was aggravated by any attempt at motion. The limb was everted, and lengthened to about two inches. Of this there could be no doubt, as the trochanter, knee, and ankle-joints, were considerably lower than those of the sound limb. The case continued to go on badly up to the time of his departure, in December following. By this time his sufferings had become intense : he lay with the limb extended, and the hand grasping the thigh just above the knee. His rest was broken ; he slept at short intervals only, and awoke starting and screaming. Hectic fever was at its height, and the patient appeared to be fast sinking. He died, I believe, soon after his return home.

It seems to me highly probable that the timidity of the child, which was always great, must have induced him to conceal whatever suffering he en- dured, for it is hardly possible to sup- pose that there was none prior to the lengthening of the limb; yet the person who had charge of him said that he never complained. There can be lit- tle doubt that the sudden elongation of the limb was owing to the destruc- tion of the ligamentum teres. The flattening of the nates which took place after this occurred was most remarka- ble, and it was rendered more so by its having been very slight before that time. As it is a matter of the greatest importance to determine the symptoms which characterise affections of the hip, especially at their commencement, I shall endeavour to point out those which appear to me most worthy of attention.

The patient at first experiences slight pains in the articulation, sometimes extending to the front of the thigh, during and after walking ; these be- coming more severe and continuous as the disease advances. He is apt at this time to stumble; gradually, limping ensues; and then the peculiar mode of resting the limb already spoken of, by throwing the weight of the body on the sound one, giving rise to the cant- ing of the pelvis and flattening of the nates. If at this time percussion, rotation, flexion, and extension, be used, pain generally follows. I have always observed, that whenever flexion of the limb is attempted, it causes more suffer-

ing than any of the former means, except perhaps percussion. There is no alteration as yet in the state of the femur, and the great trochanter retains its natural situation and form. The patient is always easier when lying down, but the sleep is disturbed and broken by frequent startings. This arises from the pain excited by the endeavour to alter the position of the limb whilst in a state of unconsciousness, and it is one of the most distressing symptoms, both in the earlier and latter periods of morbus coxæ. In the second stage, we have either shortening or lengthening of the limb, and a hard circumscribed fulness of the nates* ; but it must be acknowledged that the latter symptom is less frequent than the others. When, however, suppuration has taken place within the cotyloid cavity, and the matter has found an exit, this appearance is very common. It is at this time, and when the disease is far advanced, that pain in the knee is commonly present. It has been supposed by some that dislocation of the head of the femur on the dorsum ilii takes place through the action of the muscles when the cavity of the joint is destroyed. But that this cannot be the case, must be very apparent when we consider that the muscles themselves, and the soft parts generally, are by this time involved in the destruction.

I am inclined, for my own part, to believe, that at this stage the simple circumstance of the patient's moving himself in bed, or being moved by others, or some cause equally slight, may displace the femur from its situation. Mr. Stanley, in an interesting paper lately read at the Royal Medical and Chirurgical Society, gives instances of the head of the femur becoming dislocated, even when paralysis of the muscles existed. The two following cases are very interesting, chiefly from the circumstance of shortening of the limb without dislocation of the head of the femur. The first was that of Mary Anne Fraser, æt. 9, admitted May 13th, 1837, suffering under the following symptoms :—

Enlargement of the liver and conse-quent ascites, dyspnœa and constant cough, accompanied by muco-purulent expectoration ; pulse quick and feeble, great thirst, loss of appetite, alvine excretions unhealthy. The left hip joint was diseased, the limb shortened and turned inwards. She lay with the knee flexed, resting it on the sound one. There was a hard circumscribed tumor immediately over the articulation, and two openings, one near the usual situation of the great trochanter, and another about the middle and external part of the thigh, through which was discharged a profuse and unhealthy pus. The parts were highly sensitive, and she suffered constant pain, which was dreadfully acute on pressure or motion. The state of the patient was such that I felt it was useless to make any particular examination of the parts. From the copious discharge and constant pain in the hip and knee, and the position of the limb, I was inclined to regard the case as one of lumbar origin, and of consecutive disease of the joint. (This supposition, however, it will be seen was erroneous.) It was evident that the local and general symptoms were too far advanced to admit of any hope of recovery or alleviation. She lingered on until the 22nd June following, on which day she died.

On examination, I found the cotyloid cavity enlarged, and in a state of gangrenous softening. The head of the femur was completely destroyed; its neck was bent at right angles with the great trochanter, so that the latter was considerably higher than natural, while the former descended, as it were, into the cotyloid cavity. The soft parts in the vicinity of the joint were entirely destroyed. The altered situation of the neck of the femur and the trochanter gave rise to the shortening observed during life. Strong pleuritic adhesions existed on the left side of the chest. Many of the bronchial tubes were ossified or in a semi-cartilaginous state, and choked up with muco-purulent fluid, such as had been expectorated during life. There were several small ossific deposits in the parenchyma of the lungs. The pericardium contained about 4 ounces of fluid; the quantity that existed in the abdomen was not large. The liver was enlarged and indurated; the gall-bladder small, and containing little bile ; the spleen was small and indurated, as was likewise the pancreas. Abscess had formed in the pelvis of

* It is necessary to pay particular attention to this latter point, for, as will be shown hereafter, fulness of the nates commonly ensues when pus (following the course of the psoas muscle) insinuates itself among the interspaces of the muscles attached to the joint—thus giving rise to a soft fluctuating swelling.

DEATHS.

MORBUS COXÆ.				LUMBAR ABSCESS.								
Males.			Fem.	Males.					Females.			
1827	5—10	10—15	15—20	5—10	5—10	10—15	15—20	30—35	40—45	5—10	10—15	15—

one of the kidneys. There were several small ossific depositions found in different parts of the abdomen.

Henry Eagle, æt. 6, admitted May 29th, 1838, suffering under morbus coxæ on the left side. The limb was shortened and turned inwards; hard and circumscribed fulness of the nates; does not complain of great pain. Percussion, however, over the articulation causes much suffering. He walks on crutches: his health is delicate. This boy was suddenly attacked with cerebral symptoms, which proved fatal five days after their commencement. He died July 26th.

The head of the femur was expanded in its socket by the deposition of tubercular matter in the cancellous structure of the bone. The neck of the femur and the trochanter were in a similar condition to that of Fraser's. The fulness of the nates was formed by the latter, and was situated rather higher up than in the other case. The capsular ligament was entire. On examining the head, the dura mater was found in some places adherent to the subjacent membrane. The substance of the brain was softened*. A small quantity of serum was effused at the base of the cranium. Strong pleuritic adhesions were observed on the right side of the chest; the left lung was studded with tubercles in their miliary form. The left ventricle of the heart was hypertrophied; the valves of the aorta were highly inflamed, as were also the mitral. The liver was indurated.

Explanation of the Table.—It will be seen, on referring to the table, that the cases of hip disease and lumbar abscess are each divided into three distinct parts; and that from the year 1833 to 1838 the number of hip cases had considerably decreased, whilst those of lumbar abscess, during the same period, had increased. As I formerly stated, that from the year 1827 to 1832 I considered the diagnosis of these respective diseases defective, I have subdivided the table, for the sake of comparison, into periods of six years: the remaining two years, 1839 and 1840, are therefore necessarily separated from it.

The inferences to be drawn from it are by no means devoid of interest;

and it may fairly be considered conclusive on the point (concerning which authors have differed), that the male sex is most prone to these diseases. It will be seen, in both instances, that the males exceed the females. Morbus coxæ: males, 200; females, 131; making a total in favour of the former of 69. Lumbar abscess: males, 157; females, 89; giving a difference in favour of the males of 68*. On running the eye down the columns, it will be seen that children of both sexes suffer most from these disorders from the ages of five to ten. As these diseases are commonly the result of accident, it will follow as a matter of course that males, from being more exposed to the chances of casualties than females, must naturally suffer the most from them. I have never myself entertained any doubt on this subject; but, whatever may be the cause, the fact of males being more prone to these complaints than females, seems incontrovertible.

It will be seen, on reference to the table of deaths, that they are very few compared with the number admitted. From a calculation which I made four or five years since, the average stay of each in-door patient was a little more than twelve weeks, whilst that of the out-door scarcely exceeded ten. Many of the cases returned to the Infirmary during several successive seasons: I have purposely avoided a repetition of them, as they would not have increased the value, but merely added to the bulk, of the table.

STAMMERING.

To the Editor of the Medical Gazette.

Sir,

Several friends who have been aware of the success which, for the last six months, I have had, in curing stammering by surgical operation, have called my attention to paragraphs which have appeared in various newspapers on that subject, by which it is made to appear a still more recent discovery of others. About six months ago my attention was first drawn to this sub-

---

* Cerebral disease is by no means uncommon in the latter stages of scrofulous disease, and the brain is generally in some part, or occasionally throughout the whole of its substance, in a state of ramollissement.

* The number of patients admitted from the year 1827 to 1840 are as follows:— Males, 4092; Females, 3662: making only a difference of 430 in favour of the males,—which, if divided among the various maladies from which they suffered, the number would still be too small to affect the statement.

ject particularly, from several patients, who were severely affected with this malady, applying to me. Up to that time I had considered it to be a nervous affection, or an acquired habit, to be overcome by constitutional treatment, and particular attention in the use of the vocal organs. Amongst the number of patients who daily consulted me, I had found so many other complaints, generally considered incurable, to be amenable to surgical treatment, that the idea occurred to me that stammering might possibly arise from some physical defect, and be capable of being relieved by surgical operation; and I therefore directed my attention to the examination of these patients with this view. I very soon discovered that stammering was associated with a rigid state of the tongue in the majority of instances, which would naturally prevent the free and prompt action of the epiglottis required for permitting or restraining the passage of air through the glottis in the quantity necessary for a free and correct enunciation. The free division of the fraenum appeared to me to be the most easy and natural mode of relieving this, and I operated accordingly. The effect of the operation was the instant removal of the complaint, and which, being so evident to a number of other patients who were present at the time, their report of this success induced others to apply to me, so that I have had two or three patients in succession undergoing the operation; and, of the scores of cases I have had, I think there have not been more than one or two which have not been benefited, whilst most have been entirely cured. Although division of the fraenum will succeed in many cases, it will not in all, but may be rendered efficient in such cases by a farther division at the symphysis of the lower jaw. Other cases I found to depend on an obstruction to the free motion of the tongue, and especially to its permitting the free opening of the glottis; not from its being bridled down, but to its being pressed down by enlargement of the tonsils—a disease which I have known go so far as to cause not only stammering, but inability to articulate a single word distinctly, and at the same time producing deafness by pressing upon the eustachian tubes. All these defects I have found instantly to be removed by excision of the enlarged

tonsil or tonsils. I had a most interesting case of this kind, which I operated upon on the 7th of October last, which remains perfectly well to this time. With the instrument I use for the purpose this can be done in patients of any age in a few seconds, with perfect safety and very little pain. Any other tumor, in such a situation, might produce similar effects, and therefore ought to be removed with the same view. It is quite delightful to witness the instant relief afforded by such operations. Patients who were not able to utter a single sentence distinctly, enabled to speak correctly, and with ease, instantaneously; and others, who were almost entirely deaf, instantly restored to the possession of the valuable sense of hearing. I was compelled to perform these operations sometimes surrounded by twenty or thirty patients, so that the accuracy of what is here stated is well known to hundreds who have witnessed them.

I consider it an important fact to state that, in some cases from a distance, in which I had not an opportunity of watching the progress of the cure, and preventing the divided parts cicatrizing in their former contracted state, the stammering, which was completely removed by the operation, was about as bad as at first when the parts were so closed; but a redivision of these parts, and restoration of freedom to the tongue, had again the effect of immediately removing the malady; and by attention to guard against its closing in the contracted state, the cure has been permanent for the last five months, and therefore, it may be presumed, will now remain so for life. Stammering and coughing are occasionally associated with a relaxed or hypertrophied uvula, a portion of which I always excise in such cases. It may also arise from a relaxed state of the fauces, for which astringent and stimulant gargles, blisters, and constitutional treatment, may be required. When it is a purely nervous affection I know nothing new to recommend in such cases.

It may be difficult to assign the true cause, physiologically, of the complaint. My own opinion is, that the rigid state of the tongue prevents the epiglottis rising sufficiently to permit the free passage of air, and its acting with the promptness necessary to produce free and correct enunciation.

I understand it is given as Dieffen-bach's opinion, that stammering is caused by the inability to touch the palate with the tongue. I have the highest respect for any opinion of that ingenious and dexterous surgeon, but candour compels me to say, that if such is really his opinion, I must differ from him on this point. I have all along been aware that in many cases the bridling of the tongue rendered it dif-ficult or impossible for the stammerer to touch the palate with the tip of the tongue, when the jaws are separated to any extent; but this I consider as only a concomitant effect, not the cause of stammering, which, as al-ready stated, I was, and am of opinion, arises from an obstruction to the free action of the epiglottis, and the effect resulting therefrom on the vocal cords and other parts of the vocal organs, including the free motion of the tongue itself. In proof of this I may instance the following facts:—One patient, on whom I operated to-day, two yesterday, and one two days before, had the power of pressing the tongue along the palate when the mouth was very much opened, and could protrude it about an inch and a half beyond the lips; circumstances to which I called the attention of se-veral individuals present at the time. Two were instantly cured by the ope-ration performed, and the other two were greatly improved. Being so fa-miliar with such cases I was enabled to predict, before operating upon the latter cases, that the improvement would be only partial.

It is curious that Dieffenbach in Germany, Mr. Yearsley in London, myself in Manchester, and perhaps others elsewhere, should have been prosecuting the same subject, about the same time, in a somewhat similar manner, and each probably without any knowledge of what the other was doing. Could you, or any of your readers, favour me with information as to the date of their first operations? For my own part I can honestly say, I was not aware of any of their ideas or practice in this affection until within the last three weeks, although I had been prac-tising it successfully for the last six months; and now, by the advice of some of my professional friends, I sub-mit these remarks to the profession, with the hope that they may excite others to labour in the same interesting

field of inquiry, and diffuse its blessings more extensively on mankind than could be effected were it confined to a few practitioners.—I am, sir,
Your obedient servant,
JAMES BRAID, M.R.C.S.
10, Piccadilly, Manchester,
March 8, 1841.

ANALYSES AND NOTICES OF BOOKS.

" L'Auteur se tue à alonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Magdalenism: an Inquiry into the Ex-tent, Causes, and Consequences of Prostitution in Edinburgh. By WIL-LIAM TAIT, Surgeon, &c. Edinburgh, 1840. 8vo. pp. 268.

" MAN," quoth Aristotle, " is a mimetic animal;" and nowhere is the maxim of the Stagyrite more frequently exem-plified than in literature. Let a man write a good book on any subject, and the press straightway groans with counterfeits. Historical novels, and mock Byrons, will immediately occur to every reader. Parent-Duchatelet, again, wrote a very remarkable treatise on prostitution as it exists in Paris; on which others must needs bring out books not remarkable, on the same social defect in other cities; *e. g.* the work before us. The author is unable to deal with his subject. No one, we believe, cries up prostitutes as saints and angels; but no man of sense in-veighs against them in the style of a school-boy's theme, or would propose, like our author, that their oaths should be rejected in courts of justice. Nor is he happier in his statistical details; for if London contains only 8000 pros-titutes, as he supposes at page 5, *note,* more than 5000 of them cannot die every year, as he imagines at page 247. At the same page he adopts Dr. Ryan's statement, that since the institution of Magdalen-asylums in London, four millions of women have been sacrificed by prostitution. As these asylums have not existed a century, this makes more than 40,000 a year,—a con-siderable number to be sacrificed out of a population of 8000; not to mention that this mortality is greater than the number of all the deaths among the men, women, and children of London, within the given period. But enough of this book.

*Observations on the Religious Delusions
of Insane Persons, and on the Practi-
cability, Safety, and Expediency of
imparting to them Christian Instruc-
tion, &c.* By NATHANIEL BINGHAM,
M.R.C.S. &c. London, 1841. 8vo.
pp. 213.

MR. BINGHAM believes that religious
instruction is not sufficiently attended
to in madhouses; in some, divine ser-
vice is not performed at all, and in
others, with indifference. If we un-
derstand him aright, he would wish a
zealous and animated preacher to be
introduced into each asylum, who
should endeavour to rouse the melan-
cholic patients by his fervour, while
he soothed those who were already in
a state of excitement. He thinks that
this would not tend to the increase of
religious insanity — *judicent peritiores.*
The author does not see why atten-
dance on divine service should be
voluntary in madhouses, while it is
compulsory in private families and col-
leges. We can see one reason for it,
among others. In the latter cases each
individual is supposed to be of the same
sect; not so in the former. Would any
decent person compel Catholics, Bap-
tists, Unitarians, and Swedenborgians,
to be present at our Church of Eng-
land service? Mr. Bingham's book is
far too long, and is justly obnoxious to
the quotation which adorns our ana-
lytic department.

MEDICAL GAZETTE.
Friday, March 19, 1841.

PROPOSED ALTERATIONS IN THE
UNIVERSITY OF CAMBRIDGE.

IN our article of the 26th of February,
we commented on the admirable work
lately published by Dr. Peacock;* and
we avowed our conviction that the
great reform which he advocates must
take place. We refer to the abolition
of academical oaths—an improvement

* Observations on the Statutes of the Univer-
sity of Cambridge.

so imperiously demanded by common
sense, as well as by higher considera-
tions, that it is difficult to conjecture
what any right-minded man could urge
against its immediate adoption. All
prospective and promissory oaths are
in their nature dangerous, even when
there is some chance of their being
observed; but what shall be said of
oaths taken to observe laws which, by
universal consent, are obsolete?

Another part of the Dean of Ely's
work, that in which he proposes alte-
rations in the system of education, is,
of course, more open to controversy;
though even here his suggestions are
always those of a sagacious and expe-
rienced man, and must be useful to
those whom they do not entirely per-
suade. In the general tone of its
examinations, the University of Cam-
bridge appears to us to have steered the
due course between extreme severity
and indecent leniency,—the Scylla and
Charybdis by which examinations are
naturally endangered. If examinations
are made so severe that only a hand-
ful of hard-working students can pass
them, a university is no longer a place
of national education: if so easy that
every dullard can get through, its de-
grees sink in public esteem, until they
differ from zero, to use a mathematical
phrase, by a quantity less than any
which can be assigned. Hence, to fix
the minimum for a large body of stu-
dents requires a nice appreciation of
average abilities, and an accurate know-
ledge of the ordinary means of instruc-
tion.

The present system of education ap-
pears to have grown into shape about
the middle of the last century: the
Aristotelian philosophy had long be-
fore fallen to the ground, but time was
necessarily required to mature the sys-
tem of studies which has replaced it.

While it is necessary to fix a mini-
mum for the encouragement of ordinary

students, it is not so obviously requisite to fix a maximum for the mathematical acquirements of the highest wranglers. The maximum has, of course, gone on increasing in proportion as the previous education of students has been better, and books and modes of teaching at the University have improved. There is such a thing as an atmosphere of scientific emulation, which stimulates the brain and multiplies the efforts of the finer spirits who are subjected to its influence. If the reader will compare, in the volume of "Cambridge Problems," those proposed in 1801 with those of 1820; and, again, those of 1820 with the papers of the last two or three years, he will instantly see how great has been the progress of Cambridge teaching in this century. Dr. Peacock, indeed, is of opinion that this progress has been too great; that the questions set are far too difficult, and that "nothing short of the most peremptory orders, defining what shall be omitted, will prevent examinations from travelling over the whole range of mathematical and philosophical knowledge."

If the error has been committed for the last two or three years of proposing questions so difficult that even the best men cannot answer them, the mistake must be so glaring that it is not likely to be repeated; but it is possible to conceive that a mistake more injurious, because more defensible, might be committed, by setting many problems so hard that only two or three of the highest students could cope with them. Those immediately below the highest would thus lose the opportunity of ascertaining their relative proficiency in the most satisfactory manner, and would be deprived of the power of displaying their acquirements to the best judges of their merit. But, after all, we have rather put a case hypothetically, than drawn it from the records of fact ; for though Dr. Peacock

speaks of papers of problems of the most disheartening difficulty (p. 153, note) others have, no doubt, been set in the same examinations, of more approachable elevation ; not to mention what is called book-work, *i. e.* theorems and examples to be found in the ordinary books.

Dr. Peacock, however, would wish to set a limit to the range of examination, partly in order to enable students to read for honours without " the stimulating aid of private tuition," and partly because he wants to cut off one term from the period of residence now required before the degree of B.A. can be taken.

In proportion as examinations have grown more difficult, private tuition in the University has been more extensively adopted. The majority of pupils find that they cannot keep up with the rapid march of the public lecture-room of their College without this subsidiary aid ; and when the under-graduate is many months behind-hand, his private tutor enables him to continue his studies, and even to obtain a respectable degree. In the public lecture-room the teacher gives one hour to the whole class ; but the pupil, unless his powers are of a very high order, finds that an hour daily is not more than his own doubts and difficulties require; and this he obtains from a private tutor. Hence, although the public lecturer gives a general view of the subject, the student is too happy to seek for an explanation of details from the patience of his private tutor.

It is clear that the wished-for object is attained, and that the pupil thus prepared cuts a far better figure, both in the lecture-room and in the senate-house, than if he had been left to struggle on unaided. Yet it is equally clear that he who contends with his difficulties alone, goes through a finer discipline of the mind than the self-

indulgent student, who, at every hitch, refers to his living dictionary of difficulties. The former system of study is like the island of Ithaca, in the Odyssey, τρηχεῖ, ἀλλ' ἀγαθη κουροτροφος*; the latter like the enchanted gardens of Armida—delightful, but unmanning. The student who has unravelled a hundred geometrical problems by his own unassisted toil, will be more pleased with his progress, and better prepared for the business of life, than if whole volumes of analysis had been softened down for him by the ever-ready good-humour of his teacher. All this is perfectly true ; yet if the young mathematician desires to be a wrangler, this slow but sure plan is, in the majority of instances, quite out of the question. Dr. Peacock, indeed, proposes to cut the Gordian knot by utterly prohibiting private tutors after the first year of University residence ; and would even disallow the reading parties which now commonly pass the long vacation in the country. Such laws, if enacted, would soon share the fate of the Elizabethan statutes. The Dean of Ely would allow private tutorship during the freshmen's year; but it would seem at least equally required during the subsequent ones : school recollections may help the young mathematician through Euclid, and the Elements of Algebra, but how is he to get on without a living commentary, when the public lecturer is advancing with giant strides through the abstruser branches of analysis, and their multiform applications ? Dr. Peacock would render it more nearly possible, by diminishing the range of subjects ; but what was left would inevitably be too much for the faint-hearted exertions of a large class. It is not every one who ismarked out by nature to lead forlorn hopes. Instead

of attempting to put down private tutors by force of law, we would diminish their numbers by the following scheme. It is well known that in the first annual College examination, many pupils show an extremely superficial knowledge of the subjects. Now instead of attempting to force such pupils, the following October, into the second year's lecture room, where, even with a private tutor's aid, their progress is almost none, their College instruction should consist of a repetition of the first year's subjects. A patient lecturer might instil much knowledge into such men, who would be driven to despairing idleness by the quick march of lectures calculated for the *élite* of their contemporaries.

So much for the maximum, and those who read up to this high and undefined standard. What is the minimum by which a B.A. degree can be obtained ? Dr. Peacock enables us to answer this question. " The subjects of examination for the ordinary degree of B.A. in January, 1841 (the first year of its introduction), are portions of a Greek and Latin author*, the Acts of the Apostles, Paley's Moral Philosophy, the three first, and portions of the sixth, books of Euclid, arithmetic, and the most elementary parts of algebra, the doctrine of proportion, and some of the more important propositions (less than fifty in number) of statics and hydrostatics." According to the regulations which had been in force for about fifteen years previously, " the University required a *competent* knowledge of the first six books of the Iliad of Homer and of the Æneid of Virgil, Paley's Moral Philosophy and Evidences of Christianity, the four first books of Euclid, arithmetic, and the elements of algebra."

---

* Rough, but good to bring up boys in.

* " For this year, these subjects are the 7th, 8th, 9th, and 10th books of the Iliad of Homer, and the Bellum Catilinarium of Sallust."

To persons unaccustomed to see pupils on a large scale, and who, therefore, in their attempted estimates, inevitably substitute picked for average performances, both the late and present requirements of the University will appear to err on the side of lenity. They may learn the contrary from the Dean of Ely. His experience has shewn him that a large proportion of candidates were plucked under the late regulations; and there is no doubt that at least an equal number will be rejected under the new. The inexperienced would say, "a (picked) school-boy could do this;" the experienced know that to many a languid student of twenty-one the difficulty of such an examination seems insuperable. Nay, Mr. Peacock goes further, and says that there are many who possess considerable memory, or imagination, and who are good classical scholars, though incapable of comprehending the very elements of mathematical reasoning, whether in arithmetic, geometry, or algebra. To such men the present relations are not merely a stumbling-block, but a brazen wall of exclusion. Yet it is precisely such men who would derive the greatest benefit from these severer studies; as the Dean himself acknowledges, and as Bacon has set forth with his usual felicity.

"Nay, there is no stand or impediment in the wit, but may be wrought out by fit studies; like as diseases of the body may have appropriate exercise; bowling is good for the stone and reins, shooting for the lungs and breast, gentle walking for the stomach, riding for the head, and the like; so, if a man's wits be wandering, let him study the mathematics; for in demonstrations, if his wit be called away ever so little, he must begin again *."

Dr. Peacock, however, naturally compassionates the case of a man who, though he excels in classic lore, cannot obtain even an ordinary degree, from his utter inapprehension of the relations of number and space; and he would favour such students by commuting all or part of their mathematical examination for a classical one of considerable range and severity. This, it must be confessed, is a doubtful point. For while, on the one hand, by the present system, such students are often cut off from fair opportunities of displaying their classic acquirements in a university examination; on the other hand, by the proposed reform, they would lose that wholesome medicine of the mind, by which the infirmities of their wit are, as Bacon says, "wrought out."

The little-go (or preparatory examination in the Lent term of the second year) is useful, and in our opinion unobjectionable: though when it first began, seventeen years ago, some persons thought that it would interfere with the preparation for the *great go,* or examination for degrees. This does not appear to have been the case, nor, had it happened to a slight extent, would this have been a good argument against the little-go. Even if a few of the best mathematicians found the interruption an embarrassment, the interests of the great body of undergraduates were furthered by this excellent innovation. The examination is always in one of the four gospels, a portion of a Greek and a Latin author, and Paley's Evidences of Christianity. This year the subjects are the Gospel of St. Mark, the first book of Herodotus, and Cicero de Senectute.

Dr. Peacock has some observations on the mode of examination in the Classical Tripos, and others on the still weightier subject of professional education, but we have no space left to discuss them on the present occasion.

* Essays. Of Studies.

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

Tuesday, March 9, 1841.

Dr. WILLIAMS, PRESIDENT, IN THE CHAIR.

Dr. CLENDINNING moved that the thanks of the society should be returned to their late President, Sir B. C. Brodie, for his numerous services, and his admirable conduct while he occupied the chair. The motion was seconded by Mr. Arnott, and carried unanimously.

Mr. Partridge moved, and Mr. Davis seconded, the thanks of the society to Mr. Arnott, their late Treasurer. The motion was carried unanimously, and Mr. Arnott returned thanks, congratulating the society on the improved state of their finances. Six years ago he received a balance of five pounds from his predecessor ; he had lately transferred to his successor scarcely less than six hundred.

Dr. Webster moved the thanks of the society to their late Secretary, Dr. Lee. Mr. Davis seconded the motion, which was carried unanimously, and Dr. Lee returned thanks.

A Case of Slow Pulse, with Fainting Fits, which first came on two years after an injury of the neck from a fall, and proved fatal five years and three months after the accident. By T. H. HOLBERTON, of Hampton, Surgeon Extraordinary to the Queen Dowager.

The subject of this case was a gentleman, 64 years of age, who received an obscure injury to the neck from a fall from his horse, in December 1834. From this injury he slowly recovered, and at the end of a year complained only of some difficulty in moving his head. Nothing further was remarked respecting this gentleman until January 1837, when he had a fainting fit, and Mr. Jackson, of Stamford, then observed for the first time that his pulse beat only 20 in a minute. From this time he had similar attacks, at irregular intervals, and from various causes, and in the spring of the same year, from excitement at a horse-race and long fasting ; and another in the following June, from a somewhat similar cause. In the latter instance, his pulse was 25 in a minute. When the author first saw him, in March 1837, his ordinary pulse was 33 ; but it was easily altered. Mental excitement usually increased it ; and, in general, this was followed by a corresponding slowness of the pulse, and often by a fainting fit. The general characters of the pulse, when the patient felt well, were firmness, fulness,

and freedom ; generally it was regular, but sometimes intermittent. An overloaded state of the stomach was an occasional cause of these attacks ; and in 1838, when the patient suffered from " a severe and alarming succession of fits," the pulse fell to 12, 10, 9, 8, and, at three or four different times, was counted as low as $7\frac{1}{2}$ in a minute. One of these attacks ended in the death of the patient, in April 1840.

The examination of the body was made by Mr. Liston, from whose report the following is extracted : — " The medulla oblongata was small in size, and extremely firm in consistence ; the foramen magnum was altered in shape, the antero-posterior diameter being much diminished ; the superior part of the odontoid process of the axis appeared to have been pushed back, and somewhat raised above its usual situation ; the antero-posterior diameter was so much narrowed, that it would not admit of the little finger ; the dura mater and ligament covering the posterior part of the body of the axis were much thickened ; the atlas was in its usual situation, but the articular cavities were firmly ossified to the condyles of the occipital bone, and permitted no motion whatever between the atlas and skull." The patient never had paralysis, nor alkalescent urine ; neither did he suffer from pain in the neck after the first few weeks from the accident.

The discussion which followed the reading of the paper was rather diffuse in its objects ; we therefore give an orderly analysis of the principal parts of it, in lieu of a regular report.

Mr. Cæsar Hawkins questioned the existence of any connection between the accident and the slowness of the pulse. Nothing was accurately known of the condition of the patient's pulse previous to the accident : the patient had been a healthy man, and not examined by any medical attendant ; nor was there any indication of an affection of the spinal cord till two years had elapsed from the time of the injury : in the interval the patient had been well, and had had the perfect use of his limbs, without any indication whatever of paralysis. It was not probable either that the effects of such an injury as was supposed to have been received should be delayed for two years ; nor that, had it been delayed, its paralyzing influence should be limited to a single organ— the heart. Besides, it appeared that the fits to which the patient was subject were always brought on by some disordered condition of the stomach, such as from over-eating, or accidental distension of it ; just as was ordinarily the case with those who suffered from either functional or organic disease of the heart without any coincident

isease of the spinal cord. From these facts e could not help regarding the case as only ne of those which occur not unfrequently, a which the pulse is peculiarly slow; and hough it might be difficult, as it is in many f them, to point out the cause of the slow- ess, he could not see any reason to believe hat it was connected with the injury, if any f real importance existed, of the spinal ord.

Mr. Arnott took the same view of the ase. There was no evidence that the atient had not always had a slow pulse; nd numerous cases were recorded of pulses s low, or nearly as low, as in this, without he existence of any disease of the spinal ord. Mr. Mayo had once read a paper at he College of Physicians, in which he had ollected a great number of cases of the ind, one of which he (Mr. A.) had com- nunicated to him; but in no one of these vas the slowness of pulse at all connected rith injury or disease of the spinal cord.)n the other hand, cases were on record in vhich, with injury of the cord, such as was ere supposed to have taken place, the pulse emained unaltered. All the circumstances f the patient's history concurred to prove hat the injury and the slowness of pulse ere only accidental coincidences, but had o necessary connection with each other.

Other members believed that the slowness f pulse must have been the consequence of he injury; and, for its explanation, Mr. regory Smith asked whether the vertebral rteries had been examined, and Mr. Bransby Cooper whether they or the nervus vagus igh up in the neck and in the skull had een seen. Mr. Liston said it was so long ince he made the examination, that he eally could not remember what the con- ition of these parts was. Mr. Bransby Cooper thought the narrowing of the upper art of the vertebral canal was such that the ertebral arteries must have been com- ressed; and if this were the case, the ymptoms admitted at once of explanation rom the disturbance of the cerebral circula- ion, to which such an obstacle to the pas- age of its blood was always known to ive rise.

Dr. C. J. B. Williams also, believing hat there was a connection of consequence etween the injury and the slowness of the ulse, referred to cases in which the same ymptom followed analogous conditions of he cerebral and spinal circulation. The rdinary case of fainting was such an one; he slowness of the pulse in apoplexy from he compression of the brain was also a imilar phenomenon; and more than these, he experiments of Legallois rendered the onnection of injury of the cord with dis- rdered action of the heart probable, for he ad constantly found such disorder, either a

reduction or an irregularity of the heart's action, follow destruction of the spinal cord. That extended paralysis did not ensue from the compression of the cord, was explicable, he thought, by the circumstance of the com- pression being gradually made. It was not the immediate result of the injury of the vertebral column, but rather of thickening of the ligaments; and it therefore resembled those cases, of which many were on record, in which tumors growing within the canal, and gradually compressing the medulla spi- nalis, did not produce paralysis.

Dr. Addison related a case very closely resembling that recorded in the paper. It was that of a gentleman whom he had lately, but only once, seen, who had always had (as his medical attendants had often told him,) a remarkably slow pulse. It was only of late, however, that this had been accom- panied by any important symptoms; but now he was subject to frequent fits, of a kind something like epilepsy, but dependent on the singular action of the heart. The way in which these fits came on was as follows:— the heart ordinarily beats about 24 or 26 times in a minute, every pulsation being very strong and full. But on the approach of a fit, the pulsations become gradually more and more frequent, till they reach about the natural standard of between 60 and 70 in a minute; and then, after a time, there sud- denly ensues a dead stop of the pulse, and immediately the fit comes on. It consists of a great agitation of the limbs, with a staring openness of the eyes, and insensibility; and always lasts till the pulse again begins to be perceptible. This is often a considera- ble time; he could not say exactly how long, but certainly very long for a man to be with- out any pulse. As the fit passes off, the heart begins to act with its ordinary slow rhythm, and thus it continues till the approach of another fit, when it again becomes ac- celerated, then stops; and then again, as the patient recovers, resumes its usual pace. It was remarkable, that, so long as the pulse remained between 20 and 30, every one of the violent contractions of the heart was accompanied by a very loud grating *bruit*, so loud and so diffused that he could not say whether it proceeded from the aortic or the mitral valves; but as soon as the pulse be- came more frequent, the bruit at once ceased, and did not return till the pulse again became slow, and the contractions of the heart few but very forcible. He had examined the state of the respiration in this patient, but it was not materially affected. Since he had seen him, his regular medical attendant had informed him that he was in nearly the same state; that the fits had, however, been ren- dered less frequent by the use of stimulants; but that, on one occasion, the pulse had beat only 17 times in a minute, and that, at this

time, the pulsations and the respirations had exactly corresponded. He had detected in this case a source of fallacy, which he thought it probable had existed in many of those recorded as examples of slow pulses,—namely, that though the pulse at the wrist was thus infrequent, the contractions of the heart were more numerous ; for he had found, with the stethoscope, that between each of the violent contractions of the heart there occurred one very gentle contraction, too weak to propagate any impulse to the artery at the wrist.

Mr. Perry thought this source of fallacy might have been overlooked in the case that had been read.   It was barely possible that a man should live with a heart beating only seven times in a minute ; but it was certain that a circulation was often maintained, though the pulse at the wrist could not be felt ; as, for example, in cases of cholera.

Dr. Burne, having asked whether the condition of the great arteries in this case had been examined, and being answered in the negative, expressed his suspicion that they might have been the main cause of the slowness of the pulse. He thought too much stress were laid on what was called diseases of the heart. He had met with many cases in which irregularity of the pulse had existed to a great extent, and in which no cause for it was found but extensive disease of the arteries ; the heart itself being, except for the hypertrophy which was induced in it by the necessity for excessive exertion, perfectly healthy. He thought it probable that, in Dr. Addison's case, something of this kind existed.   In these cases, the circulation losing the assistance which it ordinarily receives from the arteries, the whole burden of carrying it on is thrown upon the heart, which for a time, growing larger and stronger, is sufficient for the purpose. But after a time, the blood accumulating more and more, the heart can no longer propel it with the necessary force, and then it becomes irregular in its action ; and at last, its efforts growing less and less availing, the blood ceases to be moved, and the patient dies.

Dr. Addison expressed his surprise at the opinion of irregularity of the pulse being ever dependent on disease of the arteries alone ; he had never met with a case in which it had so occurred.

Dr. James Johnson also said that he had never yet seen a case of irregular action of the pulse without disease of the heart, and altogether doubted the possibility of such an occurrence.

Dr. C. J. B. Williams concurred in the same opinion. He could not call to mind a single case in which the pulse had been irregular from mere disease of the large arteries, the heart and its valves being healthy.

Dr. Burne, however, felt persuaded, that now that the attention of gentlemen was drawn to such cases, they would not fail to find his opinion corroborated.   He did not regard hypertrophy as a disease ; it was only the same thing occurring in the heart as takes place in any muscle that is much exerted,—in the muscles of a smith's arm, for example : it was the result of the power which muscles seem naturally to possess of enlarging themselves, so that they may be adapted, to a certain extent, to any work which they are called on to perform.

COLLEGE OF PHYSICIANS.

To the Editor of the Medical Gazette.

Sir,

After having given the report of the Committee appointed by the College of Physicians on the subject of medical reform a perusal, I was gratified with the first resolution which was proposed, namely, that it is expedient that all physicians now practising throughout England and Wales, with a diploma of M.D., obtained from any British University, and who have attained the age of twenty-six years, should be entitled to admission into the order of licentiates of the College, without any examination, but upon the payment of fees hereafter to be determined.

There are two or three things, however, connected with this primary and very *prudential* resolution, which I think it would be only right and proper to attend to, namely, that no physician who acts as a general practitioner, (that is, one who acts at the same time as a surgeon and apothecary), should be allowed to be admitted to the privilege which it holds out, unless he forthwith gives up acting as a general practitioner.   And the next thing is, that the fee of admission be made as *low* as possible, as there are but few physicians who could *conveniently* afford to pay one of much amount.   And perhaps it would not be a bad principle by which to regulate the scale of the amount of fees, by the length of time each physician has been in practice ; say for periods of five, ten, fifteen, and twenty years and upwards ; and that the fee for the last period should be merely nominal, as any benefit accruing to them would not be so durable, and, consequently, not of equal importance. And perhaps physicians of seven or ten years' appointment, at any public hospital, or dispensary, might be allowed to be licentiates at the lowest fee of admission.

And I think it would be desirable that a registry-board should be established at the county town in each county in England and Wales, in order that every physician, in

ctual practice, should be required to be registered, in addition to the general board of registration at the College of Physicians.

MEDICUS.

March 9, 1841.

MEDICAL REFORM.

PETITION FROM THE COLL. OF PHYSICIANS.

To the Honourable the Commons of the United Kingdom of Great Britain and Ireland, in Parliament assembled.

The humble Petition of the President and College or Commonalty of the Faculty of Physic in London, under their common seal.

SHEWETH,—That a Bill is now pending in your Honourable House, entitled " A Bill for the better government of the Medical Profession in Great Britain and Ireland."

That the Royal College of Physicians of London was incorporated by Royal Charter of King Henry the Eighth, which Charter was confirmed and recognized by several Acts of Parliament ; that it has existed and exercised its jurisdiction through many changes in society during 300 years, and has included among its members many of the most learned men which this country has produced.

That under its jurisdiction and superintendence the profession of a Physician has risen to and maintained a rank in society at least equal to that which it enjoys in any civilized country in Europe.

That the proposed Bill would entirely destroy the jurisdiction of your Petitioners, and would place in the hands of a Senate composed of nine delegates, all of whom might be Surgeons or Apothecaries, most absolute power to regulate exclusively the education of Candidates for the Diploma. And your Petitioners are of opinion that Physicians are and ever must be the best judges of the qualifications of Physicians, and that consequently such a regulation would in effect be ultimately most injurious to the best interests of society.

That it is further proposed to establish one qualification, to be determined by examination, for all persons desirous of practising the medical profession, without reference to the particular branch of the profession they may intend to follow ; and it appears to your Petitioners that if the examination to be instituted be one which demands the present maximum of preliminary and medical education, it will be above the means of attainment by a very large proportion of students ; and that if such examination be of a lower grade, it will be

followed by a deterioration of the scientific and literary character of the profession, and the public will necessarily suffer.

That it is further proposed, that all powers, privileges, appointments, and acts, which have been conferred on, or held or performed by, Physicians, shall hereafter be conferred on, held, performed, and enjoyed by the licensed practitioners according to the said Bill, and by such persons only; and it appears to your Petitioners, that by conferring equal rank and privileges on all, every incentive to honourable ambition is removed, and no inducement is held out to the student to undertake an expensive general education, and a prolonged course of medical study, by which means alone the literature and science of the profession can be upheld in their present honourable position.

That the power of recovering fees for medical visits proposed to be given by the said Bill appears to your Petitioners objectionable as applying to Physicians, and your Petitioners consider that it would not be for the credit of any in their body, inasmuch as such a power would place them on a less respectable footing in society than that which they at present hold.

That should a Council (as is proposed) be elected by the votes of the profession at large, it would produce a series of jealousies, altercations, and dissensions, most injurious to the character of medical men ; nor would such a measure insure the services of the most distinguished, inasmuch as the necessary canvass would be contrary to the habits and duties of those extensively engaged in the practical labours of the profession.

That your Petitioners having carefully considered the alleged grievances set forth in the various petitions to your Honourable House for Medical Reform, and having communicated with the Universities, the other Medical Corporations, and with Delegates from several other bodies whose interests are involved in the proposed measure, are now maturing a general plan for the better regulation of the medical profession, and they have reason to believe that such plan will give satisfaction to the members of the profession, and be conducive to the better protection of the public. And your Petitioners hope shortly to be enabled to submit the same to the consideration of the Legislature.

Your Petitioners therefore must humbly pray that the said Bill may not pass into a law, and that your Petitioners may be heard by their Counsel, Agents, and Witnesses, against the same.

And your Petitioners will ever pray, &c.

MEDICAL REFORM BILL.

WE subjoin a short account of what took place in the House of Commons on Wednesday, on the subject of medical reform, which strongly illustrates the importance attached to the measure by her Majesty's ministers, as well as by the House of Commons at large. A Bill is brought forward by Mr. Hawes, and supported by Mr. Wakley, having for its chief object the establishment of the " one Faculty" system. Not a single member of the administration honoured them with his countenance ; and fewer than forty members of any kind being present, the measure fell to the ground as a matter of course : —

On the question that the Medical Profession Bill (No. 2) be read a second time, several members rose to present petitions, of which twenty-four were against the measure, and seven in favour of it.

It was then proposed by Sir T. Trowbridge that the measure should be delayed ; but

Mr. Wakley " hoped that his honourable friend, the member for Lambeth, would proceed with the measure : the objection, as he understood, was not against the principle of the measure, but against its details ; and they might be arranged in committee. If they now agreed to the principle of the bill, the committee might be postponed to a distant day."

Mr. Hawes accordingly moved the second reading of the bill, which Mr. Ewart seconded.

Mr. Darley rose to speak against it, when an honourable member moved that the house be counted ; and as there were present only thirty-three members, the house was adjourned.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, March 12, 1841.

W. Simpson. — J. R. Withecombe. — W. J. Gruggen. — A. J. Marsh. — H. Coward. — R. W. O'Donovan. — S. Seccer. — A. Anderson. — E. A. Jenkin.—H. L. Crowther.—J. Hooper.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, March 4, 1841.

J. Denny, Ipswich.—E. F. Leyson, Neath South Wales.—J. P. W. Sydenham, Oxford.— W. R. Baxter.—J. A. Clarke, Bedford.—C. B. Craske, India.

Thursday, March 11, 1841.

William Charles Calthrop, Boston, Lincolnshire —Richard Rickman Shillitoe, Hertford.— William John Blake French, Wilton, Wiltshire. —Richard Quain, Mallow, Ireland.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the Number of Deaths from all Causes registered in the Week, ending Saturday, the 6th March 1841.

A

MEDICAL DICTIONARY;

CONTAINING

AN EXPLANATION OF THE TERMS

IN

ANATOMY,	MATERIA MEDICA,	PHYSIOLOGY,
BOTANY,	MIDWIFERY,	PRACTICE OF PHYSIC,
CHEMISTRY,	PHARMACY,	SURGERY,

AND THE VARIOUS BRANCHES OF

NATURAL PHILOSOPHY CONNECTED WITH MEDICINE :

COMPILED FROM THE BEST AUTHORS.

BY THE LATE

DR. HOOPER.

Seventh Edition, revised and enlarged,

BY

KLEIN GRANT, M.D. &c.

Lecturer on Therapeutics.

The utility of the general plan of Hooper's Medical Dictionary has been sufficiently proved by the sale of very large and repeated editions of the work. In former editions, however, it had become, like many other

books of the kind, somewhat obsolete in its information ; while it must be acknowledged that it had never been greatly distinguished for philological accuracy. A very careful revisal of the whole—the correction of what was inaccurate—the omission of what was obsolete—and the introduction of much new matter—became therefore absolutely essential, to adapt the work to the present advanced state of Medical Science, and the increased acquirements of the Medical Profession.

These objects have been so fully carried out in the edition now offered to the public, that the work may be considered as almost entirely new. The lexicography, which was before in all respects defective, has gained so much both in extent and accuracy, that HOOPER'S MEDICAL DICTIONARY is now consulted on all hands, not only by medical readers, but by scholars of every profession, on account of the value of its etymologies and definitions. The strictly Medical articles, as well as those relating to the collateral sciences, have been completely remodelled, and brought up to the existing state of knowledge. Great pains have been bestowed upon the articles on Comparative Anatomy, Zoology, and Botany. The old articles connected with the practice of Physic have been replaced by new ones, in which the fullest practical information is condensed within very moderate limits. It may be added that this edition contains a more comprehensive view of the Materia Medica and Pharmacy of all ages and countries than has ever before been published ; it also gives a very full account of the chemical analysis and medicinal virtues of Mineral Waters in all parts of the world. On the whole, the work is well calculated to answer all the ends of a Dictionary of Terms, as well as those of a compendious Cyclopædia of Medicine and the cognate Sciences.

That the proprietors are not exaggerating the merits and utility of the work, as it now stands, will be sufficiently evinced by the following

xtracts from a notice of it in the *British and Foreign Medical Review,*—
han which there can be no higher authority in medical criticism :—

" It must be admitted to have been of very inferior execution, until it
assed through the hands of its present editor. Now, indeed, it will
ield to none of its competitors in point of excellence, and will stand with
hem, a permanent memorial of the industry, learning, and talents of its
uthors,—we say authors, because it will be found, on examination, that
he work, as it now stands, is more the production of Dr. GRANT than of
Dr. HOOPER.

    *   *   *   *   *   *

" We can safely assure all those to whom the former editions were
acceptable, that they will find this in every way greatly superior. Every
hing that was antiquated has been removed or renovated,—a vast mass of
errors, in the lexicographical part more especially, has been corrected,—
and the whole brought up to the level of our present knowledge. In
accomplishing this important and very difficult task, Dr. GRANT has
evinced, in a striking degree, great talents, great industry, and accurate
and extensive learning. Were not the volume before us so useful, we
ould almost regret that Dr. GRANT had not engaged in some more
original work, in accomplishing which his merits ran no risk of being lost
n those of another."
